

TROPICAL DISEASES
BULLETIN

Vol. 36]

1939

[For some time it has been considered by the staff of the Bureau that a useful addition to the abstracts in the *Tropical Diseases Bulletin* would be a series of summaries collating the information contained in the abstracts. This suggestion has received support from officers of the Colonial Medical Service abroad and it has therefore been decided to publish each month from January 1939 onwards a summary of the abstracts on a particular subject which have appeared in the volume of the *Tropical Diseases Bulletin* for the preceding year. The first of these is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938 Vol. 35. Summaries have been compiled below. The information from which the References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.]

SUMMARY OF RECENT ABSTRACTS
I CHOLERA.*Epidemiology*

PARTHASARATHY and SUBBARAJAN (p. 303) find on analysis according to the periodogram method, that in the Southern Indian State of Mysore cholera occurs in a periodicity of six years. TURNBULL (p. 738) states that epidemics in South China appear in the hot rainy months and occur about every five years. The Eastern Bureau of the League of Nations Health Organisation (p. 735) notes that epidemics are associated with high relative humidity, high temperature and intermittent rain and that cholera spreads along the highways of human traffic and that man is himself the chief agent of spread. RAYAT and LIEOL (p. 738) attribute an explosive outbreak in Shanghai to the incursion of war refugees. MALIU and PALUD (p. 738) ascribe the disappearance of this epidemic to two factors: one climatic, the passing of the hot weather and the other prophylactic, rapid segregation and vaccination.

The possibility of the spread of cholera by pollution of sea water and food materials has been investigated. The Eastern Bureau of the League of Nations Health Organisation (p. 735) reports that in Japan the vibrio is said to be capable of surviving in sea water for 47 days and that fish and shell fish may become infected and pass on the infection to persons consuming them. GENEVEY and BRUNEAU (p. 739)

[using both pure sodium chloride and crude sea salt which gave approximately equal results] (p. 742) record the following experimental results (1) the vibrio cannot grow if the concentration of salt exceeds 8 per cent. (2) It remains alive in concentrations of 9 to 11 per cent. for 24-48 hours, in 8 per cent. for two weeks or more in 5 to 7 per cent. for three weeks or more and in 2.5 per cent. for four weeks or more. [The total salinity of ocean water is from about 3.3 to 3.7 per cent.]

The same authors (p. 742) found that the degree of salinity of certain foodstuffs determined the length of life of cholera vibrios incorporated in them. Soya milk and soya cheese are consumed on the day of preparation and as the vibrios can live in them for 12 hours they may be dangerous in epidemic periods.

Aetiology

For the identification of vibrios causally related to epidemic cholera GARDNER and WHITE (p. 306) emphasize the reliability of serum containing specific O (somatic) but not "H" (flagellar) agglutinins. All specific vibrios give the type 1 Heiberg reaction (fermenting mannose and saccharose but not arabinose) which however is not peculiar to these vibrios and they fail to haemolyse goat erythrocytes. To these TAYLOR (p. 305) adds that the true cholera vibrios give positive cholera red and negative Voges Proskauer reactions. El Tor vibrios gave positive Voges Proskauer reactions in 5 of 6 strains. "There have not been isolated vibrios of any other serological type than the classical *V. cholerae* from any series of clinical cases of cholera which have been chronologically or geographically connected. DE VOGEL (p. 734) however reported an important outbreak of clinical cholera in the Celebes Islands in which from 47 patients with typical symptoms a vibrio of the El Tor type was isolated.

POPESCU-COMBESCU and WISNER (p. 307) find it impossible to lay down absolute characters in the morphology of *V. cholerae*. Indole formation is common to various vibrios but if a vibrio fails to haemolyse a suspension of goat erythrocytes and is agglutinated by specific serum it may be certainly taken to be a true cholera vibrio. Sugar fermentation according to Heiberg's group 1 is a characteristic of true cholera vibrios.

VENKATRAMAN and PANDIT (p. 739) record a severe epidemic of cholera in South India caused by the Ogawa type of vibrio. This does not support Japanese work which associates that type with sporadic or mild cases.

MARRAS (p. 309) distinguishes the El Tor vibrio by its haemolytic character and by the fact that it does not produce the symptoms of cholera and does not possess the epidemiological characters of the cholera vibrio. The Cholera Commission of the Office International d'Hygiène Publique (p. 734) agrees that the designation El Tor should be restricted to strains which give agglutination with O Group No. 1 cholera serum and that they may have Inaba or Ogawa antigenic structure.

RAJA (p. 303) states with reference to the spontaneous variability of cholera vibrios that vibrios isolated from secondary cases do not always correspond serologically with those from primary cases, though the source of infection must have been the primary cases [see below *Research*].

GENEVRAY and BRUNEAU (p. 741) give a detailed account of the characters which appear to have been uniform, of 500 strains studied

in the epidemic of Tonking Details will be found in the original abstract

LEFEBVRE and GALLUT (p 740) describe a selective medium modified from that of Vedder and van Dam for the isolation of *V cholerae* Colonies appear in 10 to 12 hours For details of the preparation of the medium the original abstract should be consulted ABE (p 310) describes a fluid medium containing a decoction of mulberry leaves in which cholera and cholera like vibrios grow with the production of acid unlike the dysentery and salmonella groups of bacilli The difference is explained by the fact that the leaves contain saccharose which is fermented by the vibrios but not by the dysentery and salmonella group WHITE (p 306) makes the point that in the case of original isolation cultures the presence of cholera phage may possibly be capable of reducing the numbers of *V cholerae* in relation to insensitive secondary invading vibrios

The Medical Research Institute of Shillong (p. 740) reports that in certain undoubted cases of clinical cholera it seemed impossible to find agglutinable vibrios and that the presence or absence of phage infecting the vibrio in nature did not appear to influence their agglutinability

PANG (p 743) describes an organism with a single polar flagellum isolated by blood culture from a debilitated patient This was antigenically related to *V cholerae* Vibrios inagglutinable by cholera sera and divisible into two groups, were isolated from cases of enteritis by HISANO (p 743) LIEOU (p 743) reports the isolation of a cholera vibrio from the heart blood of a gumeapig infected by means of the gastric contents of a patient with *cholera sicca*

Clinical

DOORENBOS (p 741) remarks that only one of the properties of the cholera vibrio remains uncontested that it is a Gram negative vibrio Clinically cholera may vary from simple diarrhoea to the typical highly fatal type There are two main types the epidemic and the endemic but there still remains only one cholera vibrio in the more or less complete state or showing dissociation in its properties

The Cholera Commission of the Office International d'Hygiène Publique (p 734) considers that in spite of the improvement in bacteriological diagnosis the practical criterion of cholera still remains the clinical one and that this should form the basis for administrative and prophylactic action

Treatment

TURNBULL (p 739) describes a routine treatment which consisted in—administering first intravenously sod. bicarb 160 grs. sod. chloride 60 grs. water 1 pint in order to counteract acidosis This was followed by intravenous hypertonic salt solution—sod. chloride 120 grs. calc chloride 4 grs. pot chloride 6 grs. water 1 pint Four pints of this solution at 104°F may be given in an hour and it may be repeated 2 or 3 times a day During the flow of the fluid the pulse and blood pressure are watched and the administration is stopped when blood pressure comes back to normal and the pulse becomes full and bounding The state of the pulse is the index for repetition of

treatment and 1/50 grain atropine is given twice daily to prevent pulmonary oedema. Cases treated in hospital amounted to 400 to 500 and the deaths to 35 to 40

LAMB (p 745) quotes a standard treatment consisting of intravenous salt solution and the administration by the mouth of kaolin 1½ lb in a quart of water the dose being one ounce every 15 minutes. NAAME (p 745) on the basis of the similarity between the symptoms of cholera and those of hypoadrenalism and the possibility that the former may be due to selective action of the cholera toxin on the suprarenal glands has instituted a treatment by adrenalin which he administers in subcutaneous doses of 4 to 6 mgm every 24 hours for some days combined with injections of artificial serum if there is much dehydration

LE ROUZIC (p 304) obtained data which appeared to show that patients receiving all types of treatment simultaneously—Raymond's hypertonic serum camphorated oil adrenalin and bacteriophage—had the greatest chance of recovery. Mortality among treated cases was 43·6 per cent. (But the average of a large number of recorded outbreaks is about 50 per cent.) TAYLOR (p 306) reports that results obtained in Calcutta show no appreciable difference in the death rate of cases treated by bacteriophage and the control series but that a certain value attaches to bacteriophage treatment added to ordinary methods when only the figures for cases in which agglutinable vibrios were isolated are taken into account

Control

Preventive measures on the occurrence of suspected cases of cholera should not await the isolation of a typical O agglutinable vibrio. This is the opinion expressed by the Cholera Commission of the Office International d'Hygiène Publique (p 734). The writer of the article in the *Washington Public Health Reports* (p 304) states that "Because protected water supplies and protective milk supplies are the rule instead of the exception in American cities to-day cholera is no longer the menace to this country that it was during the last century" (italics not in the original)

HEGGS (p 735) writing of Iraq states that among the most important means of prevention are the supply of advance information from other countries of the existence of cholera and the compulsory inoculation imposed on Haj pilgrims. Inoculation of cholera vaccine is the mainstay of preventive measures. It is intended also to use cholera phage. Police control of population movement is attempted, but cannot deal with the problem of carriers. Stress is laid on the correct recognition of the first cases, and the diagnosis is primarily based on clinical and epidemiological grounds.

TAYLOR (p 306) details the essentials for strains from which vaccine should be prepared. Strains should (1) be smooth and translucent (2) form stable suspensions in normal salt solution (3) have the serological characters of group O No 1 GARDNER and VENKATRAMAN subtype Inaba and agglutinate to a significant titre with serum prepared from the designated Inaba O antigen provided by the standards laboratory of Oxford (4) ferment mannose and saccharose but not arabinose (5) not be haemolytic (6) be isolated from cases of cholera during an epidemic (7) be highly stable even in subculture

MILLAR and MOHI UD-DIN (p 303) found the percentage incidence of cholera in three statistically comparable categories of persons in Kashmir to be as follows —

- (1) Inoculated with 0.5 cc vaccine incidence 0.49 per cent
- (2) Inoculated with 1 cc vaccine incidence 0.29 per cent
- (3) Not inoculated incidence 11.35 per cent

Vaccination with 1 cc is therefore recommended

Research

MACNEAL, FRISBEE and KRUMHOLZ (p 310) point out differences between the lysis of vibrios by cholera immune serum and that brought about by bacteriophage. Phage lysis can be transmitted in series and there are differences in the sizes of the vibrios under the two conditions. Intracellular granules which may possibly possess the power of reproduction and of the secretion of lytic enzymes are found in the vibrios altered by bacteriophage but not in those altered by serum.

The investigation of the phenomenon of bacterial variation with regard to *V. cholerae* has been conducted by means of single cell culture. LINTON SEAL and MITRA (p 742) succeeded by this method in obtaining a new strain with different biochemical cultural and serological characteristics and a different chemical structure from those which characterized the culture from which the original single cell was taken. The new strain was still however within the protein and polysaccharide framework of the original and the capacity for transformation was therefore limited. WHITE (p 743) shows that either R or S cholera vibrios may produce rugose colonies. The rugose habit of growth is due to the property of zoogaea or capsule formation by abnormally active secretion of mucinous material. Rugose colonies perpetually revert to their normal S or R habit of proliferation. LINTON (p 209) on the basis of single cell experiments similar to those mentioned above finds that the association of metabolic activity with chemical groups appears to be reasonably constant and that it changes in parallel with any change of chemical structure in the course of variation. If these changes occur also in the field they may provide an answer to the question as to whether cholera cases arise only from previous cases and contacts or whether chronic carriers of groups A and V can on occasion start epidemics.

TAYLOR (p 305) finds that no vibrio agglutinable or non-agglutinable made rough by treatment with antiserum has shown any change in its biochemical reactions.

VASSILIADIS (p 737) finds that extraction by chloroform or ether appears to accentuate the flagellar H agglutination of the cholera vibrio and to cause an H agglutination by anticholera sera to appear in inagglutinable vibrios. He also finds that the haemolysins sometimes produced by the cholera vibrio either spontaneously or under the influence of the anticholera bacteriophage although they are of the same nature as those of the El Tor vibrio are much more feeble in their action. The position with regard to the nature of the El Tor vibrio is still far from clear.

BERNARD GUILLERM and GALLUT (pp 308-309) obtained a haemodigestive ferment from nutrient bouillon after 8 days of culture of cholera vibrio which on certain denatured proteins exerts a tryptic

cannot be obtained in vitro DEYNE (p. 13) has studied the effects of undecane diamidine. Lethal doses cause liver and kidney damage with hyperglycaemia and nitrogen retention. The upper limits of dosage are discussed.

Senior WHITE (p. 14) confirms his previous work in the Jeppore Hills which showed that *A. culicifacies* though prevalent is of no pathogenic importance. Control limited to the *functus* group has not resulted in deterioration of health and has effected considerable saving in larvicides. The three transmitting species are 4 *floridulus* 1 *normana* and 4 *mirimus*. Similar results (p. 14) were found in the Singhbhum Hills in an intensely malarious country in which transmission occurred in all months except May, June and July.

SIVTOR and SHUTE (p. 15) show that under favourable conditions of environment 4 *maculipennis* infected with *P. vivax* show no higher mortality than uninfected mosquitoes. There is however some evidence that under favourable conditions infections with *Plasmodium* tend to shorten life but these conditions are not those which usually apply in nature. Death from infection with *Plasmodium* is therefore not responsible for the fact that certain species are not natural transmitters.

PERAGALLO (p. 15) describes a mosquito trap

DE JESUS (P. I.) JAO (S. G.) & GARCIA (E. J.) Malaria Survey of Calanan, Laguna.—*Jl Philippine Islands Med Assoc* 1938. May Vol 18 No 5 pp 291-310 14 refs

Calanan is a small agricultural community 77 kilometres south of Manila with a population of 3038. Though only a few metres above sea level it is situated at the foot of a mountain range. There is an extensive network of small fresh water streams which serve as breeding places for 4 *mirimus* var *flavivestris* the most important vector of malaria in the Philippines. Malaria is more prevalent in the outlying parts of the town than in the central part. *P. vivax* is most in evidence in March the spleen index of primary school-children was 13.8 in August. Very few mosquito dissections were made none was found infected.

HUTY (Clay G.) The Significance of Different Strains of Malaria and Mosquitoes in the Epidemiology of the Disease.—Reprinted from *Amer Jl Med Technology* 1938. Mar Vol 4 No 2 6 pp. [10 refs]

This paper contains several interesting speculations. The life-cycle of malaria involves three kinds of animals, parasite mosquito and man, all of which are bisexual and so subject to greater chance of variation than are unisexual organisms. It seems reasonable to assume that all three are undergoing genetic change. The author has shown that with avian malaria, susceptibility to the parasite is an inherent

characteristic of the individual mosquito this susceptibility being transmitted in a simple Mendelian fashion. If such should be the case with malaria and Anopheline mosquitoes it might be possible for a mosquito population to change from a low to a high degree of susceptibility or vice versa. This might well happen in temperate climates where only few individual mosquitoes survive the winter. With regard to strains of malaria parasites that differ only immunologically it would be consistent with general knowledge of heredity to consider such differences as genetic. V II

AFRIDI (M. K.) ABDUL MAJID (S.) & JASWANT SINGH. Malaria In Kutch State.—*Jl Malaria Inst of India* (formerly *Records of the Malaria Survey of India*) 1938. June Vol. I No. 2. pp 187-213. With 3 maps.

The observations recorded in this paper were made during ten days in January and six weeks in September-October 1937 and were prompted by an increased prevalence of malaria during the closing months of 1936. Kutch is a small State of 4,342 square miles. It is almost an island being joined to or separated from the coast of Sind by an extensive salt marsh. It has an equable climate and a low rainfall (average 12.6 inches). Bhuj is the capital population 21,858 and Mandvi on the south coast is the chief port population 25,342. The spleen rates of these two towns of children from 2 to 10 years of age were 10.5 and 2.3 per cent respectively. The highest spleen rate found was 45.1 in Vijaya Vilas Palace in 51 children examined. The most prevalent anophelines were *subpictus culicifacies stephensi* and *annularis*. specimens of *turkudis fluvialis* and *barb rostris* were also found. 4 *stephensi* was the only species found infected. Recommendations regarding measures for the control of malaria are contained in the report. A II

MITRA (H.). Increase of Malaria In Manbhum, 1938. (Abstract.—*Jl Malaria Inst of India* (formerly *Records of the Malaria Survey of India*) 1938. June Vol. I No. 2. pp 215-216.

The increased prevalence of malaria reported in the Manbhum District of Bihar was not reflected in any increased mortality ascribed to "fevers" or in increased mortality from all causes. During a brief survey here reported malaria was found to be excessively prevalent in villages near the foot-hills. The two highest spleen rates recorded 85 and 41 were in villages so situated. The anophelines found during the survey were *culicifacies annularis pallidus vagus fluvialis* and *jeyporiensis*. A W

DE MELLO (L. Froilano). La campagne anti-malarienne dans les régions rurales de l'Inde portugaise. [Anti-Malaria Measures in Rural Areas of Portuguese India.]—*Rev de Malariologia Sez. I.* 1938. Vol. 17 No. 3. pp 208-224.

Portuguese India comprises three districts. Goa 3,806 square kilometres population 505,000. Damaun 450 square kilometres pop 58,000 and Diu 37 square kilometres pop 17,000. In the part of Goa known as the Velhas Conquistas (with the exception of Old Goa) and in certain villages of the Novas Conquistas malaria is very little prevalent the spleen index being very low. On the other hand

repeated every five days in the rare cases in which crescents persist is sufficient to devitalize gametocytes. Children under one year of age do not tolerate atebryn. Λ II

BARBOSA (Amando) Estudios sobre el poder antirrecidivante de los medicamentos antipalúdicos [Study of the Value of Anti-Malarial Remedies for the Prevention of Relapses].—*Rev. de Malaria* Sez I 1938 Vol 17 No 3 pp 165-183 With 3 graphs

This paper records the results of treatment of 175 persons with primary infections and of 139 persons with reinfections of *P. vivax*. The treatments used comprised quinine alone in varying doses and for varying periods of time quinine and plasmoquine and atebryn and plasmoquine. The author concludes that in Spain the treatment of initial attacks of primary *vivax* infections and of *vivax* reinfections should not be prolonged more than seven or eight days. Atebryn associated with plasmoquine is much more effective than quinine or atebryn alone or the association of these two drugs in the prevention of relapses. Unusual symptoms ascribed to the administration of atebryn were conjunctivitis (two cases) and laryngitis (one case). Atebryn for five days followed by plasmoquine for four days also gave excellent results in *falciparum* infections. Relapses of *falciparum* infections were more frequent among children below four years of age than in later age groups. Λ II

PAKEMHAM WALSH (R.) & RENNIE (A. T.) Sulphonamides in Malaria. —*Lancet* 1938 July 9 p. 79 With 1 chart.

This short note concerns a patient suffering from general paralysis who was inoculated with *P. vivax*. Subsequently he was found to be suffering from cystitis which was treated with sulphonamide preparations. This treatment appeared to cause the elimination of parasites from the peripheral blood and the cessation of rigors. Seven weeks after the eighth rigor there was a relapse of malaria which was treated with quinine. Λ II

PIZZILLO (Giuseppe) Sulla cura di Maurizio Ascoli nelle infezioni malariche. Nota \ Studio delle infezioni primitive [Ascoli's Method of Treatment in Primary Infections].—*Rev. di Malaria* Sez I 1938 Vol 17 No. 3 pp. 184-207 With 16 graphs. [71 refs.] German summary (7 lines)

This is a description of sixteen cases of malaria treated by Ascoli's method. All were recently acquired primary infections. In nine of these cases treatment was begun during the acute febrile stage of the disease. In others the beginning of the treatment was followed, after a short interval by a return of one or more febrile attacks, the number varying inversely with the duration of the period elapsed between the onset of the primary attack and the commencement of the adrenalin therapy. Very small doses of quinine in conjunction with adrenalin treatment are sufficient to control the fever. Splenic enlargement does not occur in cases so treated. Spleens already enlarged are reduced in size. The general condition of the patient suffers but little from the infection. Febrile attacks cease altogether on the termination of the treatment or very soon after. Λ II

KRITCHEVSKI (I L.) Le phénomène de renforcement en chimiothérapie Renforcement de l'action thérapeutique des composés antimalariques de la série quinoléique [The Phenomenon of Increased Effect in Chemotherapy Increased Therapeutic Effect with Antimalarial Compounds of the Quinoline Series.]—*Ann Inst Pasteur* 1938. Aug Vol 61 No 2 pp 205-216 With 6 diagrams

The unimportance of the reticulo-endothelial system (R.E.S.) in the chemotherapy of malaria is pointed out by the author. When the system is blocked in certain birds by trypan blue the action of anti-malarial drugs is appreciably affected especially if used early in the infection. The integrity of function of the R.E.S. is necessary for intrinsic action by antimalarial drugs as well as for increased effect of such drugs by other compounds which themselves have no antimalarial properties.

The phenomenon of increased effect has been noted when using quinoline compounds along with trypan blue or pyrrrole blue in *P. praecox* infections against which neither of the latter two compounds has any action. Thus plasmocide (6-methoxy-8-diethylamino-propylamino quinoline) administered in inactive doses in *P. praecox* infections of canaries along with either of the above two compounds by injection or by mouth exerts a therapeutic effect. Pyrrrole blue when given early in treatment with maximum doses of plasmocide delayed infection for 13 days as opposed to a delay of 2 days brought about by similar doses of plasmocide given alone. The optimal dose of pyrrrole blue lies between 0.0002 gm. and 0.005 gm. for a bird of 20 gm weight. The optimal result on the infection is obtained where plasmocide is given on the third day after inoculation of the canary with *P. praecox* and is accompanied by pyrrrole blue on the first two days. The components of pyrrrole blue alone or together cannot bring about the increased action. An inactive quinoline compound was found to exert a therapeutic effect when accompanied by pyrrrole blue but the latter has no effect in presence of quinine or atabrin. Both trypan and pyrrrole blue are deposited in the R.E.S. where it is thought they react with plasmocide to give a new compound; there is no reaction between them however *in vitro*. The effect of either of these two compounds is not brought about by sensitization of the organism to them since five generations of parasites treated with pyrrrole blue behaved to an inactive dose of plasmocide like fresh parasites. The same phenomenon of increased action has been described also in human malaria.

J. D. Fulton

DEVINE (J.) Studies in Chemotherapy XVIII. Changes in the Blood and Urine produced by Administration of Undecane Diamidine.—*Ann Trop Med & Parasit* 1938 Aug 2. Vol 32 No 2. pp 163-175 [15 refs.]

A study has been made of the upper limit of dosage of undecane diamidine which may be given without serious renal or hepatic injury. Analyses were made on fasting blood samples on two successive days and on urines collected on the same days following intravenous injection of 5 mgm. of the drug per kilo into rabbits. There is no significant change in blood sugar but blood urea values increased and were again normal in two days while N.P.N. changes were smaller.

in amount but with a similar trend. Anorexia and nausea caused by the drug with consequent variation of food intake makes the interpretation of the nitrogen balance difficult. The experiments were repeated with animals on half rations to simulate the conditions in anorexia and nausea. The results were the same as above albuminuria was absent and qualitative tests of renal or hepatic injury were negative.

Similar analyses on animals receiving successive small doses showed no significant changes. When maximum doses were given there was a transient hyperglycaemia with nitrogen retention. On histological examination the convoluted tubules of the kidneys showed degenerative changes. Lethal doses caused liver damage with hypoglycaemia and rise in amino nitrogen. Histological examination confirmed the liver damage and likewise that of kidneys. In neuro-syphilitic patients there were no significant changes in blood or urine. Blood urea values increased with a large dose—albuminuria and glycosuria being absent. In man the blood sugar level is not affected by the maximum tolerated dose but danger to the kidneys is indicated. The toxic action of undecane diamine on liver and kidneys broadly resembles that due to synthalin and other alkylene diguanidines.

WHITE (R. SENIOR). On Malaria Transmission in the Jeypore Hills. Part II. A Second Year's Results.—*Jl. Malaria Inst. of India* (formerly *Records of the Malaria Survey of India*) 1938. June. Vol. 1 No. 2. pp 129-145 [10 refs.]

Part I of this paper (see this Bulletin 1937 Vol. 34 p. 627) reported that *Anopheles* of the *funestus* group *flavistilis* varus and minus were responsible for malaria transmission in the Jeypore Hills, and that *A. culicifacies* which is very prevalent is of no pathogenic importance. A second year's work has fully confirmed these findings. *Anopheles* control limited to the *funestus* group has not resulted in any deterioration of health of the imported railway staff. It has, however, effected a 78 per cent saving in expenditure on larvicides. Catches of adult females in dwelling houses were repeated throughout a year. Of the total caught *A. culicifacies* contributed 60.2, 4.1 and 35.7 per cent. respectively in cattle sheds. Pig-sties offer no attraction as a resting place to any of the twenty three species of anophelines found locally. The second year's dissections gave oöcyt and sporozoite rates as follows: *culicifacies* 0.08 and 0; *flavistilis* 6.8 and 3; *varus* 8.9 and 4; and *minus* 5.1 and 4.1. Oöcyt counts are given for the three transmitting species. The counts were low: three-quarters of them had less than six oöcyts per stomach. There is a paucity of crescents in blood films in the Jeypore Hills. Observations with a human bait trap-net led to the conclusion that each inhabitant of the village in question would receive four infected bites in September—seventeen in October and fifteen in November.

WHITE (R. SENIOR) & DAS (B. K.). On Malaria Transmission in the Singhbhum Hills.—*Jl. Malaria Inst. of India* (formerly *Records of the Malaria Survey of India*) 1938. June. Vol. 1 No. 2. pp. 160-184. With 1 fig.

The Singhbhum Hills separated from the Bay of Bengal by the Orissa Plain comprise the British Indian District of the same name.

and three Indian Feudatory States. The higher hills exceed 3 000 feet. The hills contain the chief iron ore deposits of India. The district is intensely malarious. It was formerly believed that *A. culicifacies* which is very prevalent was a vector of importance. The observations recorded in this paper indicate that as in the Jeypore Hills anophelines of the *funestus* group *fluvialis* *varuna* and *minimus* are much the most important vectors the only ones that require control to afford malaria protection. Of 1 611 *A. culicifacies* dissected the oöcyst rate was 0.3 and the sporozoite rate zero. Of 1 031 *A. fluvialis* these rates were 4.6 and 1.8. Of 189 *A. varuna* 4.2 and 1.1 and of 334 *A. minimus* 6.9 and 3.9. Transmission of malaria was found to occur throughout the year except in May, June and July. A. W.

SINTON (J. A.) & SHUTE (P. G.) A Report on the Longevity of Mosquitoes in Relation to the Transmission of Malaria in Nature.—*Ministry of Health Reports on Public Health & Med. Subjects No. 85* pp. iv+45. With 2 charts. [69 refs.] 1933. London. H.M.S.O. [9d.]

It is evident that the length of life of an adult *Anopheles* may affect its power of transmitting malaria. An insect may normally live so short a time at least under certain climatic conditions as to prevent the *Plasmodium* developing to the sporozoite stage in it. The authors review our present knowledge of longevity and contribute their own material.

The insect's length of life is influenced by a great variety of factors. Some are internal, such as the nutrition of the larva (not discussed here) the rate of metabolism of the adult and its preparation for egg-laying or hibernation. There are many external factors also of which we believe that temperature and humidity are the most important. Our knowledge of these subjects is at present fragmentary and much of the earlier work was carried out under difficult conditions and cannot be regarded as satisfactory. The authors summarize these subjects but it is not easy to present a concise résumé of them. Till much more is known about metabolism and the effects of climate it will hardly be possible to consider the natural span of life i.e. the normal length of life under favourable conditions.

In discussing the possible effect of *Plasmodium* on the length of life of *Anopheles* the authors point out that it does not produce gross lesions in the tissues. The parasite seems to provoke no histological reaction except that when salivary glands are heavily infected they become altered in shape and very friable. There is a considerable body of opinion that even a heavy infection does not reduce the insect's length of life (but apparently no previous author has devised experiments in order to investigate this point). The authors' very great experience mainly based on *A. maculipennis* supports the view that the parasite is harmless to the mosquito. They have also performed a number of controlled experiments which are set out in full. Of these one may be quoted. A number of *A. maculipennis atroparvus* were collected in nature in November a season when the insects are not using food to develop ovaries. They were divided into two groups one of which was fed on a clean man, the other on a carrier of *P. vivax*. Both groups were then kept at 75°F (24°C) and a high humidity having daily an opportunity of feeding on a rabbit. No differences were observed in the mortality either in the first 8 days the period during

which the ookinets penetrate the gut wall or later. There is reason for thinking that all or nearly all the mosquitoes which had fed on the infected man had acquired the infection. Such experiments as these show clearly that neither *P. vivax* nor *falciparum* shortens the life of *atroparvus*. This is shown by experiments under various conditions of maintenance all of which might be described as "favourable." But there is some evidence that under "unfavourable" conditions for instance partial starvation infection with *Plasmodium* tends to shorten life. The authors refer to certain carefully controlled experiments with *Culex fatigans* and *Protoplasma* in which a significantly higher mortality was observed among infected mosquitoes (see this Bulletin 1938 Vol 33 p 278) in these experiments the conditions were unfavourable and the view is put forward that the results are not applicable to what occurs in nature.

In general the authors hold that death from infection with *Plasmodium* is not mainly responsible for the fact that certain species of *Anopheles* seldom transmit malaria in nature.

PERAGALLO (Italo) Un catturatore trasparente delle zanzare. (A Transparent Trap for Mosquitoes.)—*Riv di Malariologia* Sez. I 1938 Vol. 17 No. 3. pp. 231-234. With 1 fig. French summary (4 lines)

The author figures and describes a small piece of apparatus for the capture of mosquitoes. It consists of two cup-shaped receptacles, each 100 mm in diameter mounted at right angles to each other at the end of a rod. Each receptacle contains a plug of cotton wool impregnated with petroleum. The apparatus is constructed of acetyl-cellulose and so is transparent and unbreakable. A //

YELLOW FEVER.

PRÉCIS OF ABSTRACTS IN THIS SECTION

A table is given by JAMES (p 19) showing the distribution of yellow fever in South America and Africa for the 6 months ending 31.3.1938. The epidemiological value of the protection test is shown and it is now being used in Uganda and the Sudan. Attenuated neurotropic virus in homologous serum was used for immunization with good results. Jaundice following vaccination is probably due to a filterable virus contaminating the serum used or possibly cultivated with the yellow fever virus. The development of antibodies is slow after vaccination but they persist in full strength for at least one year. SOPER (p 20) records that pantropic virus (17 D) cultivated on fowl embryo tissue from which the brain and spinal cord have been removed to prevent neurotropism has been used since 1934 for the vaccination of 168 000 persons in Brazil. The method of preparation is described. No serious ill effects have been seen and immunity was complete in 42 of 45 persons tested for it. Viscerotomy is essential in detecting early cases in an epidemic. BAUER (p 20) states that jungle yellow fever may cause well marked epidemics but the method of transmission is still obscure. Monkeys however probably constitute the most important factor in the spread of this disease according to SOPER (p 20).

SOREL (p 21) notes that yellow fever has increased in the French Colonies and O BRIEN (p 21) analyses an outbreak in British West Africa. CROUCH (p 21) describes a few protection tests found to be positive in cases of febrile jaundice in Malakal where however *Aedes* are scarce. SCHÜFFNER *et al* (p 22) discuss the finding that in spite of the absence of yellow fever from Surinam since 1908 11 per cent of 233 persons living there since that date were found to give positive protection tests. A description of an outbreak at Zongo is given by VAN CAMPENHOUT (p 22). The effects produced by Laigret's method of vaccination are described. The value of the mouse protection test in epidemics of uncertain nature is indicated and its limitations stated by the Commission (p 23). Mass vaccination is the only practical method of prophylaxis in the jungle population.

DINGER (p 23) discusses possible measures against yellow fever in the Dutch East Indies. CLERC (p 24) in discussing the epidemic on board the *Sea Rambler* considers that there are arguments against its having been yellow fever though the laboratory tests were very strongly in favour of it. SCHÜFFNER, WALCH SORDRAGER and HOEKSTRA (p 25) consider that jungle yellow fever in Surinam is epizootic and transmissible to man in whom it is a slight or masked infection different in clinical form from yellow fever. PATIÑO CAMARGO (p 25) notes that cases of yellow fever and influenza occurred simultaneously in Guadeloupe in 1929. It is not possible to say how many of the influenza cases were really yellow fever. He details the vectors of Colombia. ARAGÃO (p 26) describes a small outbreak in São Paulo.

SHANNON WHITMAN and FRANCA (p 27) found that *Aedes leucocelaenus* and *Haemagogus capricornis* were the only two species which were infective by bite and which were thus incriminated as natural vectors among 24,304 wild mosquitoes of some 30 different species

caught alive at points near where human infection had occurred in an outbreak of jungle yellow fever but an emulsion of 88 Sabethlines caught in the same neighbourhood as the infected *Harmagopus* and injected intracerebrally into mice produced yellow fever encephalitis. HUNN and NOVIS (p. 28) studied the habits of 80 species from a jungle yellow fever area. LIXS (p. 28) describes a fatal case of jungle yellow fever. The larval index of *Aedes aegypti* in various parts of Africa is mentioned on page 28.

TIBIRIÇA (p. 29) gives a full account of the microscopical appearances of the liver in yellow fever and DA ROCHA LIMA points out that the evidence provided by a number of changes in the cells must be considered in making a diagnosis.

FINDLAY and MACCALLUM (p. 30) found that 89 cases of jaundice occurred in 3100 persons vaccinated with virus and immune serum. They think it to be due either to a hepatotoxic virus in the inoculum or a combination of hepatotoxic substance and an infective agent probably that of common infective hepatic jaundice [see also above JAMES]. LEFÈVRE and CAMBESVÈNKS (p. 30) describe methods of vaccination. LLOYD (p. 31) calls attention to the difficulty of the diagnosis of yellow fever in specimens obtained by blood surveys. The necessity for anti mosquito measures and vaccination in endemic areas is stressed by BARTHAS (p. 31).

MACKIE and CRAWFORD (p. 32) give an account of a method of dissemination of aircraft by means of spray and nebulizer using a watery base pyrethrum insecticide.

SALEUX, CECALDI and PALMADICI (p. 32) describe the isolation for the first time of a strain of yellow fever virus in the French Congo. It was found to be indistinguishable from the Dakar strain. DE ASSUMPTIÃO (p. 33) shows the essential identity of a strain of the jungle yellow fever virus isolated in São Paulo and a Dakar neuro-tropic strain, though the São Paulo strain was apparently slightly less virulent than the other.

1. The number of cases of yellow fever notified during the six months ending 31st March 1938 are indicated in the following table —

South America

Country	State	No of localities with cases	No of cases	No of deaths
Brazil	Minas Geraes	31	—	100
	Pará	1	1	1
	Santa Catharina	1	1	1
	Rio de Janeiro	10	19	16
	São Paulo	1	14	—
	District Federal	2	2	2
	Cayua	1	12	3
Colombia		5	9	9
Paraguay		1 (Asuncion)	1	1

Africa

Belgian Congo		2	16	10
French West Africa—	Dahomey	1	5	—
	Ivory Coast	5	6	4
	Senegal	13	29	21
	Soudan	2	3	3
French Equatorial Africa	Oubangui-Chari	1	1	1
British West Africa	Gold Coast	13	18	12
	Nigeria	6	8	6

These figures do not differ markedly from those of the preceding six months but fewer cases have been notified from towns the majority coming from villages or rural districts with a high larval index.

With reference to epidemiology attention is called to additional evidence in support of the value of the protection test in mice as an indication of the distribution of the disease. At Entebbe Uganda the Government is helping the Rockefeller Foundation to investigate the nature of fevers of unknown origin by inoculating the blood of patients into mice. This inquiry is in progress in the regions west of the Nile in the Uganda forest in the Ruwenzori district and in the south of the Anglo-Egyptian Sudan.

Immunization is now being carried out by a single inoculation of neurotropic virus attenuated by culture suspended in 0.25 to 0.5 cc. homologous serum. Dr Sawyer reports that since 1st January 1937 in Brazil 80,000 persons have been vaccinated by this method without any complications being observed. Dr Findlay records that in London during the past five and a half years 4,300 Europeans have been vaccinated before proceeding to yellow fever countries, and not a single case of the disease has occurred among them. During this same period some 30 Europeans in these areas became infected, none of whom had been vaccinated. Col Mackie reports that the regulations now require the vaccination of all Government servants serving in British West Africa and the R.A.F. applies similar rules for those serving in yellow fever districts.

Attention is called to the occurrence of jaundice following yellow fever vaccination noted by FINDLAY and MACCALLUM (see this *Bulletin* 1938, Vol. 35:119) who found that 2.9 per cent. out of 4,300 had shown this symptom. Col Mackie records 6 per cent. out of 54 R.A.F. personnel. The cause of this jaundice is supposed to be a filterable virus inoculated with the serum and it may have been cultivated in association with the yellow fever virus, since recently Findlay has used a new strain of culture virus for 1,100 vaccinations without any of the patients developing this symptom.

An interesting letter from Dr J. H. BAUER giving supplementary notes on yellow fever in Brazil is reproduced. It confirms the view that jungle yellow fever may cause well marked epidemics. Its method of transmission however still remains obscure. Evidence of its spread is afforded by the occurrence of fatal cases in middle-aged persons who had been born and lived all their lives in the same locality.

Since last summer more than 200,000 persons in Brazil alone have been vaccinated by the method described above. Ninety per cent. have shown no reaction whatever and in the remaining 10 per cent. reactions of varying intensity have occurred generally on the 6-8th day after inoculation. There has not been a single death nor any other complication such as jaundice.

The examination about a month later of the serum of vaccinated subjects showed the existence of immune bodies in at least 85 per cent. of the patients but it would seem that the development of antibodies is rather slow and may go on increasing for about three months. Patients examined a year later showed no diminution in the degree of immunity.

ii Details are given of yellow fever vaccination in Brazil. A pantropic virus known as 17D which had been cultivated on fowl embryo tissue since 1934 by Wray LYON (see this *Bulletin* 1936 Vol. 33:627) has been used since February 1937. During 1937 38,387 persons in Brazil were vaccinated with this virus, and by the end of March 1938, the number had reached 188,000. Among the first 200 persons vaccinated at Rio de Janeiro about 20 per cent. showed symptoms attributed to the virus but in no case were they sufficient to necessitate stopping work. In 12 out of 29 patients carefully examined, small quantities of virus were found to be present in the blood for one day or more between the 4th and 10 days after inoculation. Out of 45 examined later for immunity 42 gave complete protection, one partial, and 2 were negative. Of the latter one patient had shown no immunity reaction after inoculation with another virus, and the other had received only a very small dose of virus.

The virus used for inoculation is prepared by injecting the tissue culture strain into fowl embryos within the egg shell. After incubating these eggs for some days a higher concentration of virus is obtained than in tissue cultures. The embryos are then ground up in normal human serum to make a 10 per cent. suspension, which is dried and stored in ampoules. It is essential that the virus should be living when used for vaccination and although the dried virus will live for long periods at low temperatures it is advisable to test the batches before use as a case occurred in which the virus had become inactive. No cases of jaundice have been observed in inoculated subjects nor any other serious after-effects within a year of vaccination.

With reference to yellow fever in South America recent observations show the very great importance of the jungle form of the disease which is evidently widely distributed. Viscerotomy is found to be invaluable and the early cases of recent outbreaks were all discovered by this method. The present outbreak in the States of Minas Geraes and Rio de Janeiro has been associated like many others with an increased mortality among the howler monkeys and protection tests on numerous wild animals support the view that various species of monkeys constitute probably the most important factor in the spread of jungle yellow fever.

iii. During 1937 there has been a distinct increase in the number of cases of yellow fever recorded from French Colonies. A total of 48 including 40 from West Africa, 1 from the Cameroons and 7 from Equatorial Africa is reported. Forty four of the cases were fatal including 23 Europeans, 18 Syrians and 3 natives. The diagnosis was confirmed in 43 cases by histological examination of the liver. Interesting details of these cases are given including their clinical histories and distribution. Two of the patients had been vaccinated against yellow fever (presumably by Laigret's method) one only four days and the other about eighteen months before the appearance of symptoms of the disease. The author recommends testing the blood of vaccinated subjects one month after inoculation to determine the degree of immunity acquired and a year later to test its persistence.

iv. An analysis of cases of yellow fever occurring in Nigeria and the Gold Coast during 1937. Of the 81 from the Gold Coast 68 occurred in the Eastern, 6 in the Western and 3 in the Central Province and 4 in the Northern Territories.

The main characteristic of this outbreak has been the mortality among Africans 74 cases with 65 deaths including an infant aged only three months. In addition there were four cases all fatal among Syrians and three cases, all fatal, among Europeans. The majority of the deaths occurred about the fifth day of the disease and intra nuclear inclusions were easily found in all the livers examined although in previous cases they had not been found. The principal factor for the concentration of cases in the Eastern Province seems to be the water stores in the rural districts and the necessity of preserving every available drop of water.

v. During 1933 protection tests were made on 50 sera in Malakal only one of these sera from an adult was positive. At the end of 1935 a fatal case suggestive of yellow fever occurred in a man from Eliri in the Nubian Mountains and the results of protection tests on 27 sera from that region gave 12 positive and 15 negative. During 1936 out of 10 sera from cases of febrile jaundice in Malakal, one was

positive. During 1937 12 cases of febrile jaundice occurred there 4 out of 11 examined gave positive protection tests in mice. Clinical details are given of these 4 cases all of whom recovered. With reference to the occurrence of *Aedes aegypti* at Malakal, during 1937 124,241 inspections were carried out and only 5 adult mosquitoes and 14 cases of larval infection were found. During the last quarter when two suspected cases of yellow fever occurred, no *Aedes* were found. As a precautionary measure the aerodrome at Malakal has been considered as situated in an infected zone and the usual anti yellow fever methods applied.

vi. The last two epidemics of yellow fever in Paramaribo Surinam occurred in 1902 and 1908, since when no case has been recorded. The authors have carried out protection tests in mice with the sera of 369 persons from Surinam and the results are divided according as to whether the subject lived there before 1908 or since then.

Of those living in Paramaribo before 1908 34 out of 60 were positive compared with 25 out of 233 of those living there since that date. This latter figure of 11 per cent. is rather surprising in view of the absence of any records of the disease and suggests the occurrence of small epidemics. Of those living in the interior including Indians and forest negroes the percentage infected has remained the same (16 per cent.) whether they were born before 1908 or since then. Three out of 19 were positive in the former group and 9 out of 57 in the latter. Only 1 female out of 25 was positive compared with 8 males out of 35 examined.

Finally the authors give the results of protection tests carried out on the members of the staff of the yellow fever laboratory in Amsterdam. Out of 6 persons coming into daily contact with the virus 4 were positive and 2 negative. Out of 10 persons rarely coming in contact with the virus only one gave a positive protection test.

In addition 95 inhabitants of the Netherlands who had never been exposed to the chance of infection were examined and all were negative.

vii. The description of an outbreak at Zongo on the Oubangui involving 17 cases with 9 deaths. The symptoms included headache pain in the joints, liver and epigastric region, mucous vomits, slight jaundice, the urine containing numerous cylindrical casts and typhoid state with terminal delirium. Two mice inoculated with the serum of a patient died with paralysis on the fifth day. The livers of four of the patients did not show lesions characteristic of yellow fever and out of seven sera only one gave a positive protection test and since 29 per cent. of the general population were positive in 1935 this single positive is considered of no significance. However precautionary measures were taken against it being a modified form of yellow fever especially in view of the fact that in the French territory on the other side of the river yellow fever lesions were found in the liver of a patient who died with similar symptoms.

The author gives the results of using Lalagret's method of vaccination in 30 Europeans. 10 had slight reactions and needed rest. 13 severe reactions about the 6th day lasting for 3 days. 5 serious reactions on the 14th day lasting for 10 days and 2 severe reactions from the 21st day onwards. Meningeal symptoms, with violent headaches and frequent vomiting, were present in the severe cases. The reactions in

natives were generally much less severe but cases occurred which necessitated hospitalization of the subjects

viii An examination of 50 sera from natives of this region by the mouse protection test gave 49 negative and 1 positive

ix. The Commission directed its attention to five main points

(a) With reference to the value of the mouse protection test for the diagnosis of yellow fever it is not recommended for the diagnosis of doubtful febrile disease it is not recommended for the diagnosis in a community suffering from an epidemic of uncertain nature when the only of real value for making a retrospective diagnosis is a number of positives is well above that of the surrounding population and where previously negative persons become positive after recovery

(b) It is suggested that laboratory experiments that a virus not attenuated by prolonged culture may occur in the peripheral circulation and be transmitted by a mosquito feeding on such blood On the other hand cultured virus such as strain 17D in Brazil has a very attenuated virulence and experimental attempts to transmit the virus by mosquito have been negative (c) With regard to the use of prophylactic vaccination against jungle yellow fever mass vaccination is now recommended in view of the new methods of preparing vaccine and at present this would seem to be the only practical means of anti yellow fever prophylaxis among the jungle population This recommendation only relates to the jungle form and does not in any way imply the abandonment of other preventive methods in urban districts (d) It is considered desirable that before use each batch of vaccine should undergo a test for vitality and titration of virulence and that vaccinated persons should be tested for immunity not earlier than one month after vaccination It is not at present possible to fix any period for the duration of this immunity

DANGER (J E) *Nieuwere inzichten omtrent de epidemiologie en bestrijding der gele koorts en hante beteekenis voor Nederlandisch Indië* [Significance of Present Knowledge of Yellow Fever for Netherlands India.]—*Geneesk Tijdschr v Nederl Indië* 1933 May 31 Vol 78 No 22 PP 1292-1310 [55 refs]

A detailed full introduction presents the facts that are known of the distribution of yellow fever Then comes the question What importance have these known facts for Netherlands India? Much turns here upon the mouse test which has revealed the existence in latent subclinical form of yellow fever not only on the west coast of Africa but also in the whole of equatorial Africa The danger which suggests itself is that with the development of air travel endemic areas will be rapidly connected up with air ports such as Vaurobi for example on the Cape-Cairo route Anti yellow fever landing places are already being set up at Juba and Malakal by the Anglo-Egyptian authorities Those countries which adhered to the regulations of the International Air Convention are now likely to be faced with difficulty over the interpretation of the words biologically recognizable form of yellow fever An attempt has been made to deny the specificity of the mouse tests which are now likely to be faced with difficulty over the interpretation of the words biologically recognizable form of yellow fever hygienists recognize their specific tests, but the great majority of What it is asked should be done in the matter by the Netherlands Indies Government? Can the quarantine regulations be rendered

more stringent? Mouse tests are scarcely possible as they require the use of yellow fever virus and the importation of this virus is banned by law. Vaccination on a large scale could scarcely be considered unless the menace of yellow fever became acute. This procedure moreover comes under the same ban as applies to the mouse test. Again, it is not even thinkable that an anti-*Aedes* campaign should be commenced. What seems feasible and called for is to make preparations for such a campaign by special surveys of breeding places of *Aedes*. Regulations should at least be drafted to meet the necessity for action when it arises

W F Harvey

CLERC (Marcel) L'épidémie de fièvre jaune du "Sea Rambler"
(1936) The Epidemic of Yellow Fever in the "Sea Rambler"
(1938) —*Re Méd et Hyg Trop* 1937 Nov.-Dec. Vol. 29
No 6. pp 281-292.

A discussion of the epidemic on board the "Sea Rambler" in 1936 which was diagnosed as yellow fever by Dr P. G. STOCK [see this *Bulletin* 1937 Vol. 34 p. 683].

It may be recalled that this epidemic broke out among a crew of 24 about a week after the ship had left Dakar but previously had been for two weeks in Kaolakh and Zighinchor below Gambia where mosquitoes were said to be very troublesome when loading cargo before returning to Dakar. On arrival at Madeira, various members of the crew became ill, and at Funchal the port authorities considered it an outbreak of food poisoning. Seven of the crew died five remained in hospital at Madeira and two of the original crew who had been ill, remained on the ship. Eight new men were recruited at Madeira and the ship returned to Sunderland.

An investigation of this epidemic was made by the port authorities. Dr FINDLAY examined the blood of 14 of the crew. Six gave positive mouse protection tests against yellow fever including four of the crew hospitalized at Madeira and the two patients who remained on duty whilst the eight new members of the crew recruited in Madeira all gave negative tests. Agglutination tests against *S. icterohaemorrhagiae* made by Major H. C. BROWN gave negative results with all the sera examined, thus excluding the possibility of Weil's Disease. Agglutination tests were also made to exclude *Salmonella* infection. Finally the blood of two patients was examined for malaria parasites, also with negative results.

In spite of these strong arguments the author is of the opinion that there are certain arguments against the diagnosis of yellow fever.

All the cases occurred within eight days, and therefore one must assume that they were bitten by infected mosquitoes at more or less the same time. But there were no subsequent cases although one might have expected some of the mosquitoes on the ship to have become infected by feeding on the patients and thus to produce a new series of cases after the usual incubation period. A much more serious objection is the absence for many months previously of any notifications of yellow fever from the localities visited by the "Sea Rambler" and the fact that no other ships from these localities have records of similar outbreaks. On the other hand cases of malaria are common on ships returning from the west coast of Africa and details are given of serious outbreaks among crews causing the deaths of several members.

The complete absence of black vomit among the cases on the Sea Rambler is also noteworthy since all the described symptoms exist in other diseases and especially malaria. The laboratory tests however would seem to provide overwhelming evidence in support of the diagnosis of yellow fever.

In the discussion following this paper BOYÉ disputed the value of the mouse-protection test and rejected the diagnosis of yellow fever because of the absence of black vomit. STEFANOPOULO whilst admitting that no serological reaction is absolutely infallible stated that the results of serum protection tests for the diagnosis of yellow fever had been of great value and could not be ignored even in certain cases the results seemed open to question.

SCHÜFFNER (W) WALCH SORDRAGER (B) & HOEKSTRA (J) Laatste resultaten van het onderzoek naar het voorkomen van Gele koorts in Suriname [The Occurrence of Yellow Fever in Surinam].—*Geneesk Tijdschr v Nederl Indië* 1938. Mar 15 Vol 78 No 11 pp 571-592.

Two epidemics of yellow fever have occurred in this century in Paramaribo the capital of Dutch Guiana on the Surinam River one in 1902 and the other in 1908. It is well known that the immunity after yellow fever may be taken to be life long. Now that we have in the mouse a method of testing this immunity, it became possible to estimate what permanent effect epidemics had left upon the population of Surinam. It was found that 58 per cent of the people had a serum which was strongly protective for mice. In the same age group of Indians and bush negroes among whom no epidemic had occurred a 16 per cent immunity was demonstrated. This immunity is placed to the account of the jungle form of yellow fever so far as relates to the clinical manifestations. In these matters the authors agree more or less closely with the American workers. Jungle fever is not a serious disease and it would seem that it can easily be overlooked. This explanation is forthcoming for the existence of immunity among jungle folk. But what of the immunity found to exist in the people of younger age in Paramaribo and district? No epidemic is recorded which could have affected them or account for their 11 per cent immunity (reduced to 5-6 per cent, with more stringent test). A lengthy argument centres round this immunity and other points in the text and the conclusion is drawn that it can only be due to a jungle type of the fever. This jungle type is to be regarded as being an epizootic and as capable of transmission to man in whom it is a slight or masked infection. Nothing is yet known regarding the nature of the enzootic.

PATINO CAMARGO (Luis) Notas sobre fiebre amarilla en Colombia. [Yellow Fever in Colombia].—Reprinted from *Rev Facul de Med de Bogotá* 1937 Nov Vol 6 No 5 74 pp With 4 maps [115 refs.]

The author in the opening sections of this article gives a general account of yellow fever its source and early outbreaks applying it locally to Colombia. To readers of this *Bulletin* important parts are

those giving the dates of outbreaks of which 45 are listed between 1830 and 1900 and another 23 between 1900 and 1929. In the table of the first information is given of nine only, and that is very meagre a statement being made of the duration of the outbreak, the population and the mortality. In seven the actual figures, in two the percentages only (presumably case mortality). In the second table of twenty-three ten places are mentioned as being free from *Aedes aegypti* and in two others they were very scarce and the outbreaks were very likely of the rural type. FRANCO MARTINEZ and TORO concluded that the Muzo outbreak of 1907 was a mixture of yellow fever and leptospirosis (*icterohaemorrhagiae*). In the Socorro outbreak (Santander) of 1929 there were 150 cases, 100 mild, 50 severe and 37 died. In Guadalupe, adjacent to Socorro, cases occurred in January and February, some being diagnosed as influenza. This outbreak was studied by PEÑA CHAVARRIA, SERPA and BEVIER and they came to the conclusion that a certain number definitely suffered from yellow fever but they are unable to say how many, or what proportion of the "influenza" cases were cases of yellow fever.

The author states that vectors conveying the infection in Colombia by their bite are five namely *Aedes aegypti*, *Aedes scapularis*, *Aedes taeniorhynchus*, *Aedes fluviatilis* and *Culex fatigans* (this occasionally transmits but more often fails). Others are infective if the triturated bodies are inoculated into *M. rhesus*, *Aedes serratus*, *Aedes terreus*, *Psorophora cingulata*, *P. ferox*, *Mansonia fasciolata*, *M. chrysomelum*, *M. illians* and *Culex fatigans*. A list of 117 species of mosquitoes found in Colombia is also given. The *Aedes aegypti* index varies greatly in a district. Thus in Cúcuta in 1923 it was 90 per cent. In 1932 none was found. In Bucaramanga in 1923 it was 86 per cent. in 1932 nil. In Barranquilla in 1923 51 per cent., in 1932, 72 per cent. in Santa Marta 64 and 17 per cent. in 1923 and 1932 respectively.

The article ends with a sketch of the measures taken by the National Department of Hygiene co-operating with the staff of the Rockefeller Foundation and recommendations both on the usual lines of examining samples of blood for the protection test, viscerotome sections, epidemiological and entomological studies, vaccination and determination by spot maps of distribution and so forth. H. H. S.

ARAGÃO (Henrique de Beaupre) Observações a respeito de um foco limitado de febre amarela silvestre no estado de São Paulo [A Limited Focus of Rural Yellow Fever in the State of São Paulo].—*Brasil-Médico* 1938, Apr. 23, Vol. 52, No. 17, pp. 401-412. With 1 map.

The locality affected is in the municipalities of Presidente Wenceslau and Santa Anastácio, some 870 kilometres from São Paulo and 400 metres above sea level. Between 14th December 1937 and 8th February 1938 there were twenty-one cases, four of them fatal. The diagnosis was made on clinical, epidemiological and serological grounds, and by examination of the liver in the fatal cases. The serological tests comprised inoculation into white mice and *rhesus* monkeys. Anti-armyax vaccinations were performed on the inhabitants between the 14th and 25th January 7,784 in Presidente Wenceslau and on the 29th January 315 in Santa Anastácio. None showed any untoward symptoms worthy of note after the inoculations, a few had a transient

rise of temperature malaise and nausea. During the time of vaccination two cases occurred in the unvaccinated and a week after vaccinations ceased another case occurred a man who had been away and had not been vaccinated. A map of the district is reproduced in the article but on so reduced a scale as to be undecipherable. A list of the mosquitoes caught in the district is given and includes *Aedes serratus* *scapularis* *fulvus* and *leucoclaenus*. H H S

SHANNON (R. C) WHITMAN (Loring) & FRANCA (Mario) *Yellow Fever Virus in Jungle Mosquitoes*.—*Science* 1938. July 29 Vol 88 No 2274 pp 110-111

During the 1938 outbreak of jungle yellow fever in the state of Rio de Janeiro the authors had mosquitoes collected from points where human infection had occurred and forwarded daily to the laboratory at the capital.

Out of 24,304 wild mosquitoes sent in during a period of eleven weeks yellow fever infection was produced in two monkeys by the bites of *Aedes leucoclaenus* (Dyar and Shannon) and *Haemagogus capricornis* (Lutz) respectively. The mosquitoes tested are indicated in the following table —

List of Wild-caught Mosquitoes Tested for the Presence of Yellow Fever Virus

Group	Species	Used	Fed	Remarks
1	<i>Aedes scapularis</i> (Rondani)	180	100	
2	<i>A. leucoclaenus</i> (Dyar and Shannon)	4 671	2,270	Positive by bite.
3	<i>Haemagogus capricornis</i> (Lutz)	1 216	646	" "
4	<i>Psorophora ferox</i>	253	143	
	<i>P. albipes</i>	15	7	
	<i>A. fulvus</i> (Wiedemann)	8	5	
	<i>A. serratus</i> (Theobald)	1 570	545	
	<i>A. terreus</i> (Walker)	503	59	
5	<i>Sabethes</i> 3 species	1 092	369	
6	All other sabethines (<i>Sabethodes</i> <i>Limatus</i> <i>Wyomyia</i> <i>Goeldii</i> and <i>Trichoprosopon</i> (<i>Joblotia</i>) totalling about 20 species	14 786	3 443	Positive by injection.

In addition to the positive results obtained in the feeding experiments, which prove that these two species of forest-inhabiting mosquitoes are natural vectors of yellow fever the intracerebral injection of fluid from an emulsion of 118 *Haemagogus capricornis* into mice produced typical yellow fever encephalitis and similarly positive

results were obtained by the inoculation of 88 specimens of *Sabethine* mosquitoes. These results are of very great interest as constituting the first definite evidence as to the species concerned in the natural transmission of jungle yellow fever in Brazil. E H

KUM (H W) & NOVIS (Oswaldo) Mosquito Studies on the Ilha de Marajó, Pará, Brazil.—*Amer J Hyg* 1938. May Vol. 27 No 3 pp. 498-515 With 2 maps 1 graph & 2 plates. [11 refs.]

A total of 10 121 adult mosquitoes and 1 260 larvae representing 80 different species were collected in an area where jungle yellow fever was known to have occurred. No specimens of *Aedes aegypti* were found. The most common species biting man by day in the forests were *Aedes nubilus* *Psorophora ferox* and *Haemagogus janthinomys*. The daily curves of activity of these three species showed significant differences *Aedes* being predominantly crepuscular *Haemagogus* occurring especially about noon and *Psorophora* showing both morning and afternoon peaks of activity. Wide variations were found in the abundance and variety of mosquitoes occurring in the two main types of forest in this region. E H

BULLETIN DE L'OFFICE INTERNATIONAL D'HYGIÈNE PUBLIQUE. 1938. Sept Vol. 30 No 9 pp 1970-1978. With 1 map Renseignements relatifs aux index *Aedes aegypti* dans les divers pays d'Afrique pour 1937 I. A. Relevé des index larvaires dans les centres de la Côte de l'Or en 1937 B. Relevé des index larvaires dans les centres de la Nigéria en 1937 C. Index *Aedes aegypti* au Kenya [O'BRIEN (A. J. R.)] II Distribution et incidence d'*Aedes aegypti* au Soudan Anglo-Egyptien en 1937 [PRIDIE (E. D.)] [Data on the Larval Index of *Aedes aegypti* in the Gold Coast, Nigeria and Kenya in 1937 Distribution and Abundance of *Aedes aegypti* in the A. E. Sudan in 1937]

The papers give information on numbers of *Aedes aegypti* found in human habitations in the Gold Coast Nigeria, Kenya and the Anglo-Egyptian Sudan. The larval index "i.e. the percentage of buildings and compounds in which larvae of this species were found, is used as an expression of the insect's commonness.

There appears to be a healthy rivalry, between these territories and even those in West Africa feel able to report indices much below 1 per cent. As to who collected the figures, or how thoroughly the reader must judge for the authors do not help him. P 4 Barton

LIXA (Sinval A.) Caso classico de febre amarela de origem sylvestre. [A Typical Case of Jungle Yellow Fever]—*Folia Med* 1938. May 5 Vol. 19 No. 13 pp 149-153 With 1 chart & 2 figs.

A Brazilian of 29 years of age robust and of good physique an engineer by profession was working for the telephone company in Barra Mansa, Rio State and Bananal in São Paulo where no *Aedes* is to be found. He was seized with shivering headache and marked prostration, with early vomiting. The next day the urine diminished owing it was thought to the vomiting. The last developed to black vomit and there was almost total suppression of urine. He was

brought to Rio on the fourth day of illness and died on the sixth day. An autopsy was performed and the findings are described. These need not be detailed here they were those characteristic of yellow fever. Photomicrographs show well the destruction of the liver cells and the condition of the kidney tissue.

IBIRICA (Paulo O T) *Pathologia microscopica do fígado na febre amarella* [Histology of the Liver in Yellow Fever]—*Ana Paulist Med e Cirurg* 1938 May Vol. 35 No 5 pp 429-452. With 6 figs 40 refs; English summary

This is an account of a careful painstaking study of the microscopical anatomy of the liver in yellow fever and also of the chemistry of the changes observed. Bile pigment was seen to be retained in the hepatic cells proper and in the Kupffer cells many of these cells were necrosed. The author discusses with a good deal of supposition, unchanged, the nuclei appeared oedematous at first later when the chemical changes brought about and the method of their production. The jaundice he regards as haematogenous at first later when damage to the liver cells interferes with their function, it is hepatogenous or a mingling of the two. The photomicrographs reproduced in the article are not very convincing probably colouring is needed to demonstrate the points stressed.

DA ROCHA LIMA (H) *Rückblickende Betrachtungen ueber die Entwicklung der Histodiagnose des Gelbfiebers*. [A Retrospective View of the Development of the Histo-Diagnosis of Yellow Fever]—*Reprinted from Festschrift Bernhard Nocht's 80 Geburtstag von seinen Freunden u Schülern Hamburg* 1937 pp 497-512. [33 refs.]

The author gives an interesting historical review of the subject including extracts from the publications of various pathologists showing the manner in which his early work of 1912 had been over looked possibly owing to the fact that at the time his views were not generally accepted. Attention is called to the fact that it is impossible to base the histological diagnosis of yellow fever on any single character such as hyaline necrosis etc but only by a careful consideration of the evidence provided by a number of changes in the cells. The author stresses the importance of correct diagnosis and calls attention to some of the difficulties encountered by inexperienced observers.

FINDLAY (G M) & MACCALLUM (F O) Hepatitis and Jaundice associated with Immunization against Certain Virus Diseases.—*Proc Roy Soc Med* 1938, May, Vol. 31 No 7 pp 799-805 (Sect. of Comp Med. pp. 35-41) [12 refs.]

Among 3 100 persons immunized against yellow fever by the use of virus and immune serum over a period of five years 89 cases of jaundice have been traced.

The symptoms closely resemble those produced by common infective hepatic jaundice cases of which have often been noted as occurring in the same areas. Cases almost always tend to occur in groups in regional areas and have been observed in England Egypt Anglo-Egyptian Sudan South Africa and the West African Colonies while apart from this series jaundice has followed yellow fever immunization in South America and in French Gabon. The average period between the time of inoculation and the development of hepatitis has been two to three months. It is of interest that hepatitis in horses has also been noted to occur two to three months after immunization against the virus of horse sickness and equine encephalo-mylitis and also after the injection of horse serum containing anti-toxins against *Ct. arabis* toxina.

The only common factor between the two was the injection of homologous proteins either in sera or tissue extracts. The only theories which at present explain the observed facts are that either (1) a hepatotoxic virus is introduced with the virus inoculum or that (2) two factors combine to induce the hepatitis—(a) a hepatotoxic substance present in the homologous sera or tissue extract inoculated and (b) an infective agent which at least in the case of human beings, is probably the causal agent of common infective hepatic jaundice

LEVÊQUE Note sur l'utilisation du vaccin antiamaril de l'Institut Pasteur de Tunis dans la région nord du Cameroun [A Note on the Use of Anti-Yellow Fever Vaccine from the Pasteur Institute, Tunis, in the Region North of the Cameroons].—*Arch Inst Pasteur de Tunis* 1938, Mar Vol. 27 No 1 pp. 108-110 With 1 fig

A note on the results of vaccinating 35 Europeans and 29 natives with single injections of neurotropic mouse yellow fever virus coated with egg yolk. Only mild reactions were observed except in two cases both Europeans one of whom showed an attack of fever on the 14th day rising to 40°C and lasting for about five days. E H

CAMBRÉSINI (H) A propos de l'état actuel des vaccinations contre la fièvre jaune. [The Present Position of Vaccination against Yellow Fever].—*Rev Méd et Hyg Trop* 1937 Nov-Dec Vol 29 No 6 pp 273-279

A general review of the development of methods of vaccination against yellow fever up to the use of attenuated culture virus. In the discussion Dr STEFANOPOULO mentioned that the number of subjects in Brazil, vaccinated by this latter method, then reached more than 32,000 without any serious ill-effects having been observed. E H

LLOYD (Bolivar J) The Role of Viscerotomy in the Diagnosis and Control of Yellow Fever—*J Trop Med & Hyg* 1938 June 15 Vol 41 No 12 pp 197-200

A general account including interesting personal reminiscences in which the author emphasizes the importance of accurate diagnosis in order to avoid unreasonable quarantine measures. Viscerotomy is admitted as a simple and convenient method of obtaining specimens from the deep viscera but the diagnosis of yellow fever from pathological conditions found in the liver requires a very skilled observer. Cases are mentioned of the erroneous diagnosis of yellow fever from examination of liver tissue by admitted authorities and the author is of the opinion that one should not accept as final a diagnosis of yellow fever based entirely on the microscopic appearance of the liver. All outbreaks classed as yellow fever should be checked by blood surveys and it is considered that seasoned men of known administrative ability should take the responsibility of evaluating all evidence before the opinions of the pure scientist are made a basis for administrative action. BARTHAS (E) Possibilités d'expansion et prophylaxie de la fièvre jaune. [Possibilities of the Expansion and Prophylaxis of Yellow Fever]—*C R Soc Méd et Hyg Trop d'Egypte* Alexandria. 1936-1937 8th Year pp 56-70

A general discussion with special reference to the possibility of the spread of yellow fever into Egypt and the Indies. Attention is called to the necessity of maintaining anti mosquito campaigns in all infected or menaced regions combined with anti yellow fever vaccination in endemic areas. E H

LANCET 1938 June 18 p 1414—Destruction of Mosquitoes in Aeroplanes. A Test Flight.

The risk of conveyance of infection by mosquitoes in aeroplanes is well recognized but to deal satisfactorily with that risk has been no easy matter. It is difficult to ensure that every aeroplane at a port of disembarkation is free from living mosquitoes. The International Convention for Aerial Navigation has laid down certain regulations regarding disinsection and for their being carried out the sanitary authorities of the countries traversed are responsible and their ideas as to the performance may and probably will vary further forced landings may occur at places where there is no sanitary organization and infected mosquitoes could enter there. A method of disinfection in flight offers the solution of the difficulty and a test was made in the presence of experts from the London School of Hygiene and Tropical Medicine the Air Ministry, the Colonial Office, the Ross Institute and others with officials of the Imperial Airways. The apparatus is devised by Dr Park Ross deputy chief health officer for the Union of South Africa and Mr LARJUTH of the South African Fumigation Company. Jets of insecticide spray are propelled by the pressure of an ordinary CO₂ sparklet bulb or by a phantomyst nebulizer using Deslito—an aqueous base extract of pyrethrum—which is non inflammable non-staining non-corrosive and not objectionable to passengers.

In the actual test in an aeroplane over the Solent twelve boxes of mosquitoes were distributed in various parts of the craft. The phantomyst apparatus was started in the rear cabin and after 10 minutes was moved forward to the next and so in succession. Of six hundred mosquitoes liberated all but one or two were killed by 15 minutes' exposure or even less.

H H S

MACKIE (F P) & CRABTREE (H S) The Destruction of Mosquitoes in Aircraft.—*Lancet* 1938 Aug 20 pp. 447-450 With 3 figs.

A valuable account of a method of disinfection of aircraft whilst in flight, a method which would do away with the practical difficulties of providing sanitary or insect free aerodromes under different local authorities apart from the fact that a large number of small refuelling stations are springing up in undeveloped country where there is no ground organization capable of efficient disinfection.

The choice of an insecticide presented certain difficulties as it was essential that it should have no effect on the passengers or crew and in view of the risk of fire, any substances with a paraffin-base had to be avoided. The most satisfactory of the samples tested was found to be Messrs Stafford Allen's "Deskito" a watery base pyrethrum insecticide, which was distributed through the interior of the aircraft by spray apparatus. The latter was of two types a disseminator specially designed to distribute dry insecticide in the passenger cabins, and an Ejector suitable for luggage holds, bedding lockers and all other parts of the aircraft.

The phantomyst nebuliser made by Messrs. Andre (Components) Ltd., was used for the passenger cabins and Larmuth's device driven by the pressure of CO₂ in a sparklet bulb for the ejector type.

The results of various experiments carried out for Imperial Airways, Ltd. show the efficiency of this method, and although in some instances the action of the pyrethrum was delayed all the insects exposed to its action eventually succumbed.

Further experiments are necessary in order to perfect the method, which is doubtless that of the future for cabin type aircraft.

SALEUN (G) CECCALDI (J) & PALINACCI (A.) Isolement de la première souche de virus amaril au Congo (Afrique Equatoriale Française) [The Isolation of the First Strain of Yellow Fever in the (French) Congo (French Equatorial Africa).]—*Bull Soc. Path. Exot* 1938. May 11 Vol 31 No. 5 pp. 418-429

An isolated case of yellow fever occurred at Brazzaville and from the blood of this patient on the fourth day of the disease the authors infected mice by intracerebral inoculation. The resulting strain of virus labelled "S.C." has been passaged for several generations in the brains of mice and by means of cross immunity tests has been shown to be indistinguishable from the Dakar strain of yellow fever. In addition to mice, the authors also succeeded in adapting the virus to guinea-pigs by intracerebral inoculation of the patient's blood.

The autopsy on the patient also confirmed the diagnosis, since typical pathological changes were observed, and on histological examination of the tissues (by M. BARLET) typical fatty degeneration and intranuclear bodies were found. The sera of seven persons who

had been in direct contact with the patient were examined for yellow fever immune bodies with negative results
 This is the first strain of yellow fever to be isolated in French Equatorial Africa and furnishes conclusive evidence of the existence of the disease in that region

DE ASSUMPTÃO (Lucas) Prova de protecção intracerebral em camondongo com o virus isolado em São Paulo de um caso de febre amarela silvestre [The Intracerebral Protection Test with Jungle Yellow Fever Virus Isolated in São Paulo]—*Ann Paulista Med e Cirurg* 1938. Apr Vol. 35 No 4 pp 351-363
 With 14 figs English summary

The author carried out protection tests using the camondongo (Brazilian house rat) and a strain of jungle yellow fever virus isolated in São Paulo in the last outbreak there and compared the results with those of a Dakar neurotropic strain. Serum dilutions ranged from 1 in 100 to 1 in 100 000 and each series of tests was made on seven groups of five animals. All the control animals died with the neurotropic strain and all except one (in the highest dilution of serum) with the São Paulo strain. With the immune serum the results were not quite parallel. The Dakar virus had a shorter incubation some of the animals began to show symptoms on the third day and were definitely ill by the fourth with dilution of 1 in 100 longer in higher dilutions but death occurred after a couple of days illness. With the São Paulo virus and death did not take place till three or four days later. It may be that the differences—the São Paulo virus being apparently somewhat weaker—are ascribable to the fact that the strain had reached its fifteenth transfer. The essential identity however is proved by these immunity tests.

HELMINTHIASIS.

PRECIS OF ABSTRACTS IN THIS SECTION

BASNUEVO and AMIDO (p 35) describe a method of preserving helminth eggs. HOEPLI FENG and CHU (p. 35) show that adults and larval stages of helminths can be kept alive in various artificial media for considerable periods. No development took place under these experimental conditions.

The prevalence of helminthic infections in Italy and Japan is noted by GIULIO (p 35) and YUKUTO and Co (p. 36). The former examined water, soil and house dirt for ova with positive results.

SCOTT and BARLOW (p 36) found that hookworm, ascariis and schistosome infection in Egyptian peasants after treatment and in some instances after the construction of bore-hole latrines, was as prevalent within 3 years of that treatment as it had been before regardless of the presence or absence of the latrines. As these infections except ascariis, are acquired under field conditions it could hardly be expected that house sanitation could influence them. Sanitation should, however, be extended in the hope that with education the natives can be persuaded to use latrines in the fields. Other methods of control, and medicinal treatment, should be fully used.

Schistosomiasis is reported for the first time in Libya by CICCHITTO (p. 37). TANG (p 37) describes the morphological features of *S. japonicum*. PERDOMO HURTADO *et al* (p 37) attribute infection with *S. mansoni* to working in river sand. WILLIAMS (p 38) reports a case of schistosomiasis in Szechwan (China). Eggs were found in the appendix but not in the stools. The first case from Kwangsi is reported by YAO (p 38).

GORSILL (p 38) reports that the level of Lake Nyasa has been rising for some years, and the fertile and thickly populated land of the lake shore is becoming a swamp. *Limnusa laurenti* and *Physopsis africana* are found there and cercariae of *S. mansoni* have been observed penetrating the former and of *S. haematobium* the latter. Ova of both are frequently found in the Natives. Intravenous antimony tartrate is the best treatment. CAWSTON (p 38) notes the important mollusc hosts in Mozambique. KLENERMAN (p 38) records a family presumed to have been infected with schistosomes after bathing in a river in Natal. MARTINS and VERSIANI (p 39) found an infected *Australorbis glabratus* in a lake in Bello Horizonte (Brazil).

MAINIER (p 39) shows that in all kinds of infections with *S. haematobium* and *S. mansoni* X-ray examination constantly reveals pulmonary involvement. Asthma may result from infection but is an allergic phenomenon not related to the pulmonary lesions. It depends upon the constitutional tendency of the patient and his response to the substances liberated by the schistosomes.

CAMPBELL (p 40) suggests that a large proportion of oriental cases of splenomegaly are due to schistosomiasis. Ova may sometimes be found by duodenal sound though absent in the faeces. If operation for splenectomy is contemplated, the first step should be the excision and examination, by the frozen section method, of a portion of liver tissue. If schistosome ova are found in the liver splenectomy should not be performed. BUCKLEY (p 40) describes a swamp itch in Malay due to cercariae of *S. spindale*.

RODRÍGUEZ MOLINA and HOFFMAN (p 40) describe two cases of infection with *Fasciola hepatica*. Emetine treatment was useful. OHABE (p 40) shows that *Leucogobia gracilis* is an intermediate fish host of *Clonorchis sinensis*. OTTO (p 41) describes the blood changes and serum reactions in infections with *Cl sinensis*. VAZQUEZ-COLET and AFRICA (p 42) detail the fish hosts of two heterophyids found in man.

HOEPLI (R.) FENG (L. C) & CHU (H. J.) Attempts to culture Helminths of Vertebrates in Artificial Media.—*Chinese Med J* 1938 Mar Supp No 2 pp 343-374 [88 refs]

Adults and larval stages of parasitic helminths were kept alive in artificial media for a considerable period no development took place in any case.

Adult *Clonorchis sinensis* did best in serum with an equal quantity of Tyrode solution and also in undiluted heparinized rabbit plasma surviving at 37°C. as long as five months when there was weekly change of medium when there was no such change the maximum was 65 days in a solution of prontosil, 1 in 8,000 in diluted horse serum. Adult *Schistosoma japonicum* at 37°C lived in horse serum pure or diluted with an equal amount of Tyrode solution changed once or twice weekly for over 5 months weak prontosil or mercurochrome-220 killing them within a few days. Larvae of *Ascaris suum* hatched by feeding mature eggs to guineapigs lived 2 or 3 days in horse or rabbit serum in normal saline with saline extract of guineapigs liver or in living cultures of chicken fibroblasts. *Microfilaria immitis* lived up to 11 days without growth or development and without absorption by white corpuscles. The metacercaria of *Clonorchis sinensis* lived in different media up to 2 weeks emptying the excretory bladder at various intervals but undergoing no development. Other animal parasites were also used and the work of other persons is noted.

SCOTT (J. Allen) & BARLOW (Claude H.) Limitations to the Control of Helminth Parasites in Egypt by Means of Treatment and Sanitation.—*Amer Jl Hyg* 1938. May Vol. 27 No. 3 pp 619-648. With 11 figs. [17 refs.]

"A study has been made of the changes during a period of 6 years in the level of infection with hookworms, ascaris, and the two species of schistosomes in Egyptian peasants living under varying conditions. The prevalence of the parasites and the average intensity of infections as indicated by egg counts have shown sharp fluctuations which cannot be correlated with known causes. Greater changes, always in the direction of reduction, have followed the administration of as much needed treatment as the people could be persuaded to take. Bored hole latrines were built in all of the houses of some of these villages, but whether or not they were present, the infections had in most cases returned, within 3 years, to their pre-treatment levels. Since these parasites, with the exception of ascaris are transmitted only under field conditions it could hardly be expected that house sanitation would affect them significantly. It is to be hoped that, after becoming accustomed to sanitation in their villages, the people can eventually be taught to accept and use latrines in the fields. Education may also be effective in reducing schistosome infections through teaching the avoidance of pollution of water. At the same time snail control through canal clearance and modifications in methods of irrigation, gives promise of success. Although sanitation has not been effective as a means of controlling worm parasites under these conditions, its general value should not be underestimated and its further extension to field conditions should be advocated. Furthermore, while the effects

of therapeutics have been shown to be only temporary treatment to alleviate the condition of the critically ill should not be abandoned
C L

CICCHITTO (Elio) I primi casi di schistosomiasi intestinale da Schistosoma Mansonii in Libia. [The First Cases In Libya of Intestinal Infection by *S. mansonii*].—*Policlinico Sez. Prat.* 1938. May 30 Vol 45 No 22. pp 1049-50 1053-4 1057 [13 refs.]

TANG (C. C.) Some Remarks on the Morphology of the Miracidium and Cercaria of *Schistosoma japonicum*.—*Chinese Med. J.* 1933. Mar Supp No 2. pp 423-432. With 12 figs on 4 plates. [17 refs.]

A confirmation of observations by other workers with some new ones the investigation being made possible at the Peiping Union Medical College by a Fellowship granted by the Rockefeller Foundation. It is reported that caudal to the nerve centre the body consists of caudad flame cells. In all of a large number of eggs observed during hatching the split in the shell was longitudinal, and if the vitelline membrane does not also split by osmotic pressure the enclosed miracidium dies. As in the case of *S. haematobium* and *S. mansonii* there are in the cercaria five pairs of cephalic glands the two cephalad pairs oxyphilic and the three caudad pairs basophilic, but in *S. japonicum* the granules in the former are not distinctly coarser than in the latter otherwise they conform to the characteristics reported for cercariae of the other two schistosomes of man

WILLIAMS (T H) Human Schistosoma Infestation in Szechwan. A Case Report.—*Chinese Med Jl* 1938 Aug Vol. 54 No 2 pp 159-161 With 1 fig

An autochthonous case of schistosome infection is reported from an area of the Szechwan province not hitherto reported as an endemic zone. Eggs were present in an appendix which seems to have been excised for epigastric and general abdominal discomfort "with later symptoms of peptic ulcer". Though the stool was then examined many times and cultured once no ova or miracidia were seen. *Oncomelania* snails were found in the area in question. C L.

A first record of the infection in the Pin yang district C L.

GOSALL (N L) Some Observations on Schistosomiasis in North Nyasa District.—*Nyasaland Protectorate Ann Med & San. Rep* for Year ending 31st December 1937 Appendix III pp 85-98.

The most thickly inhabited and most fertile parts of the North Nyasa District are the flat lands on the lake shore. For a number of years the level of the lake has been rising and this land has become a swamp harbouring *Limnaea laurentis* and *Physopsis africana* but no *Planorbis* has been found. Cercariae of *S. mansoni* have been watched penetrating the former and those of *S. haematobium* the latter. Ova of *S. mansoni* have been found in 163 of 204 stools and of *S. haematobium* in 79 of 204 urines. Few of those with the latter infection complain of it. Antimony tartrate intravenously has proved more effective than any of the more modern remedies and in 100 patients after antimony treatment the percentage of haemoglobin rose from 65 to 75 though 63 per cent. of those who had also hookworm infection were still suffering from this. C L.

CAWSTON (F Gordon) Molluscs which serve as Hosts for Schistosomes in Mozambique.—*Jl Trop Med & Hyg* 1938 June 1 Vol. 41 No 11 pp 181-182

Of the 150 non marine shells from Portuguese East Africa Major M CONNOLLY has noted 43 aquatic species and, apart from *Cleopatra* and *Melanoides tuberculatus* which if implicated are rare hosts the molluscs important for the spread of schistosomiasis are *Physopsis africana*, *Ph. globosa*, *Planorbis pfeifferi* and *Bulinus forskali*.

In Southern Tunisia *Bulinus contortus* has been found in unobvious places such as under culverts. The note is of local importance

Martins (A. Vianna) & Versiani (Waldemar) Schistosomose mansoni em Bello Horizonte [S. mansoni in Bello Horizonte].—*Brasil-Medico* 1933 May 14 Vol. 52. No 20 pp 471-472. English summary (10 lines) C L.

By means of a barrage a lake has been formed in the Prefecture of Bello Horizonte to insure abundant supply of water to the city in future. At its margin were collected 42 examples of *Australorbis glabratus* of which one emitted cercariae identified as those of *S. mansoni*. Steps have been taken to clean up the lake and bathing in it has been forbidden.

Mainzer (Fritz) Bilharzial Asthma. Bronchial Asthma in Schistosoma Infection.—*Trans Roy Soc Trop Med & Hyg* 1933. Aug 25 Vol. 32. No 2. pp 253-264 With 3 figs on 2 plates. C L.

Three cases of bilharzial asthma are described as a type of allergic reaction dependent on constitutional factors and substances liberated by *Schistosoma* (*haematobium* or *mansoni*). One of these cases showed febrile asthma with simultaneous urticarial rash.

"The two other observations concerned blood relations (uncle and nephew). It was possible to prove that the asthmatic paroxysms had no relation to lesions of the lungs brought about by the parasite the pulmonary bilharziasis. In all kinds of infections with *S. haematobium* and *mansoni* X ray examination constantly reveals pulmonary involvement. The causal relationship between bilharzia infection and asthma is demonstrated by the complete parallelism in the course of both diseases subsequent to specific therapy.

The allergic nature of this kind of asthma has been proved by its association with urticaria and the constitutional and hereditary character of this allergy which is very infrequently encountered, by its occurrence in relatives.

"The resistance of the atypical bilharziasis of the liver and lungs to foudin treatment is noted.

CAMPBELL (Horace Emerson) Schistosomiasis and Banti's Disease. An Inquiry into their Possible Relationship.—*Chinese Med J* 1938. May. Vol. 53. No. 5. pp. 459-466. [36 refs.]

As a working hypothesis then I suggest schistosoma as the etiology in a large proportion of these Oriental cases of splenomegaly of unknown origin, variously known as splenic anaemia, Banti's disease, cryptogenetic splenomegaly etc."

Campbell notes how cases of this kind have been reported from Peiping, Swatow and Formosa but that no known cases of schistosomiasis have been reported from the first or last of these places. He reviews experience in China including his own [this *Bulletin* 1937 Vol. 34 p. 389] in Egypt and in Italy by GREPI [this *Bulletin* 1937 Vol. 34 p. 387] and points out that ova may not be found in stools in schistosome infection and yet may be got by duodenal sound, and that they cannot of course be found when infection is by male parasites alone. Repeated intensive study may be needed to disclose ova, liver biopsy with immediate sectioning of frozen tissue being undertaken as a first step in a splenectomy, this last not being proceeded with if eggs are so found.

BUCKLEY (J. J. C.) On a Dermatitis in Malays caused by the Cercariae of *Schistosoma spindale* Montgomery 1906.—*Jl Helminthology* 1938. May. Vol. 16. No. 2. pp. 117-120.

A swamp itch has been attributed by Malays to paddy cultivation in waters which contain snails. These snails were identified as *Planorbis eximius* and a *Limnaea* species. From these emerged an echinostome cercaria, one with an oral stylet and a furcocercous cercaria. The two first produced no itching when put on the forearm, the last did and developed in mice into *S. spindale*. Probably the local optimum definitive host is the Indian water buffalo which is used in cultivation. The Malays have found that the wearing of boots and puttees may prevent the itch.

RODRIGUEZ MOLINA (Rafael) & HOFFMAN (William A.) The Coincidence of *Schistosoma mansoni* and *Fasciola hepatica*.—*Rev. Med. Trop. y Parasit.* Habana. 1938. May-June. Vol. 4. No. 3. pp. 133-140.

In these two cases the schistosome infection had apparently been controlled before the fasciola infection was acquired, the latter seems to have been got by chewing grass in one instance and eating watercress in the other picked from the areas polluted by cattle. In one the symptoms were suggestive of gallstones and in the other of duodenal ulcer. After emetine all symptoms disappeared in the first and fasciola eggs could not be found in the faeces, while in the second the symptoms greatly improved but fasciola eggs did not disappear.

OKAZAKI (Koyo) On the Second Intermediate Hosts of *Clonorchis sinensis* (Cobbold) in Fukuoka Prefecture.—*Fukuoka Acta Med.* (Fukuoka-Ikkadaigaku-Zasshi) 1938. July. Vol. 31. No. 7. [In Japanese pp. 1217-1229. [29 refs.] English summary pp. 140-144.]

The paper contains the names of 43 fish which have been reported as second intermediate hosts of *Clonorchis sinensis* together with those

of the authors responsible for placing them on the list and the countries in which the observations were made Okabe's present addition is *Leucogobia gracilis* C. L.

OTTO (J H F) TSCHAN (Tsching Ji) & AU (Lifu) Weitere Beobachtungen und Erfahrungen in Canton tierische Schmarotzer der menschlichen Verdauungsorgane betreffend. [Further Observations on Parasites of the Digestive Organs of Man in Canton.]—Reprinted from *Tung-Chi Med Monatsschrift* 1938, No 6 17 pp [25 refs]

The report is on 978 patients whose stools were examined by the Telemann technique. Of them the percentages shown to be infected were in all 48-6 (over 100 patients with more than one kind of parasite) with *Opisthorchis* [*Clonorchis*] *sinensis* 40.5 in men and 34.5 in women after one examination. Urobilinogen was present in 17.1 of opisthorchis cases, fasting blood sugar was not affected by any parasite. In fasting blood eosinophilia was higher by 5 per cent in those with *clonorchis* than in those with any other infection or with no infection. *Clonorchis* infection seems to increase reflex irritability and in the graduated Takata reaction mentioned by MAWCKE gave more precipitate in the sera and increased when there was a diagnosis of gastric and duodenal ulcer C. FREUND (Ludwig) Die Einschleppungsmöglichkeit der Haemoptoc parasitaria nach Mitteleuropa. [The Possibility of the Importation of Parasitic Haemoptysis into Mid-Europe.]—*Med Klin* 1938, June 24 Vol. 34 No 25 (1748) pp 831-832.

The possibility that the parasite of haemoptysis may gain a footing in middle Europe is considered. The likelihood that *Paragonimus westermani* may gain this footing remains an interesting theoretical problem which one may hope will never have a practical significance but it gives to European medical men an insight into the pathology of man's parasites. [Readers should not accept either generic or specific names as correct in the varying forms in which they appear] C. I.

infiltration about hair follicles and small blood vessels. The lesions of yaws subside rapidly, while those of syphilis become indurated by new formation of fibrous tissue.

The distribution of the spirochaetes in hair follicles and epidermis is essentially the same in comparable lesions of the two diseases.

In the larger lesions of syphilis necrosis and an exudation of polymorphonuclear leukocytes are prominent, and spirochetes are numerous. In the lesions of yaws there are few spirochetes and they disappear rapidly.

There is no evidence of phagocytosis of spirochetes by any type of cell in either yaws or syphilis.

TAKAHASI (H) Beiträge zur histopathologischen Untersuchung der experimentellen Syphilis und Frambösie bei Kaninchen. I. Mitteilung Pathologische Veränderungen der Aortenwand. Contributions to the Histopathological Investigation of Experimental Syphilis and Yaws. 1st Communication Pathological Changes of the Aorta.—*Japanese Jl. Experim Med* 1937 Oct. 20. Vol. 15. No. 5. pp. 321-327. [Summary appears also in *Bulletin of Hygiene*.]

For a number of years Takahasi has been examining the aortas of rabbits infected respectively with 8 strains of *Sp. pallida* with 4 strains of *Sp. pertensis* and with the spirochaetes of rat-bite fever. The aortas were examined histologically after staining for tissue changes and for bacterial (including spirochaetal) content and were tested culturally as well as by inoculation into the scrotum of other rabbits. Of 168 rabbits infected with syphilis the number with aortic changes was 29 but in 34 normal rabbits 13 infected with yaws and 3 with rat-bite fever no such changes were found. Of 78 syphilitic rabbits examined less than 100 days after infection only 5 showed aortic changes the remaining 24 occurring in 80 rabbits with older infections. No difference between the strains was found in respect of frequency with which they infected the aorta. The changes were in two main forms sometimes combined in one specimen, namely with necrotic changes in the media and with inflammatory changes of the media and adventitia. The two forms of which the first was by far the commonest, are described in detail. Aneurysms were found in 12 of the 29 rabbits. They were in all stages, so that the author is able to confirm that the changes in the media play the chief rôle in the development of aneurysm. No spirochaetes or other bacteria were found in the sections but by inoculation experiments *Sp. pallida* was found in two cases of mesoaortitis.
L. B. Harrison.

TAKAHASI (H) Beiträge zur histopathologischen Untersuchung der experimentellen Syphilis und Frambösie bei Kaninchen. II. Mitteilung Orchitis und Initialklerose der Rückenhaut sowie des Hodensacks. [Contributions to Histopathological Investigations of Experimental Syphilis and Framboesia in Rabbits. Second Communication. Orchitis and Primary Sclerosis of the Skin of the Back and the Scrotum].—*Japanese Jl. Experim Med* 1937 Dec. 20. Vol. 15. No. 6. pp. 401-406. With 4 figs. on 2 plates. [13 refs.] [Summary appears also in *Bulletin of Hygiene*.]

Takahasi refers first to the work of numerous authors who have tried to settle the problem of the identity or otherwise of syphilis

and jaws by histological examination and criticizes it on the ground of the authors having concentrated too narrowly on the tissue changes and paid too little attention to the biological peculiarities of the micro-organisms. His researches have aimed to fill this gap and he claims to demonstrate a strong difference between the two diseases in respect of distribution of spirochaetes in the testes and skin of rabbits after experimental inoculation. The spirochaetes used in the research were three laboratory strains of *Sp. pallida* and four of *Sp. pertenues*. The rabbits studied in the investigation were inoculated with emulsions obtained from the testes of rabbits which had reached the acme of the syphilitic or framboesial orchitis according to the case following inoculation with the respective organisms. The emulsion was of a strength of 3 to 5 organisms per field. The inoculations were into the testes and the skin of the back and the scrotum.

In the tunica albuginea and tunica vasculosa of the testes inoculated with *Sp. pallida* the usual result was a diffuse cellular infiltration and mucoid degeneration which contrasted with the circumscribed infiltration and degeneration found after inoculation with *Sp. pertenues* but often in the syphilitic testes the infiltrations were circumscribed making a differentiation on the score of histological changes in the tissues difficult. The differentiation was however quite easy when the distribution of the spirochaetes was considered. In the syphilitic testes *Sp. pallida* was spread widely throughout the cell infiltrates and especially so in the vessel walls and connective tissue fibres of the organism was congregated in heaps. In the interstitial tissue of the syphilitic testes there was widespread mucoid degeneration or necrotic change often leading to great increase of connective tissue. In the framboesial testes there was no mucoid degeneration or necrotic nodules formed of circumscribed infiltrates of round cells and the connective tissue was only slightly increased. At the same time some syphilitic testes showed changes that were difficult to distinguish from those seen in the framboesial but again the distribution of the spirochaetes in the same way as in the tunicae made the differentiation easy. The blood vessels both veins and arteries of the testes inoculated with *Sp. pallida* showed innumerable spirochaetes in their walls while in the framboesial testes such appearances were rare and only slight immediately adjoining corium as well as the increase of the epithelial and vessels of the corium were necrosed and the changes in the very marked, while in the yaws-infected skins the changes were chiefly in the epidermis though again the tissue changes were chiefly widely through the deeper tissues especially in the corium and connective tissue fibres vessel walls and nerves of the subcutaneous tissues. *Sp. pertenues* on the contrary was seen only seldom in the corium and not at all in the subcutaneous tissues but abundantly in the epidermis the prickly cell layer and the outer hair sheath. This distribution of *Sp. pertenues* in the rabbit's skin accords with that found by SCHÜFFNER, SIEBERT, HALLENBERGER and others in the skin of human beings suffering from yaws. The induration of the primary lesion was proportional to the increase of the reticular tissue and the mucoid degeneration of the corium, being therefore much more marked in the syphilitic chancres than in the primary yaws.

The article is illustrated with four photomicrographs two of the testes in yaws and syphilis respectively and two of the skin in yaws, to demonstrate the differences in the distribution of the two varieties of spirochaetes.

L. W. Harrison

JOLLY (A.) & DI RUGGIERO A propos d'un cas de gangosa observé en Guadeloupe [Gangosa seen in Guadeloupe].—*Bull Soc Path Exot.* 1937 Oct 13 Vol. 30 No. 8. pp. 706-712. With 1 fig.

The designation rhinopharyngitis mutilans or gangosa has been used by various authors for a number of conditions of varying aetiology including yaws syphilis leishmaniasis blastomycosis, *Tucumania* etc.

The case now described, the first the authors believe to have been observed in the Antilles occurred in the person of a 39-year-old male native of Guadeloupe who came from a yaws area but who had no history or sign of infection with yaws. There was ulceration of both nostrils with destruction of the columna and septum but no perforation of the palate. There was also noted a number of nodules the size of a pea in the skin of the lobules of the nose which on pressure yielded a drop of pus. Smears made from the several lesions revealed yeast-like elements resembling Breinl's *Cryptococcus mutilans* but no spirochaete, leishmania nor acid fast bacilli. Culture and animal inoculation were negative. Pathological examination of a biopsy specimen showed a granulomatous change of doubtful syphilitic origin. The Mennicke reaction of blood serum was strongly positive and the ulceration healed completely in three weeks with treatment by acetylsan.

The authors believe the disease in this case to have been due to the cryptococcus and not to have been a manifestation of yaws or syphilis with a secondary infection. (This opinion will probably not be shared by many of those who read the article. It should be noted also that this is by no means the first case of gangosa to be reported from the West Indies.)

HELENFELDT (G.) Ueber einen Fall von Goundon. [A Case of Goundon].—*Arch f Schiffs- u Trop Hyg.* 1938. Feb Vol 42. No 2. pp. 74-75.

The case record of a 54-year-old man who exhibited small symmetrical paranasal swellings. These were oval in shape the one 2.3 x 5 cm. the other 2.0 x 1.4 cm. and due as radiological examination showed to hyperostosis of the nasal processes of the maxillae. They had not been noticed by the patient or his relations and were so small that they could not be demonstrated by photograph. The nasal mucous membrane was normal the skin moved freely over the swellings there was no pain. Though the man had been in German S W Africa in 1904 for eight months there was no history of yaws or syphilis or indeed of any tropical infection. He had had in 1911 a resection of nasal septum done for some condition which had been called asthma.

[It seems a pity to label this a case of goundon, since that term has been used to denote some more specific lesion. Goundon-like swellings may occur in a number of osseous affections as in Paget's disease osteitis fibrosa and leontiasis ossea.]

the cerebrospinal fluids from 26 cases of tertiary yaws exhibiting lesions of throat and nose were examined. All showed a negative W.R. and normal cellular and biochemical contents. The cases were chosen carefully to exclude syphilis and tuberculosis.
H S S

DE HAAS *Periostitis framboetica infantilis* (Periostitis in an Infant with Yaws.)—*Geneesk Tydschr v Nederl Indië* 1938, Sept 13 Vol. 78, No 37 pp 2281-2282. With 2 figs. on 1 plate.

The subject was a child of 18 months who had been ailing for a month during the first ten days of which there had been fever. A framboeal rash was present which yielded to sulpharsenol and bismuth in 2½ weeks.
X rays showed a periostitis along the radius and ulna and the tibia and fibula and some callus at the lower end of the right fibula. Though the difficulty of differentiating yaws from congenital syphilis is well known the author regards the basic condition in the present case as yaws because the W.R. was positive in the child but negative in the mother
H H S

HECKENROTH (Marcel) [Médecin des Troupes coloniales Ancien Préparateur de Médecine exotique, Diplôme de Médecine coloniale] *Les arséno-résistances et les arséno-réduces au cours du traitement du pian.* [The Treatment of Yaws with Arsenicals Resistance and Relapse.] [Thesis.]—132 pp [Bibliography] 1937 Bordeaux Imprimerie Librairie Delmas 6 Place Saint Christoly

Like many theses presented for the M.D. of French Universities this Bordeaux thesis by Dr Marcel Heckenroth is merely a discussion upon the subject on the title page without any new facts being presented.
Another common failing and one noticeable in this paper is an attempt at over-elaboration and lack of precision in conclusions. The first part of the book is devoted to a discussion of so-called arsenic-resistance in syphilis and trypanosomiasis. The work of
(1937)

Warrington YORKE and his colleagues really forms the basis of our knowledge on this subject and nothing of value is added. In the second chapter the well known fact that quite a fair proportion of cases of yaws relapse after short courses of treatment is dealt with and referred to as arsenical relapse (*arséno-récidives*) followed by the citation of some few cases from other observers in which it is argued arsenic-resistance was exhibited. It is further suggested on clinical grounds that arsenic resistance may be broken by resort to bismuth or some other drug. It is further believed on clinical reports of two native cases that arsenic-resistance is transmitted by the parasite of yaws (but nothing is proved).

GÄLINDER (Ernst J.) *Pyoktanin in der Behandlung der tertiären Frambœsiengeschwüre.* [Pyoktanin in the Treatment of Tertiary Lesions of Yaws.]—*Arch. f. Schiffss- u. Trop. Hyg.* 1938, Jan. Vol. 42, No 1 pp. 23-25

Writing from the Mission Hospital Agogo Gold Coast the author finds Pyoktanin coeruleum Merck in 1 per cent. solution a very useful remedy in treating the tertiary lesions of yaws.
H S S

SPRUE

PRÉCIS OF ABSTRACTS IN THIS SECTION

SALAH (p 54) records a patient (believed to be the first case of sprue in an Egyptian) successfully treated, on the lines laid down by FAIRLEY by dieting and the administration of liver and HCl. STALDER (p 54) describes two patients suffering from non tropical sprue the first treated successfully with Campolon the second failing to respond either to Campolon or Cortin. He considers that a secondary B₁₂ avitaminosis is concerned in this condition. ROHR (p 55) finds that in non tropical sprue the calcium content of the stool is high not because absorption powers are deficient but because calcium combines with the unabsorbed fatty acids to form relatively insoluble soaps. The three co-acting factors in non tropical sprue are gastro-intestinal disorder deficiency of vitamin, or iron calcium and Castle's factor and endocrine disturbance of which the first is the most important. VAN LEEUWEN (p 56) also stresses the importance of gastro-intestinal disorders and endocrine disturbance. BARKER and RHOADS (p 57) as a result of investigations on cases of sprue conclude that malabsorption of fat is the cause of the diarrhoea rather than *vice versa*. HOPMAN (p 58) explains tropical sprue as one of a series of results which follow defective adjustment to the metabolic requirements of hot climates. This series includes obesity and diabetes which like sprue are safety valves against overheating. He has treated patients successfully with intravenous calcium. JELKE (p. 59) reports a patient with non tropical sprue who improved on a fatless diet liver and calcein. PESCE (p. 59) treated a case of sprue successfully with milk and describes a condition which has close affinities with Hill Diarrhoea of India.

LINDEBOOM and WIJNTJES (p 60) describe a patient with sprue complicated by a condition resembling tabes. The Wassermann reaction was negative and the authors think that the condition may have been due to deficiency of vitamin B.

RIETSCHEL (p 61) quotes the work of VERZAR, who regards suprarenal hypofunction as the cardinal point in idiopathic steatorrhoea. He deals more particularly with coeliac disease the Gee-Herter syndrome of children not with sprue as seen by physicians in the tropics. The treatment suggested is described. RODRÍGUEZ OLLEROS (p 61) describes the results of gastroscopic examination of patients with tropical sprue. Atrophic gastritis similar to that seen in pernicious anaemia was the predominant lesion. It improved under liver extract therapy. BING and BROAGER (p 62) record the remarkably beneficial effect of nicotinic acid in the relief of the diarrhoea of idiopathic steatorrhoea. The other symptoms were not ameliorated to the same extent.

MEIRA (João Alves) Espru (noções atuais) [Sprue. Present Views.]
—Reprinted from *Letras Médicas* São Paulo 1937 Vol. 2.
No 3 pp 41-47

An article of a general character of the nature of a lecture on the subject giving the geographical distribution, symptomatology and

clinical features the pathology diagnosis and differential diagnosis from idiopathic steatorrhoea and Gee's syndrome prognosis and treatment. As the title indicates the author gives a résumé of present day knowledge but adds nothing fresh. H H S

SPACEK (M. R. W.) Sprue.—*Irish Jl Med Sci* 1938. Apr. 6th Ser. No 148 pp 171-183

A general account of this condition containing however nothing that is not well known to readers of this *Bulletin*. Suitable for a student's lecture. H H S

SALAH (M.) Sprue in Egypt. Report of a Case.—*Trans Roy Soc Trop Med. & Hyg* 1937 Nov 30 Vol 31 No 3 pp 351-358 With 1 chart [12 refs.]

This is a clinical description of what is regarded as the first case of sprue in an Egyptian. The patient a male of 40 years was admitted with the provisional diagnosis of steatorrheic pancreatic disease or sprue.

The demonstration of marked glossitis macrocytic anaemia and the chemistry of fatty stools excluded pancreatic disease.

The diagnosis of sprue was confirmed by the response of the condition to treatment and the increase of weight by 21 kgm. on appropriate treatment. This was based on the principles laid down by FAIRLEY—the production of alimentary rest by a suitable dietary treatment of the anaemia by 300 gm. of liver *per os* followed by intramuscular injections of liver extract (2 cc. campolon for 15 days) and replacement of deficiency of gastric secretion by the addition of HCl in doses of 4 cc. t.d.s. for two months. The anaemia was of the hypochromic macrocytic type, with hypoblastic bone marrow of megaloblastic characters, suggesting deficiency of both iron and haemopoietic principle.

The patient was kept under observation for fourteen months after discharge during which time he remained normal.

P H Manson-Bahr

STALDER (H.) Die endemische Sprue. Ein klinischer Beitrag [Non-tropical Sprue—a Clinical Contribution.]—*Schweiz. Med Woch.* 1937 Nov 13. Vol 67 No 46 pp 1091-1093. With 1 chart

The differential diagnosis of endemic sprue (or non tropical sprue) from pellagra, Addison's disease pernicious anaemia tetany osteomalacia pancreaticogenous diarrhoea and mesenteric tuberculosis has been placed on a secure basis by the work of HESS THAYSEN and the monograph of HANSEN.

Reference is also made to the newer work of VERZAR who has demonstrated experimentally a relationship between the suprarenal secretion and Vitamin B₂.

Few cases of non tropical sprue have been recorded so far in Switzerland and according to Stalder they number twenty-seven in all.

Hansen has shown that many different degrees of severity of the same illness are encountered from slight cases with painless diarrhoea to the most severe with steatorrhoea Addisonian pigmentation and anaemia of the pernicious type. Tetany and osteomalacia which are also noted suggest avitaminosis.

Two further cases are reported here. The first was in a man of 61 who exhibited symptoms of medium severity with fatty stools emaciation pigmentation and pernicious blood changes. Injections of Campolon produced a remarkable change in a brief period. The second was of a woman of 69. At first on account of her severe condition and pigmentation she was thought to be suffering from Addison's disease. The patient is still under treatment and a successful issue appears likely. She received a new yeast concentrate (made by the Physiological Institute in Basle) and of this she could assimilate 150-200 cc. a day. At the same time Campolon (5 cc.) every second day and occasional intravenous injections of Cortin (20 cc.) were also given. Campolon injections in the second case did not appear to exert the least effect either on the stools the general condition or the blood picture. The injections of Cortin either subcutaneously or intravenously did not influence the size of the stools. Further trials with this preparation were carried out with difficulty on account of expense. The author considers that in endemic sprue probably a secondary B₂ avitaminosis is concerned. P H M B

ROHR (Karl) Die einheimische Sprue. [Non-tropical Sprue.]—*Deut. Ztschr. f. Verdauungs u. Stoffwechselkrankh.* Leipzig 1938. Vol. 1 No 1 pp 46-51 With 1 fig.

The author's remarks are based on twenty-two cases of idiopathic steatorrhoea seen by him in the University clinic at Zurich. In nearly all the earliest symptoms were alimentary which preceded systemic disturbance by six months or so and it was the latter that led them to seek advice. The symptoms have been detailed so often and they were typical in the author's patients there is no need to repeat them here. He states however that the calcium content of the sprue stool is very high not owing to deficient absorption but to the combining of the calcium with the unabsorbed fatty acids to form calcium soaps which are soluble with difficulty. He divides anaemias into four groups: 1 Cryptogenic pernicious anaemia where Castle's principle is lacking—gastric anaemia Biermer's disease 2 Sprue anaemia from interference with resorption of anti-pernicious factors. 3 Anaemia of liver disease in particular cirrhosis, when the anti-pernicious factor is not stored in sufficient amount. 4 Anaemia resulting from toxic conditions in pregnancy diphyllobothrium infestation etc.

Sprue—he is speaking it would appear of idiopathic steatorrhoea, non tropical sprue—is explained as resulting from three coacting

factors gastro-intestinal disorder deficiency of vitamin or iron, calcium, and Castle's principle and disturbance of endocrine function. Of these the first is the most important (See Illustration.)

Illustrating the various factors which, in the author's opinion, interact to cause sprue.

[After a diagram in the *Deutsche Zeitschrift für Verdauungs- und Stoffwechselkrankheiten*]

VAN LEEUWEN (H C) De aetiologie van spruw spruwoid en chronische enteritis (Aetiology of Sprue and of Sprue-like Conditions).—*Geneesk Tijdschr v Neder Indië* 1938. Feb 1 Vol 78. No 5 pp 227-253 [53 refs.]

This is a discussion of the aetiology of sprue of idiopathic steatorrhoea and of allied conditions and is followed by a report of ten cases. The author thinks that chronic amoebiasis, deficiency of gastric hydrochloric acid, psychological factors, disturbances of endocrine glands as well as a damp and cool climate are all of importance in the causation of sprue and of sprue-like conditions. He considers idiopathic steatorrhoea to be primarily due to allergy of the small intestine and he compares the condition with vasomotor rhinitis. Pathologically there is a swelling of the intestinal mucous membrane which produces the picture of chronic enteritis with an acceleration of the passage of intestinal contents. Owing to changes in the small intestine the absorption of vitamins is impaired and this leads to other symptoms of sprue such as stomatitis. Therapeutically the author obtained good results with intravenous injections of calcium.

BARKER (W Halsey) & RHOADS (C P) The Effect of Liver Extract on the Absorption of Fat in Sprue—*Amer J Med Sci* 1937 Dec. Vol. 194 No 6 pp 804-810 With 4 figs

Some disturbance of fat absorption from the intestinal tract in patients suffering from sprue has always been assumed to be an integral part of the disease

Previous studies on the fat content of sprue faeces have suggested that it is largely split thus indicating that it is not one of pancreatic function It is not clear however whether the sprue diarrhoea is to be regarded as caused by the mal-absorption of fat or whether it is the direct result of the presence of so much unabsorbed split fat in the intestines.

In previous communications CASTLE Rhoads LAWSON and PAYNE have described the improvement of the intestinal symptoms of sprue patients which follows the suitable administration of liver extract whilst MACKIE MILLER and Rhoads have demonstrated characteristic alterations of motility and outline as seen by X ray examination and that these alterations become less pronounced subsequent to injection of liver extract

In the present communication the amount of fat in the blood of normal subjects following the taking of a meal rich in fat is compared with that in patients during exacerbations of sprue diarrhoea as well as during the remissions which follow the administration of liver extract.

The method employed for the determination of the blood lipids was that described by KIRK PAGE and VAN SLYKE. Heparin was employed as an anticoagulant The subjects fasted overnight and a sample of blood was taken before the test meal of fat After repeated studies it was found that little or no change in the levels of free and total lipid cholesterol occurred after the fat meal.

The amount of lipid in the blood of four normal individuals before and after taking a fat meal was measured by the Kirk method. The results were remarkably constant the fasting levels of total lipid carbon were in the range between 320-480 mgm. per cent. The peak of the rise was reached at the end of four hours and the maximum level attained was between 550-650 mgm. per cent The results obtained from the study of the normal individuals were in agreement with those reported by Kirk Page and van Slyke.

Subsequently the amount of lipids was ascertained in three cases of sprue before and after treatment with liver extract and in two cases before treatment. All five were typical cases of sprue acquired in the tropics and of long duration. During the preliminary period of not less than four weeks all sprue patients were given a diet which contained almost no fat and limited carbohydrates but which was rich in protein and fresh fruits.

The amount of lipid in the blood of all five cases showed practically no increase following a fat meal. This fact coupled with the well-known observation that a large amount of fat is present in the intestinal contents seems to be adequate evidence that the absorption of fat is interfered with in the active phases of the disease even though anaemia and stomatitis are not present The three cases were tested again after treatment with liver extract injected intramuscularly and showed wholly different amounts of lipids in the blood. In one case one injection of liver (10 cc Lilly NNR derived from 50 gm. of

liver) was sufficient whereas in other cases several injections repeated daily were required. In all three cases a pronounced rise in the level of the total lipid carbon resulted. The resulting curve approached normal in both duration and height and presented a striking contrast to the practically flat curves obtained before treatment.

It seems to be clear that normal individuals react to a meal containing 2 gm. of fat per kilo of body weight by a pronounced and well-sustained increase of the amounts of lipid in the blood. Patients with sprue who still manifest symptoms after treatment with a diet low in fat content exhibit no such increase under similar experimental conditions.

The passage of loose bulky stools follows the taking of a test meal of fat before treatment with liver extract but this does not occur during the 6-hour period of the test but only 12-48 hours after the experiment has been terminated. The time relationship of the diarrhoea to the withdrawal of blood samples for analysis suggests that the lack of increase of the content of the blood lipid cannot be ascribed to the loss of fat from the intestinal canal but to actual failure of absorption by the intestinal mucosa. The view is gaining ground that malabsorption results in diarrhoea rather than that the diarrhoea is the cause of the malabsorption.

HOPMAN (B. C.) Over de aetiologie van tropische spruw en verwante ziekten [The Causation of Tropical Sprue and Allied Diseases].—*Geneesk. Tijdschr. v. Nederl. Indië* 1935 Apr 19 Vol. 78. No 16 pp 904-914

Many explanations are current regarding the causation of tropical sprue. There are an infection theory, a vitamin theory, an antecedent intestinal disease, adrenal cortical insufficiency and hyper-susceptibility of the small intestine. Treatment of the disease goes hand in hand with the theory adopted and therefore the importance of the theory in the case of sprue is very obvious. The author approaches the subject by a very full consideration of basal and active metabolism for each of the standard constituents of food and lays great stress on disturbance of metabolism in the European who transported to the tropics. The whole of this argument need not be set out. A European finds himself in a warm climate and his basal metabolism falls. In spite of this his temperature is raised by half degree. He must then reduce his active metabolism in order to compensate for this rise of temperature that is to say, he takes less exercise and uses his muscles less. Correspondingly his consumption of energy should be lowered. Now the native has long ago adjusted himself to metabolic requirements but it is difficult for the European more or less suddenly to make the necessary alteration of his use and wont. One sickness or another is apt to develop in consequence of the disturbance of carbohydrate and fat metabolism.

A summary of the findings of the author may be given. For every latitude there exists an appropriate basal and active metabolism. If carbohydrate and fats are taken in too large quantity for metabolism or are insufficiently utilized various possibilities arise. 1. There develops sunstroke, an acute disease in which suddenly too few calories are used up and the man dies of overheating. 2. There develops summer diarrhoea in sucklings for the protection of the infant by excretion of undigested food, which has been ingested in

too large quantity. 3 There develops obesity. A too large intake of food, developed through excessive function of the digestive organs results in the deposit of too much fat under the skin and in the organs. 4 There develops diabetes. This usually occurs after the appearance of obesity. A dysfunction succeeds the hyperfunction of pancreas and liver. Insulin which is produced in too small quantity is no longer able to retain glycogen in the liver. 5 There develops sprue. After hyperfunction of the liver and pancreas comes a dysfunction of both organs but mainly of the liver. Bile acids are excreted in insufficient amount and the fats are badly absorbed.

Obesity, diabetes and sprue are the safety valves which protect the organism against overheating. If the body is forced to a metabolism which is beyond its powers obesity will result or it may be a more serious disease still. The treatment to be adopted is moderation in food and a sufficiency of exercise. *W F Harvey*

JELKE (Hugo) Om sprue i anslutning till ett fall av idiopatisk steatorrhé hos vuxen. [Sprue and Idiopathic Steatorrhoea].—*Hygiea* 1938, July 31 & Sept 14. Vol. 100 Nos. 14 & 15 pp. 529-568 577-629. With 6 figs. [66 refs.] German summary

The author describes a case of what he designates idiopathic steatorrhoea or sprue nostras in a man of 39 years who exhibited the symptoms of tetany. The blood phosphorus was about normal but the calcium was only 5 mgm per cent when he first came under the author's observation and he was very emaciated. Under treatment with a fatless diet liver and calcein he improved much the calcium rose in a few days to 6 mgm. and in another 3 weeks to 11.2 mgm. Cramps and tetany ceased after a week and he put on 4.6 kgm. in weight. Three months later he was attacked with a dry pleurisy and though the intracutaneous tuberculin reaction was negative X-rays showed small central calcifications. He continued to make satisfactory progress but after about a year he stopped taking any more treatment the cramps returned and a few months later he died with inflammation of the lungs.

This case is made the text for a long discussion and much quotation of literature regarding the similarities and differences between tropical sprue idiopathic steatorrhoea coeliac disease their cause and treatment but no fresh views are presented. *H H S*

PESCE (Hugo) Un caso de sprue tratado a la antigua y el síndrome espruiforme Chahuatam Akan en Andahuaylas (Apurímac, Peru). [A Case of Sprue treated in the Old Way "Chahuatam Akan, a Sprue-like Condition in Peru].—*Rev Méd Peruana* 1938, Jan. Vol. 10 No. 109 pp. 9-27

The patient was an unmarried half-breed aged 32 living in the hilly region of Cuzco. He stated that he suffered from diarrhoea 3 or 4 motions daily, copious yellowish white fatty frothy with slight tenesmus and no fever. These attacks were separated by intervals of good health [the length neither of attack nor healthy interval is mentioned]. Examination showed pallor and anaemia sprue-like tongue. There was no laboratory available, so the blood changes

cannot be detailed. Treatment by milk brought about great amelioration in a month and 18 months-2 years later there had been no relapse.

In connexion with this case the author describes and discusses a syndrome known as *chakudam akan* [which seems to mean the passage of stools of undigested food] a form of diarrhoea with pasty stools, meteorism, weakness and anaemia among those living at higher altitudes and particularly at the rainy season and affecting chiefly males. It is common in the Department of Apurimac, Peru. It has close affinities with Hill Diarrhoea of India. H H S

LINDEBOOM (G A) & WIJNTJES (J E B). *Pseudotabes bij spruw* [*Pseudotabes in Sprue*].—*Nederl Tijdschr v Geneesk*. 1938. May 7 Vol. 82 No 19 pp 2260-2266 English summary, 119 refs

If in pernicious anaemia a subacute combined degeneration of the cord can occur it might be expected that in sprue with its hyperchromic anaemia such neurological symptoms would also occur. Little mention of such symptoms is to be found in the literature. A case is brought forward by the authors in which symptoms very suggestive of tabes dorsalis were present along with apparently clear sprue. The patient, an unmarried woman 58 years of age had spent some time in Java a number of years previously but had remained well there except for one day's mucous diarrhoea. At the time of the present examination she was emaciated and her face of brown colour like Addison's disease. There were atrophic glossitis, a macrocytic anaemia and a fat diarrhoea, making the diagnosis of tropical sprue a very likely one. While this was fairly established it was the nervous syndrome which proved interesting. Patellar and tendo Achillis reflexes were absent as also were the plantar and abdominal reflexes, while the tendon and periosteal reflexes of the upper limbs were sluggish. On the other hand, except for a slight temporary hypalgesia, there was no loss of surface or deep sensibility. It seemed possible then that not a subacute combined degeneration of the cord but a peripheral neuritis might account for the symptoms but there was no trace of reaction of degeneration. More interesting still were the pupillary reactions. One pupil was of medium diameter the other was narrowed and there was a definite Argyll-Robertson phenomenon. One explanation of the case would be that there was present a combination of tabes and sprue but the Wassermann reaction was negative and examination of the cerebrospinal fluid gave no support to that suggestion. Then again it is known that pupillary disturbances are a common symptom in chronic alcoholism. But here the question arises how far that symptom is to be attributed directly to alcohol and how far to an avitaminosis B dependent on gastritis and defective absorption. This brings the authors to the main point of their thesis, that neural symptoms and even an Argyll-Robertson pupil should at least be looked for as a manifestation of vitamin B deficiency.

In this particular case treatment with diet and liver cured the sprue but even parenteral administration of vitamins B₁ and B₂ failed to make any impression on the neurological syndrome.

RIETSCHEL. Zur Pathogenese und Therapie der Sprue insbesondere der Sprue der Kinder [Coeliakie] (Gee-Herter Heubnersche Erkrankung) [Pathogenesis and Therapy of Sprue with Special Reference to Sprue of Children (Coeliac Disease, Gee-Herter-Heubner Disease)]—*Deu. Med. Woch.* 1938 Jan. 14 Vol. 64 No 3 pp 73-78

[The terminology which we in English-speaking countries recognize as Coeliac Disease appears to present considerable difficulties to Continental writers. The plea to term the syndrome "Sprue der Kinder" (child sprue) will have few supporters and fewer still to add another cognomen in honour of HESS THAYSEN HANSEN and V. STAA, who have striven to unite all the steatorrhoas under one heading. We venture to think that hardly a single pediatrician in English-speaking countries will be found to support the view that coeliac disease in children and sprue in the adult are in fact the same disease.]

In this paper no new observations are made but it is a restatement of all the various theories which have been adduced from time to time. The theory of bacterial infection or vitamin deficiency finds few supporters. The work of VERZÁR (on animal experiments) is discussed at length. As is well known this authority has shown that the absorption of sugar through the intestinal wall is dependent upon the functions of the suprarenals—in the adrenalectomized animal the fat which is split in the intestines is no longer synthesized so that the animal does not grow mainly because it lacks lactoflavin—a kind of pro-vitamin—and can no longer create the active flavin phosphoric acid which is a ferment necessary for respiration. VERZÁR has applied this knowledge to sprue (or more accurately idiopathic steatorrhea) and looks upon the suprarenal as the vital point in this disease and he believes that he can explain the whole symptom complex of sprue by a hypofunction of the suprarenals of the cortex as well as the medulla therefore lactoflavin (B_2) and the cortical hormone in large doses are recommended as therapeutic agents. The author believes that he can combine the various theories of Thaysen Hansen and Verzár into some intelligible system of therapeutics.

The cardinal therapeutic indications are to overcome the overwhelming bacterial preponderance in the small bowel the restoration of the normal bactericidal action and the neutralization of acidosis.

It is intelligible that one can restore the normal hormone interchange by the addition of vitamins in avitaminotic disturbance. As a means of restoring the normal intestinal function especially in children the use of human milk is advocated, a matter which he thinks has been much neglected. The administration of albumin has also a favourable action and a pure fruit and apple diet (pektin) is also advocated.

RODRÍGUEZ OLLEROS (Angel) The Stomach in Tropical Sprue.—*Puerto Rico Jl. Public Health & Trop. Med.* 1938 June. Vol. 13 No 4 pp 503-521 [11 refs.] [Spanish version pp 485-502.]

The present paper is concerned with the results of 28 gastroscopic examinations in as many patients suffering from tropical sprue. The investigated cases were divided into complete, "incomplete and latent" types but in every instance at one time or another each patient had shown all the features which are accepted as

characterizing the fully-developed sprue syndrome. The predominant lesion demonstrated by gastroscopy proved to be some type of atrophic gastritis—sometimes it was generalized and at other times only a limited area of the stomach was implicated. The gastroscopic findings were similar to though less intense than those described in pernicious anaemia and the atrophy of the gastric mucosa was regarded as developing secondarily to the syndrome of sprue and the anaemia. The condition improved with liver extract therapy in much the same manner as has been found in pernicious anaemia.

A Hamilton Fairley

BING (J) & BROAGER (B) *Undersøgelser over virkningen af nikotinsyre-indgift paa to patienter med idiopathisk steatorrhoe (sprue)* [Investigations of the Action of Nicotinic Acid Medication on Two Patients with Idiopathic Steatorrhoea (Sprue)]—*Ugeskr. f. Læger* 1938 Vol 100 pp. 1131-1137 With 3 figs. [54 refs.]

This Danish study shows the remarkably beneficial action of nicotinic acid in sprue which has of late been found to be by no means rare in Denmark. The authors give an account of two patients, women of 49 and 28 respectively who suffered from well-defined idiopathic steatorrhoea. Not only did the diarrhoea cease with the administration of nicotinic acid (as is usual in the diarrhoea of pellagra) but it also recurred when this drug was discontinued. The improvement in the other manifestations of the disease—emaciation meteorism stomatitis anaemia low blood-pressure pigmentation a flat blood-sugar curve hypocalcaemia and osteoporosis—was by no means so marked. [That tropical sprue and idiopathic steatorrhoea of temperate climates are the same is by no means proved at present.]

MEDICAL AND SANITARY REPORTS

UGANDA PROTECTORATE (1937).

The Uganda Protectorate lies in the northern part of the Great Lakes region of Africa. It has no sea coast, being bounded by the Anglo-Egyptian Sudan on the north, Kenya Colony on the east, Lake Victoria Nyanza and the Tanganyika Territory on the south, and the Belgian Colony on the west. The area of the Protectorate is estimated at 94,204 sq miles including 13,616 sq miles of water. (The area of England without Wales is a little over 50,000 sq miles.) The head quarters are at Entebbe and the chief commercial towns are Kampala and Jinja. All three are on or near the north shore of Lake Victoria.

Vital Statistics—For the native population only, the principal facts are as follows—

Province	Estimated Population	Live Births	Birth Rate	Deaths	Death Rate	Infant Deaths	I.M.R.
Buganda ..	888,244	20,073	22.6	16,004	18.0	1,593	79.4
Eastern	1,189,204	29,977	25.2	26,141	22.0	5,188	173.1
Western	741,231	19,010	25.6	11,921	16.1	2,494	131.2
Northern	807,520	23,009	28.5	14,669	18.2	5,037	219.8
Protectorate	3,626,549	92,069	25.4	68,735	18.9	14,332	155 "

The above figures summarize the excellent Tables which provide data in great detail for both Provinces and Districts in the Protectorate.

European Officials resident numbered 595 with an average number resident of 499. One invaliding and four deaths were recorded. Among European *non-officials* 1,837 cases of sickness were treated by Government Medical Officers, *malaria* accounting for 371 of the cases dealt with, *injuries* 113 and *diseases of the digestive system* 110. There were 16 deaths recorded among European *non-officials*.

Asian Officials resident numbered 387 with an average number resident of 323. Three were invalided but no deaths were recorded. The Government Medical staff treated 8,124 cases of sickness among *Asian non-officials* and 75 deaths were reported within this group.

African Officials (African Civil Service) resident numbered 212 with an average number resident of also 212. There were no invalidings but one death occurred within this group.

Among all groups of officials and *non-officials malaria* was the principal cause of ill-health.

Maternity and Child Welfare—Though the Provincial and District infant mortality and maternal mortality rates have been subject to variation during the past seven years for the Protectorate as a whole these rates have declined steadily and testify to the efficacy of ante-natal and child welfare work in the territory. It is said that little progress has been made in increasing the number of maternity centres yet despite this and other handicaps the tabulated facts supply ample evidence not only of the considerable volume of work dealt with but also of the success achieved in this important field. For example during the year under review 16,676 women attended for ante-natal supervision.

at the larger centres 1 745 of them terminated their pregnancies in hospitals or at maternity centres and among them 1 576 live births and 82 maternal deaths were recorded. On the other hand a further 484 women who had not availed themselves of ante-natal treatment were delivered in hospitals of 311 live babies with 42 maternal deaths. The figures for those who did not attend for ante-natal supervision again compare unfavourably with those who did. Then again, 2 116 women after attending ante-natal centres were reported to have been confined in their own homes where they gave birth to 2 024 live babies with only 16 maternal deaths. *Infants attending Welfare Centres* numbered 17 792 these figures relate only to healthy children brought to the centres for advice and supervision—sick children are included in hospital and dispensary returns.

Patients admitted to the wards of the *Lady Coryndon Maternity School* numbered 569 during the year 410 confinements, 312 live births, 14 infant deaths and 33 maternal deaths were recorded. The Out-patient Department dealt with 2 948 expectant mothers and undertook the post natal supervision of 631 babies. At 22 country centres there were 1 809 confinements, 1 523 live babies were born, infant deaths numbered 37 and maternal deaths 6 at these centres 11 184 new ante-natal cases were dealt with 13 899 attendances were recorded at child welfare clinics, and total out patient attendances were 63 742.

To the wards of the *Vsambwa Maternity Training School* 371 patients were admitted, confinements numbered 285 live births 260 while 18 infant deaths and 10 maternal deaths were recorded. At 15 country centres confinements totalled 1 906 live births 1 805 infant deaths 23 and maternal deaths 11 records at these centres also include mention of 4 272 new ante-natal cases 2 892 attendances at child welfare clinics and 37 872 out-patient attendances.

With regard to the *training of nurses and midwives* at the *Lady Coryndon Maternity Training School* of the 39 students in training 14 were successful in obtaining the Certificate of the Uganda Midwives Board, and at the *Nsambya Maternity Training School* 7 of the 30 native students in training obtained this qualification. There are now 63 European and Asian and 217 African Midwives on the registers of the Uganda Midwives Board. It remains to add that during the year a district midwife was posted to the township of Horma for special ante-natal work among native women. If this experiment proves successful it may lead to extension of trained supervision of maternity work among African women with corresponding decrease in obstetrical disasters.

School Hygiene—Periodic visits of inspection continued to be made to schools in most districts by Medical Officers and their assistants (see this *Bulletin* 1938 Supp. p. 67*). In Busoga the Senior African Medical Assistant examined the pupils at Mwiru College treatment was provided where necessary. The experiment in nutrition in the Mengo District (see this *Bulletin* 1938 Supp. p. 67*) was concluded with the most encouraging results. In an Appendix to the Report under review Drs J. Scott Brown and L. J. A. LOWENTHAL report the results of the investigation under the title of *The Value of Milk as an Adjunct to the Diet of School Boys*. After a routine examination of the boys attending the C.M.S. School at Mukono 30 were chosen at random and each given half-a pint of milk on every day of attendance. Briefly results show a significant extra gain in

height, that the small superiority in weight gain was not statistically significant and that optimum nutrition is not obtainable from normal African diets. A fuller account of the investigation appeared in the *East African Medical Journal*. The investigation continues and a similar experiment is in progress at Teso.

Public Health Sanitation etc—No new schemes of development were introduced during the year. The policy outlined in 1934 (see also this *Bulletin* 1937 Supp pp 46-47*) was however steadily pursued and of this it is said that in certain places the first fruits are beginning to appear. Considerable progress is reported with the Kampala *sewerage system* and though the disposal works are not yet completed a number of houses have already been connected up to the sewers. Several houses in Entebbe have septic tank installations though these cannot be brought into use until the piped water supply from Lake Victoria has been completed. Government houses in Mbale also have septic tank installations operated in connexion with the newly constructed gravity water supply. In Government quarters in Fort Portal the double bucket system is in use and in the larger and some of the smaller townships the single bucket system is used. Dr W H KAUNTZE C M G Director of Medical Services contributes an interesting commentary on rural sanitation and of how sanitary ideals are to be realized in spite of inherited native beliefs. The provision of a filtered and chlorinated piped *water supply* was partially completed in Mbale and in Entebbe while in rural areas the protection of water supplies continued to receive special attention.

With regard to *housing and town planning* it is reported that new Asian dwellings are being built to better design that building rules are strictly enforced, and that Africans are gradually developing an interest in model housing schemes. The provision of cheap housing for Africans is a problem of urgency in the townships where efforts are being made to improve living conditions by laying out plots in areas zoned for certain classes of housing. A detailed description is given of a two-roomed house suited to the needs of the general African population and costing between £20-£25 to build. A Committee has been appointed to investigate *labour conditions* in Uganda meanwhile the standard of housing of labourers is said to improve.

The question of *food in relation to health and disease* is receiving special attention. The Report of the Nutrition Sub-Committee of the Agricultural Survey indicates that large sections of the population suffer from malnutrition steps have already been taken with a view to improving existing conditions (see the experiments with milk diets under *School Hygiene* above). Agricultural surveys continue to be made to determine the quantity and quality of locally grown foodstuffs while selected youths are trained in improved farm methods at farm schools at Lira and Gulu. Rules for regulating the sale of *milk* are in course of preparation.

Health propaganda continues to be carried out in all districts with encouraging results.

The training of African Sanitary Inspectors has progressed satisfactorily (see this *Bulletin* 1938 Supp p 58*) and the final examination of the first batch of students will take place in November 1938 under the auspices of the Royal Sanitary Institute London.

Hospitals Dispensaries etc (see also this *Bulletin* 1938, Supp p 59*) The Tororo Hospital which will provide in and out-patient accommodation for Asians and Africans approaches completion.

To the Jinja Hospital, two new African wards an Asiatic Maternity Ward, out-patient block and other constructions were added. Minor improvements were carried out to other hospitals in the Protectorate. Three new dispensaries and two additional dressing posts were opened during the year.

The training of African female nurses continues at the hospitals at Namirembe and Mulago with successful results.

The records of the year's work at hospitals and dispensaries is summarized below —

Hospitals, etc.	Beds	Admissions	Treated	Deaths	Total New Cases	Total Re-Attendances
4 European	34	533	—	—	499,834	533,727
9 Asiatic	56	1,655	—	—		
23 African	1,277	31,250	—	—		
87 Dispensaries	625	?	—	—	548,727	1,152,941
Totals	1,992	33,443	34,487	1,799	1,088,661	1,686,668

A new nomenclature has been adopted for the tabulation of diseases and deaths in the Uganda Annual Medical Reports. This new departure permits the presentation of the relevant facts within the limits of *three pages* in place of the 13 pages formerly necessary for this section.

Medical Education—The Report of the Commission appointed by the Secretary of State for the Colonies to advise on higher education in East Africa drew attention among other matters to the fact that the basic education of the African recruit to the medical course is very deficient and that his knowledge of the preliminary sciences is not of a sufficiently high standard. To meet these requirements the new biology, chemistry, and physics laboratory under construction at Makerere College should enable the standard of these courses to be raised considerably. A new building is to be erected to replace the present medical school which lacks adequate accommodation.

The Report of the Uganda Medical School describes the year's work and presents details of the numbers of students taking the various grades of examination results of those examinations and the more significant comments made by the external examiners. It is noted that since 1923 thirty-five students have been licensed to practise and 30 of these are in the service of the Uganda Government.

With regard to *morbidity experience* during the year it is stated that with the exception of malaria and blackwater fever a general decrease in the incidence of the major communicable and infectious diseases was noted during 1937. The notes which follow briefly summarize more extensive commentaries in the Report relating to the principal diseases dealt with at hospitals and dispensaries.

A further increase in the number of malaria cases is reported viz 72,258 as compared with 71,407 in the preceding year (see this *Bulletin* 1938, Supp. p. 59*). Of the total cases recorded 31,314 were dealt with at station hospitals and 40,924 at dispensaries, while at all centres approximately 50 per cent. of the cases were microscopically diagnosed. On the other hand the *Return of Diseases and Deaths* shows that 32,142 in- and out-patients were treated for the

disease the distribution of types of infection being *t-rign tertian* 1,997 *quartan* 1,304 *subtertian* 7,800 and *unclassified* 21,041 hospital deaths ascribed to the disease numbered 134. The usual routine anti-malarial measures continued to be carried out at most stations with reclamation of swampy areas sub-soil drainage controlled tipping and other works in specific areas.

Of *blackwater fever* 170 cases and 43 deaths were reported and of these 86 cases with 23 deaths were treated by Government Medical Officers and the remainder by private practitioners. Of the total cases 14 were European (4 deaths) 150 Asians (38 deaths) and only 6 African, with 1 death. The incidence and distribution of blackwater fever in Uganda is set out in great detail in an admirable series of tabulated statements with distinction as to race province district age etc.

No case of *yellow fever* was reported during the year. In view of the suspicious cases reported by the District Medical Officer Masaka in 1936 that District first engaged the attention of the *Yellow Fever Commission* of the Rockefeller Foundation (see this *Bulletin* 1938 Supp. p. 60*). No cases of clinical yellow fever were seen while sera from 35 cases of fevers of undetermined origin when inoculated into animals gave negative results. Protection tests were carried out sera from 37 children all gave negative results but 6 from 174 adults were positive. The Commission continued investigations in the Bunyoro Chua and West Nile Districts of the Northern Province with somewhat similar results. In Bwamba County of the Toro District (Western Province) 25 sera from 53 adults gave positive findings. Protection tests were carried out on 141 people of all ages—sera from 16 were positive. Results suggest that a jungle type of yellow fever may be present in Bwamba. Measures to combat *Aedes aegypti* were continued. The Government Entomologist reports that investigations into the incidence of *Aedes aegypti* were carried out in rural areas in the West Nile District and in the vicinity of Kampala these investigations continue.

It is said that *plague* appears to be undergoing its periodic fall in incidence and that the decrease in the number of cases during 1937 is not due to any real improvement in its control which will only become effective when the African builds for himself a house which contains no real harbourage for rats and adopts habits of food storage and refuse disposal which deprive the rodent of any food. During the year under review 515 cases with 478 deaths were recorded and of these 371 cases with 338 deaths occurred in the Eastern Province, and 112 cases with 108 deaths in the Mengo District of Buganda Province. Cyano-gassing of infected huts continues as a routine measure but de-thatching of infected huts has been applied more extensively. At the Laboratory 377 smears were examined for the presence of *P. pestis* but findings are not recorded. The Government Entomologist reports that tests carried out with ferrets for the destruction of rats (see this *Bulletin* 1938 Supp. p. 60*) were unsatisfactory the size of the male animals preventing them from reaching places accessible to the rodents two female ferrets are to be tried. Rat and flea surveys were carried out in various areas.

Of *relapsing fever* 453 cases were reported, but total deaths due to this cause are not stated. Of the total cases 375 were microscopically diagnosed and 367 were treated in hospitals with 25 deaths. The Government Entomologist experimented with various larvicides for

the destruction of *O. mombasa* these tests continue. Five cases of typhus were recorded. The value of the Carnie disinfectant in controlling the disease is again emphasized (see this *Bulletin* 1936 Supp. p. 47* and 1937 p. 49*). There were 310 cases of cerebrospinal meningitis with 118 deaths. The disease appears to be endemic in the Western Province and Masaka (Buganda Province) while sporadic cases occurred in other areas. All the cases (72) reported from Busoga (Eastern Province) are stated to have occurred in immigrant labourers. Segregation of contacts in temporary shelters has been continued (see this *Bulletin* 1938 Supp. p. 61*).

No case of smallpox was notified but the vaccination campaign was continued. 487,525 vaccinations were performed during the year and it is said that over 75 per cent. of the total population are now protected. Attention is being directed towards maintaining immunity by vaccinating all children at schools inspected by Medical Officers.

Trypanosomiasis.—During the year under review only 728 new cases with 14 deaths were reported. The decline in incidence by comparison with 1936 experience is striking but it is noted that the disease remains a major problem in the West Nile District where 700 of the total cases and 8 deaths occurred during 1937. The Kolch River area of the West Nile District has suffered such serious depopulation through the gradual voluntary movement of the people southwards that it is doubtful whether the small numbers of inhabitants remaining will be sufficient to maintain the clearings at the river crossings. The movement of people to new areas has served to increase the incidence of trypanosomiasis in those areas, and has introduced new difficulties and problems to be dealt with. Control measures were maintained as previously described (see this *Bulletin* 1938 Supp. p. 61*) particular attention being paid to the experimental "rod-clearings" which are clearings 10-20 yards wide along the banks of a stream designed to reduce fly density to limits within which the risks of infection become very small. The pass system allowing natives to travel between Uganda and the Sudan along certain defined routes was introduced during the year and has functioned successfully. Illicit movements of people have been converted into controlled movements with examination of travellers at certain gland posts. The pass system over the Tanganyika-Uganda border is being maintained.

The Government Entomologist completed his tsetse fly surveys of the Gulu District. It was recommended that re-population of the restricted areas must be carried out gradually and under strict administrative control. The clearings in the West Nile and Madi areas (Northern Province) were also visited.

Cases of tuberculosis (all forms) among in and out patients dealt with at Government hospitals totalled 613 and of these 520 were cases of the pulmonary type of the disease. Hospital in-patient cases were pulmonary tuberculosis 283 with 82 deaths other forms of tuberculosis 57 with 20 deaths. The investigations of Dr. CARMICHAEL, Senior Veterinary Research Officer were continued. During the year 51 specimens of sputum from phthisis patients were examined, the causal organism in all cases being of the human type. It is observed that among upwards of 250 specimens of sputum examined up to the end of 1937 four were caused by the bovine type of bacillus. With regard to other respiratory ailments, the pneumonias were responsible for 2,038 cases and of these 1,665 were treated as hospital in-patients.

and 369 died. *Bronchitis* was responsible for 6 777 cases of which 439 were in patients and 6 died.

At Government hospitals 102 patients were treated for *typhoid fever* with 31 deaths and 8 for *paratyphoid fever* with 1 death. A small epidemic which broke out in Kampala was traced to a polluted water supply a piped water system was brought into use and the outbreak ceased within 14 days. *Dysentery* gave rise to 2 023 cases with 58 deaths, the distribution of types of infection being amoebic 652 bacillary 281 and unclassified 1 090. It is also noted that the returns show 6,231 cases of *diarrhoea and enteritis* and 29 147 cases of other diseases of the digestive system.

Helminthic diseases especially infections with *ascaris* and *ancylostoma* are said to occur widely. Infected persons are treated with anthelmintic drugs but re-infections are frequent by reason of insanitary habits preventive measures are directed mainly towards the provision of latrines and educational propaganda. Of *ankylostomiasis* 1 761 cases were recorded during the year the results of stool examinations by Medical Officers in seven areas showed infection rates ranging between 23 and 77 per cent. The condition though widespread is said to be the cause of little disability. *Taeniasis* is common in the Western Province and in districts where animal husbandry is an important industry. 2 034 cases were dealt with in Uganda during 1937. *Dracontiasis* of which 639 cases were recorded is again said to be confined to the Nikotic districts of the Northern Province efforts are being made to provide protected water supplies. *Ascariasis* gave rise to 881 and *schistosomiasis* to 126 cases during the year under review. No cases of *filariasis* were treated in hospitals but *Onchocerca volvulus* is said to be extremely common in the Sezibwa river area of Buganda while the infection is also said to be common round the head waters of the Nile.

Veneral Diseases show increased incidence. The incidence and distribution of *syphilis* and *yaws* read as follows —

Province	Hospital Cases		Dispensary Cases	
	Syphilis	Yaws	Syphilis	Yaws
Buganda	11,881	992	19,230	2,062
Eastern	10,871	3 918	11 718	6 780
Northern	1,821	12,701	1 666	11,245
Western	2,189	4 673	8 045	22,887
Totals	26,862	32,284	40 659	43 074

The distribution of *gonorrhoea* is not given but the 16,236 cases treated are an increase over 1936 records. The results of treatment are said to be unsatisfactory owing to the irregular attendance of patients.

Leprosy—At Government hospitals and dispensaries 1 067 lepers attended for treatment during the year under review. The Reports of the *Mission Leger Colonies* testify to the admirable work which continues to be carried out at these institutions from these Reports the following details have been extracted —

Leper Colony	Supervised by	Inmates
Buluba, Basoga	Franciscan Sisters	68
Nyengo, Mengo		208
Bunyoni, Kigeni	Church Missionary Society	847
Kumi Children's Home	" "	354
Teso Ongwo	" "	411

Other diseases mentioned in the Official Returns include 2,403 cases of *trachoma* which still remains an important cause of blindness in Uganda other diseases of the eye and annexa were responsible for 11,725 cases. Out of 53,289 cases of affections of the skin cellular tissue and organs of locomotion no less than 35,059 were due to tropical ulcers this condition was commented upon in the 1936 Report (see this Bulletin 1938 Supp. p. 63*). For rheumatic conditions 20,081 patients received treatment nephritis gave rise to 2,927 cases and 82 deaths while 48,725 patients were treated in the group external causes.

Scientific—The Laboratory Report records that examinations carried out during the year totalled 50,464. The numbers of specimens received and examined are grouped under various headings parasitology serology but findings are not recorded. The Report of the Government Entomologist has already been referred to in the above summaries.

Scientific papers published by members of the staff of the Medical Department include the following—

LOEWENTHAL (L. J. A.) A note on Tick typhus in the Eastern Province of Uganda.—*East African Med. J.* 1936 Vol. 13 p. 141.

— The place of logic in Medical Education.—*East African Med. J.* 1936 Vol. 13 p. 204.

Financial—Expenditure on Medical Services during 1937 amounted to £178,500 a sum which represents 9.0 per cent. of the total revenue of the Protectorate during the same year. P. Grawville Edge

NYASALAND PROTECTORATE (1937)

Nyasaland Protectorate consists of a strip of land about 520 miles long by 50 to 100 miles broad lying to the west and south of Lake Nyasa. Its neighbours are Northern Rhodesia to the west Tanganyika to the north and north-east and Portuguese East Africa to the south. Its total area is approximately 37 596 sq miles of land and 10 353 sq miles of water and its chief towns are Blantyre Lumbe and Zomba (the headquarters of the Government)

Vital Statistics—In previous issues of this Supplement attention has been called to the commendable efforts made by Dr A. D. J. BEDWARD WILLIAMS Director of Medical Services and Medical Officers to secure dependable records relating to the population and state of the public health in Nyasaland. These efforts have continued unabated and the Report under review refers repeatedly to the first-rate importance of vital statistics as an instrument for the efficient administration of public health work. Dr Bedward Williams observes that Vital statistics are a measuring rod of the sanitary progress of a country they have become an essential for every properly organized community and again One of the most important problems to be solved is the collection of accurate vital statistics. It is absolutely necessary to have a yard-stick to measure the progress made in preventive and curative medicine. No programme of development can be efficiently prepared until data are obtained as to the morbidity of the people as to birth and death rates infant mortality etc. The legal mechanism exists in the form of the *Statistics Ordinance 1935* this should now be applied.

But though registration of births and deaths is not yet compulsory in the Protectorate small scale enquiries have continued to be carried out in limited areas as in previous years (see this *Bulletin* 1936 Supp p 58* and 1937 Supp p 61* and pp 63*-65* and 1938 Supp p 72*) to secure dependable facts relating to a primitive people. For example in the *Fort Manning District* records of births and deaths continued to be maintained throughout the year among an estimated population of 35 000 the birth and death rates were 49.4 and 22.8 per 1 000 persons respectively and the infant mortality rate 61.9 per 1 000 live births. In the *North Nyasa District* vital statistical effort was confined to 24 villages having a population of 4 757 persons and in this group birth and death rates were 42.4 and 28.5 per 1 000 respectively and the infant mortality rate 272.2 per 1 000 live births. In the *West Nyasa District* three native authorities sought permission to introduce birth and death registration in their respective areas. This commendable pioneer effort received the warm support of the district Commissioner and the necessary Order was introduced on July 1st 1937 and remained in force until the end of the year whole-time clerks being employed travelling from village to village collecting the returns. The records for these areas for the last six months of 1937 include the following—

Native Authority	M.	F.	Persons	Births	B.R.	Deaths	D.R.
Mbwana	4 481	5 118	9 599	229	47.7	67	14.0
Kabunduh	2 626	2 872	5 493	237	86.2	74	26.9
Atonga Tribal Council	15 707	18 259	33 966	482	28.4	291	17.1
West Nyasa District	22 814	26 249	49 063	948	33.6	432	17.6

With the exception of the isolated effort made in the West Nyasa District and referred to above *official recognition* so far as the vital statistics of Africans are concerned *has been given to the census enumeration only*. It is regrettable to note that financial considerations will not permit the continuance of this valuable experiment on the part of the Native Authorities in the West Nyasa District during 1938.

That other important medico-statistical enterprise which in recent years has been a special feature of public health work in Nyasaland and which takes the form of *Medical Surveys* will be discussed at a later stage in this Summary. Meanwhile the available statistics for the Protectorate as a whole may be set out as follows —

Race	Population	Births	Deaths
Europeans and Whites	1,894	29	18
Asiatics	1,631	83	19
Africans	1,635,804	Not known	Not known

European Officials resident numbered 279 with an average number resident of 225. Five were invalided and one died. *Native Officials* (and Native Troops and Police) numbered 2,752 and among these 12 deaths were recorded.

Maternity and Child Welfare Work.—It is observed that owing to lack of funds and staff little progress can be reported on the field of medical endeavour devoted to the interests of women and children in Nyasaland until provision has been made for the establishment of maternity and infant welfare centres facilities for the adequate nursing of women and children, accommodation for native women undergoing training as nurses and midwives and the appointment of health visitors etc. And yet despite these serious handicaps there has been a satisfactory increase in all branches of maternity and child welfare work at the African Hospital Zomba which is the only Government centre so far established in the Protectorate. At this centre 83 new ante natal cases were dealt with 55 labour cases conducted and attendances at the child welfare clinic totalled 1,262. At this Hospital two certified midwives are employed, and 14 native nurses are undergoing training. Maternity work performed at other Government African Hospitals is said to be "almost negligible" owing to the lack of European nurses or trained native female staff. Extracts from the Annual Report of the Jeanes Training Centre are of first rate interest and importance and strikingly demonstrate some of the difficulties encountered when efforts in the interests of expectant mothers are attempted among a primitive people and how some of these difficulties may be overcome. For example after pointing out that "the root of the trouble is in the deeply grounded fears and tribal taboos in the uneducated village woman" the Report goes on to say

We have found it wise to let the village women observe any African taboos to which they firmly believe so long as these do no harm."

the mental distress caused to patient and relatives by needless infringement of the taboos only adds to the reluctance of village women to seek help or enter the hospital, etc. Native midwives are allowed to be present at deliveries of their patients in the hospital. This permission, it is said, "has done much to remove the antipathy of these professional African practitioners who might naturally be

expected to be suspicious of and to resent anything which would lead to the loss of their means of livelihood, i.e. midwifery fees while it is hoped that as observers they may acquire knowledge of European midwifery methods.

Government continued to collaborate with and subsidize the Missions undertaking maternity and child welfare work. At the centre maintained by the Church of Scotland Mission at Blantyre four women were trained as midwives during the year and two new infant welfare centres were opened. Native midwives are also trained at the Mlanda Centre of the Dutch Reformed Church. Eight girls are in training at Bandawe and at the infant welfare centre 3,805 attendances were recorded.

The figures below summarize the volume of work carried out at centres other than the African Hospital Zomba subsidised by Government—

(a) Infants registered at Welfare Centres (b) Confinements conducted	Mlanda Mission	Blantyre Mission	Jeanez Centre
	532 118	203 437	46 73

School Hygiene—All European schools were inspected during the year and general health conditions of the pupils reported to be satisfactory. With regard to African schools it was hoped that at least one such school in each district would be examined during the year but the pressure of routine work prevented this programme from being carried out and only a small percentage of the schools were visited and 731 children medically examined. The Report under review describes the results of inspections carried out at five African schools viz—

The Central School Karonga where 251 boys and 38 girls were examined. Two early cases of leprosy were discovered.

Providence Girls School Mlanje—A high incidence of helminthiasis among the 167 pupils examined.

Kasina Mission School Dedza—General improvement in physical condition, etc. among the 108 pupils examined due to adequate dietary and attention paid to personal hygiene.

Mission School Mponda's Fort Johnston—Latrine accommodation insufficient. Pupils examined 107. medical treatment given where necessary.

Catholic Institute Blantyre—A considerable improvement noted in the condition of the 60 pupils examined. stricter attention to matters of diet etc. recommended.

The results of *Medical Surveys* (see hereafter *Public Health* also this *Bulletin* 1937 Supp. pp 63*-64* and 1938 Supp. pp 72*-73* 76*) are presented in detail in a series of Tables in the Report under review.

Results are assembled from seven areas in the Protectorate in three age-groups the first of which relates to children aged 0-10 years haemoglobin estimations the results of blood film aged spleen urine and stool examinations are among the data tabulated.

Public Health Sanitation etc.—Under the heading of *Public Health* Dr Bedward Williams contributes an admirable account of the

Providence Girls School Mlanje—A high incidence of helminthiasis among the 167 pupils examined.

Kasima Mission School Dedza—General improvement in physical condition, etc., among the 108 pupils examined due to adequate dietary and attention paid to personal hygiene.

Mission School Mponda's Fort Johnston—Latrine accommodation insufficient. Pupils examined 107 medical treatment given where necessary.

Catholic Institute Blantyre—No considerable improvement noted in the condition of the 60 pupils examined stricter attention to matters of diet etc recommended.

The results of *Medical Surveys* (see hereafter *Public Health* also this Bulletin 1937 Supp pp 63*-64* and 1938 Supp pp 72*-73* 76*) are presented in detail in a series of Tables in the Report under review.

Results are assembled from seven areas in the Protectorate in three age-groups, the first of which relates to children aged 0-10 years haemoglobin estimations the results of blood film spleen urine and stool examinations are among the data tabulated.

Public Health Sanitation etc.—Under the heading of Public Health Dr Bedward Williams contributes an admirable account of the

historical development of the health services of Nyasaland, reviews the work performed by the Medical Department and progress made during the past 25 years, and submits recommendations for the future development of public health work in the Protectorate. This valuable section of the Report should be read in its entirety for limits of space in this *Supplement* prohibit the adequate summary which the contribution merits.

With regard to the work of the Department generally it is said that there is little that is new to record. In the larger townships the disposal of night soil and rubbish has been satisfactorily dealt with water supplies installed, drainage schemes carried out, and other sanitary improvements effected. But in the rural areas difficulties of a very special nature are encountered while the lack of trained sanitary staff European and African, tends to retard progress. Nevertheless, that the arduous and self-sacrificing efforts of Medical Officers have in many instances been successful in bringing about notable improvement in several areas, is evident from the extracts quoted from the reports of Medical Officers, as for example —

Fort Johnston — A determined effort was made to commence the important task of rendering the natives really used to the idea of latrines as part of their ordinary life, and not a meaningless ritual forced upon them. The idea was to have finally a latrine for every hut. No labour was provided. No compulsion of any kind was used. explanatory talks were given. Nearly 200 latrines are in use and construction is still going on.

Dedza — The degree with which advice has been followed with regard to sanitary matters varies in direct proportion to the character and capability of the Native Authority concerned. Kachindamoto's area is the most satisfactory. A mass hookworm campaign was carried out. A propaganda meeting was attended by some 300 natives.

Doma — Of Sendeza it is said. Some sanitary work has been done. The village headman is helpful, and the local school-teacher helps him. New houses constructed and latrindization is complete.

Kola Kola — Vaccinators have done good work in rural sanitation. Of the Protectorate as a whole it is noted that increased attention has been given to the protection of water supplies and that the boring of wells has been undertaken by the Geological Department.

The objects envisaged by the *Medical Surveys* to which reference has been made above and in previous issues of this *Supplement* are (a) to bring Medical Officers into closer contact with village life and (b) to obtain by actual examination of the inhabitants of selected areas a knowledge of the population, births deaths, and morbidity etc. of such areas. These surveys have proved conspicuously successful, and during the year under review enquiries were carried out in seven areas. In three areas it was found possible to undertake surveys (a) among villagers resident at lake level, and (b) among others living at an altitude of over 3 000 feet. The results of these investigations are set out in three age-groups in a series of Tables (see above also *School Hygiene*) together with the commentaries on results by the Medical Officers conducting the surveys. The report of an additional survey conducted at the Jeanes Training Centre is dealt with separately as it relates to natives from many districts.

Inspections of labour conditions on estates were continued, the visits have been instrumental in bringing about general sanitary improvements. The emigration of adult males to the Rand mines continues (see this *Bulletin* 1937 Supp p 65* and 1938 Supp p 75*) with serious results so far as native social life is concerned—there is a lack of fit adult males for carrying on the routine work characterizing the daily lives of the people while returning emigrants bring with them the seeds of disease. While measures have been taken for the better care of repatriated labourers arriving in Nyasaland no information is available of the thousands of returning emigrants who do not present themselves for examination.

Housing and Town Planning schemes and Food in relation to Health and Disease are subjects of comment (see this *Bulletin* 1938 Supp p 75*). Replies to the questionnaire on nutrition drafted by the Health Department and submitted to District Commissioners to Missions and certain educated Africans and to Medical Agricultural and Forestry Officers were analysed and the results tabulated and embodied in a Memorandum presented to and adopted by the Native Welfare Committee. This Memorandum appears as an Appendix to the Report under review under the title of *A Review of the Present Knowledge of Human Nutrition in Nyasaland*.

The scheme for the training of Africans had to be modified considerably owing to sickness among the nursing staff (see this *Bulletin* 1938 Supp p 78*). At the African Hospital Zomba provision is made for the training of various grades of African personnel male and female while at the Jeanes Centre the training of welfare community workers is undertaken.

Measures taken to spread the knowledge of Hygiene and Sanitation continued to be energetically implemented. *Recommendations and Proposals for Reorganization and Future Development of Health Services* are discussed at considerable length (see also this *Bulletin* 1938 Supp p 75*).

Port Health Work—The quarantine camp at Port Herald on the Berra Blantyre Railway continued to function during the year 71 Africans were detained for vaccination having been in contact with infectious disease etc.

Hospitals Dispensaries etc—At present there are six Hospitals each with 50 or more beds and nine with 30 beds. It is recommended that three of the 50-bed hospitals should be increased to 100 beds each with augmented staffs and equipment and that the 30-bed units might have accommodation reduced to 15 beds and be placed in the charge of African hospital assistants. Financial considerations render the construction of a new hospital at Zomba impossible. In the Northern Province the non-official European community provided the funds for the construction of a small cottage hospital at Lilongwe. Government will maintain and staff this unit. As regards native hospitals no new buildings have been erected nor have any additions been made to existing institutions. There is a growing demand from the Native Authorities for the provision of additional rural dispensaries. During the past two years upwards of 23 applications have been received for new dispensaries in some cases Native Authorities have provided the funds for the erection and maintenance of these units. The volume of work dealt with at hospitals and dispensaries during 1937 may be summarized as follows—

Race	Hospitals			Dispensaries Out-patients
	In-patients	Deaths	Out-patients	
Europeans	223	7	1,218	—
Africans and others	10,595	270	115,000	302,318

The commentaries upon general morbidity experience contained in the Annual Report under review are briefly referred to in the notes which follow.

Cases of malaria dealt with at hospitals and dispensaries totalled 16,774 the distribution by race and types of infection being as follows —

Type of Infection	Europeans		Africans and Others		Rural Dispensaries Out-patients
	In-patients	Out-patients	In-patients	Out-patients	
Benign tertian	6	11	62	180	—
Quartan	—	1	32	113	—
Subtertian	2	41	527	717	—
Cachexia	—	1	40	50	—
Blackwater	—	2	—	—	—
Undefined	10	82	354	3,702	9,729
Totals	28	138	1,031	4,831	9,729

There were 22 deaths among Africans due to malaria, and 2 cases of blackwater fever with 1 death among Europeans. The Government Entomologist has pointed out that although *A. costalis* is almost absent during the dry season it is overwhelmingly abundant during the late rains, while the other common species *A. funestus* shows no numerical increase during the year. He also found that the infection rate among *costalis* was very much higher than in *funestus*. The usual anti-malarial measures were successfully employed and it is reported that as a result the mosquito nuisance has been abated to a large extent in some areas.

At the Government Laboratory Zomba 1,379 out of 4,827 blood films examined were found to contain malaria parasites, the positive findings being *P. falciparum* 1,154 *P. malariae* 180 and *P. vivax* 36. The reports of the Medical Surveys (see above) present the results of blood film and spleen examinations at high and low altitudes in various areas.

Only 88 (non-fatal) African cases of smallpox were reported during the year 173,162 vaccinations were performed.

A somewhat serious epidemic of cerebrospinal meningitis occurred in the Southern Province and necessitated the promulgation of special rules under the Public Health Ordinance for the control of the movements of natives etc. The first case occurred in August and spread was rapid altogether 780 cases were reported and of this total 603 occurred in the Mlanje District. Dr W. T. C. BERRY the Medical Officer seconded for special duty in connexion with the epidemic contributes a detailed report which is presented as an Appendix to the Report under review.

Of relapsing fever 139 cases were notified. Of the total cases recorded 51 were dealt with in the Kota district alone where most of the cases gave a history of having slept in Government rest houses. The importance of having these rest houses constructed of vermin proof materials is emphasized. The Medical Officer Kota also reports among the results of his *Medical Surveys* in the area the carrier of relapsing fever is to be found in every hut.

Only one (non fatal) African case of enteric fever appears in the Hospital Returns but 1,538 cases of dysentery were treated during the year and of these 62 occurred among Europeans. The distribution of types of infection was (a) Europeans amoebic 56 undefined 6 and (b) Africans amoebic 150 bacillary 10 undefined 1,316. One European and 5 African deaths were ascribed to the disease. Among 1,398 faecal specimens examined at the Government Laboratory 88 were positive for *E. histolytica*.

Tuberculosis is considered to be increasing though it is not known even approximately what the incidence of the disease really is. Of the 251 cases reported during the year 145 patients were suffering from the pulmonary form of the disease. Out of a total of 252 Nyasaland native labourers repatriated from Southern Rhodesia during the year 39 were stated to have had tuberculosis and of these 35 were said to have suffered from phthisis. With a view to obtaining more accurate information concerning the incidence of the disease surveys were carried out in three areas and among 344 children examined by the dermal method using Moro's tuberculin ointment 31 gave positive reactions. It is said to be practically impossible to keep African patients in hospital for periods long enough to treat the disease effectively.

Of *trypanosomiasis* only two cases were reported—both from the Kota district. The medical Entomologist Dr W. A. LAMBORN reports that the steady retreat of the tsetse in a northerly direction continues. He estimates that the flies have vacated approximately 400 square miles of country since 1927. Dr Lamborn discusses the probable causes which have brought about the continued diminution of the numbers of flies and concludes that the decline must be due largely to the dearth of animal life on which the insects depend for their food. The opening up of large estates shooting organized hunts by natives etc. have all played their part in scaring game animals which have withdrawn to the Reserve in the North. A survey for parasites of the tsetse was commenced with a view to determining to what extent they may be responsible for the steady decline in the numbers of fly but first results suggest that parasites do not play an important part in bringing about the observed reduction.

Helminthiasis.—The following data relating to patients treated for helminthic diseases have been extracted from Hospital and Dispensary Returns—*ankylostomiasis* 12,242 cases *ascariasis* 2,231 *taeniasis* 161 *schistosomiasis* 7,487 and other helminthic diseases 342 giving a total number of 22,463 cases dealt with. [These figures refer to Out-patients only. It would appear that either in patient cases were first seen as out patients and not regarded as new cases if afterwards admitted to hospital or in patient cases have been omitted in error from the total in the Report under review. The text of the Report specifically states The total number of cases treated was 22,463. But in addition to the 22,463 out patients there were 1,845 non European in-patients and one European in patient.] The results of stool and

Race	Hospitals			Dispensaries Out-patients
	In-patients	Deaths	Out patients	
Europeans	223	7	1,215	—
Africans and others	10,545	270	113,669	302,318

The commentaries upon general morbidity experience contained in the Annual Report under review are briefly referred to in the notes which follow.

Cases of *malaria* dealt with at hospitals and dispensaries totalled 15,774 the distribution by race and types of infection being as follows —

Type of Infection	Europeans		Africans and Others		Rural Dispensaries Out-patients
	In-patients	Out patients	In-patients	Out patients	
Benign tertian	5	11	62	189	—
Quartan	—	1	32	113	—
Subtertian	2	41	827	717	—
Cachexia	—	1	46	50	—

Totals	25	138	1,051	4,831	9,729

There were 22 deaths among Africans due to malaria, and 2 cases of *blackwater fever* with 1 death among Europeans. The Government Entomologist has pointed out that although *A. costalis* is almost absent during the dry season it is overwhelmingly abundant during the late rains while the other common species, *A. funestus* shows no numerical increase during the year. He also found that the infection rate among *costalis* was very much higher than in *funestus*. The usual *anti-malarial measures* were successfully employed and it is reported that as a result the mosquito nuisance has been abated to a large extent in some areas.

At the Government Laboratory Zomba 1,379 out of 4,827 blood films examined were found to contain malaria parasites, the positive findings being *P. falciparum* 1,154 *P. malariae* 189 and *P. vivax* 36. The reports of the *Medical Surveys* (see above) present the results of blood film and spleen examinations at high and low altitudes in various areas.

Only 88 (non-fatal) African cases of *smallpox* were reported during the year. 175,162 vaccinations were performed.

A somewhat serious epidemic of *cerebrospinal meningitis* occurred in the Southern Province and necessitated the promulgation of special rules under the Public Health Ordinance for the control of the movements of natives etc. The first case occurred in August and spread was rapid. Altogether 780 cases were reported and of this total 603 occurred in the Mlanje District. Dr W. T. C. BERRY the Medical Officer seconded for special duty in connexion with the epidemic, contributes a detailed report which is presented as an Appendix to the Report under review.

Of relapsing fever 139 cases were notified. Of the total cases recorded 51 were dealt with in the Kota Kota district alone where most of the cases gave a history of having slept in Government rest houses the importance of having these rest houses constructed of vermin proof materials is emphasized. The Medical Officer Kota also reports among the results of his *Medical Surveys* in the area the carrier of relapsing fever is to be found in every hut. Only one (non fatal) African case of enteric fever appears in the Hospital Returns but 1,538 cases of dysentery were treated during the year and of these 62 occurred among Europeans. The distribution of types of infection was (a) *Europeans* amoebic 56 undefined 6 and (b) *Africans* amoebic 150 bacillary 10 undefined 1,310. One European and 5 African deaths were ascribed to the disease. Among 1,396 faecal specimens examined at the Government Laboratory 88 were positive for *E. histolytica*.

Tuberculosis is considered to be increasing though it is not known even approximately what the incidence of the disease really is. Of the 251 cases reported during the year 145 patients were suffering from the pulmonary form of the disease. Out of a total of 252 Nyasaland native labourers repatriated from Southern Rhodesia during the year 39 were stated to have had tuberculosis and of these 35 were said to have suffered from phthisis. With a view to obtaining more accurate information concerning the incidence of the disease surveys were carried out in three areas and among 344 children examined by the dermal method using Moro's tuberculin ointment 31 gave positive reactions. It is said to be practically impossible to keep African patients in hospital for periods long enough to treat the disease effectively.

Of trypanosomiasis only two cases were reported—both from the Kota Kota district. The medical Entomologist Dr W. A. LAMBORN reports that the steady retreat of the tsetse in a northerly direction continues he estimates that the flies have vacated approximately 400 square miles of country since 1927. Dr Lamborn discusses the probable causes which have brought about the decline must be due largely to the dearth of animal life on which the insects depend for their food the opening up of large estates shooting organized hunts by natives etc have all played their part in scaring game animals which have withdrawn to the Reserve in the North. A survey for parasites of the tsetse was commenced with a view to determining to what extent they may be responsible for the steady decline in the numbers of fly but first results suggest that parasites do not play an important part in bringing about the observed reduction.

Helminthiasis—The following data relating to patients treated for helminthic diseases have been extracted from Hospital and Dispensary Returns—*ankylostomiasis* 12,242 cases *ascariasis* 2,231 *taeniasis* 161 *schistosomiasis* 7,487 and other helminthic diseases 342 giving a total number of 22,463 cases dealt with. [These figures refer to *Out-patients* only. It would appear that either in patient cases were first seen as out-patients and not regarded as new cases if afterwards admitted to hospital or in-patient cases have been omitted in error from the total in the Report under review. The text of the Report specifically states The total number of cases treated was 22,463. But in addition to the 22,463 out patients there were 1,845 non European patients and one European in patient.] The results of stool and

urine examinations carried out in the course of *Medical Surveys* in various areas are presented in a series of tabular statements together with the commentaries of Medical Officers in charge of these investigations. The Medical Officer in charge of the survey of the North Nyasa District commenting on the high incidence of *schistosomiasis* in the area surveyed observes —

"In this marsh *B. africanus* is prevalent. *Lymnaea* were also found but in a search extending along the Lake shore from the River Songwe to Deep Bay (approximately 50 miles) I did not see a single *Planorbis*. It would appear that this mollusc is not the carrier of the disease in this district and another snail must be concerned.

In an Appendix to the Report under review Dr W. L. Gopsill contributes an interesting account of the incidence in this area under the title of *Some Observations on Schistosomiasis in North Nyasa District*.

At the Government Laboratory among 1 078 specimens of urine examined 219 contained evidence of bilharzial infestation, while the findings among 1 396 faecal specimens dealt with included *ancylostoma* 520 *ascaris* 27 *S. mansoni* 37 *E. histolytica* 88.

Of venereal diseases 3,324 cases were reported and of these 2,377 cases were of syphilis and 947 gonorrhoea. The out-patient clinic at Blantyre continued to function with fair success, but subsequent attendances following first visits for treatment were disappointingly few. It is noted that a native nurse was posted to the clinic and 145 female patients paid a first visit. At Denza among 1 433 labourers examined only 28 were rejected on grounds of venereal disease. The finding is interesting in view of the common belief that venereal diseases are increasing. Hospital and Dispensary Returns also show that 2,960 cases of yaws were treated during the year under review.

Leprosy—The treatment of the disease in Nyasaland is carried out almost entirely by the Missions with the financial aid of Government. There are 12 clinics established throughout the country, the majority of the centres being in charge of qualified nurses. "Approximately 646 lepers were under treatment at these clinics during the year 280 were admitted 96 were discharged, and 35 died. It is not known to what extent the disease is prevalent in Nyasaland, but it may be possible to obtain fairly dependable information during the course of the next census.

Among other diseases mentioned in the Report deficiency diseases were the subject of special investigation by the Medical Department, the results of the enquiry being embodied in a Memorandum presented to the Native Welfare Committee (see above *Public Health*). Five cases of rickets, 3 of scurvy, 5 of beriberi and 48 of pellagra were recorded during the year. Rabies is said to have caused anxiety and to have shown no signs of abatement, but no cases appear to have been recorded unless they have been included under the title *Injuries inflicted by animals* (bites, kicks, etc.)" Over 50,000 cases of ulcers among African patients and 43 781 cases of bronchitis were dealt with.

Scientific—The Report of the Government Pathologist is confined to a summary of the specimens received and examined at the Government Laboratory and findings recorded. Altogether 8 058 specimens were dealt with. The principal findings have been referred to in preceding sections of this summary. The Annual Report of the Medical Entomologist has also been quoted in the section *trypanosomiasis* above. In addition to the tsetse fly surveys, Dr Lamborn continued

his survey for rodents and their ectoparasites and his investigations of the breeding habits of *Tabanidae* and commenced a study designed to determine whether *Myxo tuberculosis* undergoes any morphological changes within the fly *Musca sorbens* and whether the organisms remain viable after they have been ingested by the fly.

Four Special Reports appear as Appendices to the Report under review viz —

- (1) Post-Operative Complications in the Natives of Nyasaland by Dr C H HOWAT
- (2) Cerebrospinal Fever in Nyasaland by Dr W T C BERRY (Reviewed in *Bulletin of Hygiene* 1938 Vol 13 p 867)
- (3) Some Observations on Schistosomiasis in the North Nyasa District by Dr W L GORSILL. (Reviewed above p 38)
- (4) The Native Welfare Committee Report on Nutrition. (Reviewed in *Bulletin of Hygiene* 1938 Vol. 13 p 981)

Three of these Special Reports have already been the subject of brief reference in the preceding notes. It remains to say that Dr Howat's contribution discusses four common complications of operation viz post-anaesthetic vomiting infection of the surgical wound retention of urine and pulmonary lesions—bronchitis pneumonia etc. His surgical practice in Nyasaland leads him to conclude that these complications are encountered rarely or not at all in the Protectorate.

Financial—Actual expenditure on Medical Department services during 1937 amounted to £51,322 as against an approved expenditure of £52,712.

P. Granville Edge

ZANZIBAR PROTECTORATE (1937)

Zanzibar Protectorate off the East African Coast comprises the islands of Zanzibar and Pemba and the islets within their territorial waters. Zanzibar is about 53 miles long by 24 miles broad with an area of 640 sq miles. Pemba to the north-east of Zanzibar is about 42 miles long by 14 miles broad. The only town of importance is Zanzibar Town.

Vital Statistics—Published figures are compiled from returns submitted by the *Mfidirs* through the Provincial Administration and in the words of the Report cannot be regarded as even approximately correct for registration is incomplete. The principal facts are given as follows —

Estimated Population	Registered Births	Birth Rate	Registered Deaths	Death Rate
243 135	4 199	17.0	4,026	16.9

The infant mortality rate for the year is not stated but it is observed that rates in specially defined areas in 1937 were 141 for natives and 159 for Indians per 1 000 live births. The maternal mortality rate

of 9.2 per 1 000 live births relates principally to the town of Zanzibar for the Protectorate as a whole it is believed this rate would be greatly exceeded. The investigations of the Welfare Clinic are being continued and it is hoped that by the end of 1938 sufficient data will have been assembled to provide reasonably dependable infant and maternal mortality rates.

European Officials resident numbered 110 with an average number resident of 70. One death was recorded. *Non European Officials* resident numbered 462, with an average number resident of 423. Five were invalided but no deaths were recorded in this group.

The most common causes of sickness amongst Europeans and Non European officials were *influenza malaria and diseases of the respiratory and digestive systems*.

Maternity and Child Welfare Work—The year 1937 saw the results of the first full year's work of the Lady Medical Officer and her staff (see this *Bulletin* 1938 Supp., p. 81*). During the year the 7,310 new patients registered at the special day clinics made 45,306 attendances for treatment. of special significance is the fact that the proportion of women in Zanzibar attending hospitals for treatment rose from 22 per cent. in 1935 to 40 per cent. in 1936 (when the clinic started) and to 59 per cent. in 1937. In the Pemba Hospitals where there is no woman doctor the proportion of women patients has remained roughly constant at 23 per cent. The striking success of the venture in Zanzibar will be followed by the appointment of a second woman doctor in 1938 with extension of similar activities to the island of Pemba and to rural areas in the Protectorate when financial resources permit. Meanwhile at the hospitals at Chake Chake and Wete in Pemba a start has been made by providing women's out patient departments separated as widely as conditions permit from the men. In commenting upon these new departures and of the success of the initial venture in Zanzibar Dr W Leslie Webb Director of Medical Services quotes from the memoirs of one of the daughters of the first Sultan of Muscat and Zanzibar and published in 1880 in which the enlightened lady observed that if a "female physician could be brought to undertake service in Zanzibar she would be able to do more good than ten medical men combined."

At the three *Infant Welfare Clinics* held weekly attendances totalled 3 612, and at the *Ante Natal Clinic* 847. During the year under review cases of *diseases of the puerperal state* dealt with in Government Hospitals numbered 302 as compared with 115 in the preceding year. Clinics were also actively functioning during the year at four rural dispensaries with encouraging results.

The *Zanzibar Maternity Association* is no longer under the control of the Medical Department (see this *Bulletin* 1937 Supp., p. 70* and 1938, Supp. p. 81*) and returns of the work of that organization will no longer be included in the Annual Medical Report.

School Hygiene—A most satisfactory feature of the year's work was the extension of the School Medical Service. During 1937 over 1 600 children were medically examined and nearly 1,300 were seen by the Dental Surgeon—the largest numbers of school-children ever dealt with in a single year in the Protectorate. The service is well established in both islands and fewer difficulties are met with, for examinations are willingly accepted by both parents and children. The results of these examinations are set out in considerable detail in the Report under review but for present purposes it must suffice to summarize

briefly the principal findings. In both Zanzibar and Pemba *malnutrition* is grossly evident amongst rural African children less so among rural Arabs the town-dwelling African child is better nourished than his rural contemporary but is less well fed than the town Arab child. Malnutrition is less evident amongst pupils at the Government girls school than amongst male children. With one or two exceptions the cleanliness of school-children leaves much to be desired—*scabies* is common in the rural schools owing to the filthy condition of the cotton garments worn by pupils. In all schools *dental caries* is very common—about 92 per cent of the pupils showing defects. Pathological eye conditions were frequently met with being most common in areas where malnutrition is evident. *Arkylostomiasis* is said to be universal in the rural areas with *ascariasis* common in the southern area in schools on the east side of the island of Zanzibar. Treatment for diseases met with amongst school-children is regularly carried out but for *ankylostomiasis* results have not proved so encouraging owing to the frequency with which re infestations occur. Lectures on health subjects are given to school-children special attention being devoted to talks on the dangers of hookworm and malaria *scabies* etc. and how these diseases may be avoided.

Public Health Sanitation etc—Dr W Leslie WEBB observes Adequately trained native staff still remains one of the crying needs of the department and it is difficult to see how any material extension of service can be effected without considerable cost until it is provided. In 1935 Government approved a scheme for the formation of a Zanzibar Native Medical Service through the framework of a rural Africans could be given a comprehensive training in medical work with a view to subsequent absorption into the Department as rural dispensers nurses and midwives. However at that time there were no rural Africans of the required educational standard available for training though subsequently with the co-operation of the Education Department arrangements were made for the further general education of a number of boys and girls the first of these classes of boys will be available for Medical Department training in 1940 and of girls in 1942.

The anti-malarial survey conducted by Dr D D McCARTHY (see this *Bulletin* 1938 Supp p 84*) under a grant from the Colonial Development Fund was completed in September 1937 and it is expected that his Report will be published early in 1938. Preventive measures continue to be actively carried out along the lines described in previous issues of this Supplement.

Present-day methods of sewage disposal were described in earlier Reports and referred to in this *Bulletin* 1937 Supp p 72* and 1938 Supp p 82*. The posting of three locally trained African Sanitary Inspectors for permanent employment to rural areas in connexion with a scheme for providing *dore-kole latrines* for the whole population in those areas marks the first serious attempt to cope with the problem of rural sanitation. Scavenging services are ample and satisfactory for the removal and disposal of refuse continued along lines previously described.

In Zanzibar water supplies were reasonably satisfactory but in Pemba water-mams are laid but in the native town the population have to employ water carriers to bring water to their houses. The supplies to Chake and Wete were reasonably satisfactory but in Mkoani water is of poor quality and insufficient in quantity. The

of 9.2 per 1 000 live births relates principally to the town of Zanzibar for the Protectorate as a whole it is believed this rate would be greatly exceeded. The investigations of the Welfare Clinic are being continued and it is hoped that by the end of 1938 sufficient data will have been assembled to provide reasonably dependable infant and maternal mortality rates.

European Officials resident numbered 110 with an average number resident of 70. One death was recorded. *Non European Officials* resident numbered 462, with an average number resident of 423. Five were invalided but no deaths were recorded in this group.

The most common causes of sickness amongst Europeans and Non European officials were *influenza malaria* and *diseases of the respiratory and digestive systems*.

Maternity and Child Welfare Work—The year 1937 saw the results of the first full year's work of the Lady Medical Officer and her staff (see this *Bulletin* 1938 Supp. p. 81*). During the year the 7,310 new patients registered at the special day clinics made 45,308 attendances for treatment. Of special significance is the fact that the proportion of women in Zanzibar attending hospitals for treatment rose from 22 per cent. in 1935 to 40 per cent. in 1936 (when the clinic started) and to 59 per cent. in 1937. In the Pemba Hospitals where there is no woman doctor the proportion of women patients has remained roughly constant at 23 per cent. The striking success of the venture in Zanzibar will be followed by the appointment of a second woman doctor in 1938 with extension of similar activities to the island of Pemba and to rural areas in the Protectorate when financial resources permit. Meanwhile at the hospitals at Chake Chake and Wete in Pemba a start has been made by providing women's out-patient departments separated as widely as conditions permit from the men. In commenting upon these new departures and of the success of the initial venture in Zanzibar Dr W. Leslie WERN, Director of Medical Services, quotes from the memoirs of one of the daughters of the first Sultan of Muscat and Zanzibar and published in 1880 in which the enlightened lady observed that if a "female physician" could be brought to undertake service in Zanzibar she would be able to do more good "than ten medical men combined."

At the three *Infant Welfare Clinics* held weekly attendances totalled 3,612, and at the *Anti-Natal Clinic* 847. During the year under review cases of *diseases of the puerperal state* dealt with in Government Hospitals numbered 302 as compared with 115 in the preceding year. Clinics were also actively functioning during the year at four rural dispensaries with encouraging results.

The *Zanzibar Maternity Association* is no longer under the control of the Medical Department (see this *Bulletin* 1937 Supp. p. 70* and 1938 Supp. p. 81*) and returns of the work of that organization will no longer be included in the Annual Medical Report.

School Hygiene—A most satisfactory feature of the year's work was the extension of the School Medical Service. During 1937 over 1 600 children were medically examined and nearly 1,300 were seen by the Dental Surgeon—the largest numbers of school-children ever dealt with in a single year in the Protectorate. The service is well established in both islands and fewer difficulties are met with, for examinations are willingly accepted by both parents and children. The results of these examinations are set out in considerable detail in the Report under review but for present purposes it must suffice to summarize

ness the principal findings. In both Zanzibar and Pemba nutrition is grossly evident amongst rural African children less nourished than his rural contemporary, but is less well fed than the town Arab child. Malnutrition is less evident amongst pupils at Government girls' school than amongst male children. With one or two exceptions the cleanliness of school-children leaves much to be desired—scabies is common in the rural schools owing to the filthy condition of the cotton garments worn by pupils. In all schools dental caries is very common—about 92 per cent of the pupils showing defects. Pathological eye conditions were frequently met with being most common in areas where malnutrition is evident. *Ankylosomiasis* is said to be universal in the rural areas with *ascariasis* common in the southern area in schools on the east side of the island of Zanzibar. Treatment for diseases met with amongst school-children is regularly carried out, but for *ankylostomiasis* results have not proved so encouraging owing to the frequency with which re-infections occur. Lectures on health subjects are given to school-children special attention being devoted to talks on the dangers of hookworm. Public Health Sanitation, etc.—Dr W. Leake W. E. B. N. observes and how these diseases may be avoided.

Adequately trained native staff still remains one of the crying needs of the department and it is difficult to see how any material extension of service can be effected without considerable cost until it is provided. In 1935 Government approved a scheme for the formation of a Zanzibar Native Medical Service through the framework of a rural Africans could be given a comprehensive training in medical work with a view to subsequent absorption into the Department as rural dispensers, nurses and midwives. However at that time there were no rural Africans of the required educational standard available for training though subsequently with the co-operation of the Education Department arrangements were made for the further general education of a number of boys and girls. The first of these classes of boys will be available for Medical Department training in 1940 and of girls in 1942.

The anti-malarial survey conducted by Dr D. D. McCarthy (see this *Bulletin* 1938 Supp. p. 84*) under a grant from the Colonial Development Fund was completed in September 1937 and it is expected that his Report will be published early in 1938. Preventive measures continue to be actively carried out along the lines described in previous issues of this Supplement.

Present-day methods of *sewage disposal* were described in earlier Reports and referred to in this *Bulletin* 1937 Supp. p. 72* and 1938 Supp. p. 82*. The posting of three locally trained African Sanitary Inspectors for permanent employment to rural areas in connexion with a scheme for providing *bore-hole latrines* for the whole population in those areas marks the first serious attempt to cope with the problem of rural sanitation. Scavenging services were ample and satisfactory and disposal of refuse continued along lines previously described.

In Zanzibar *water supplies* were reasonably satisfactory, where water mains are laid but in the native town the population have to employ water carriers to bring water to their houses. In Pemba supplies to Chake and Wete were satisfactory but in Mkoani water is of poor quality and insufficient in quantity. The

Public Works Department have carried out experimental borings and it is expected that the present unsatisfactory conditions will shortly be remedied. In rural areas water is still obtained from deep and shallow wells and from rivers. Sanitary Inspectors are required to supervise and endeavour to improve supplies in such areas.

Under the heading of *Housing and Town Planning* a somewhat detailed account is provided of general conditions and of attempts to bring about improvement so far as urban housing is concerned in Zanzibar and Pemba. Numerous surveys and inspections of properties brought to light many cases of unsatisfactory housing and steady pressure was maintained to persuade or enforce owners to effect necessary improvements. Rural housing conditions did not alter during 1937. It is said that though on the whole rural housing is not good there is little overcrowding.

As regards *foods etc.* it is stated that the publication of a *Nutritional Review of the Natives of Zanzibar* early in the year served to focus attention on the subject for it was clearly demonstrated that native dietaries are invariably lacking in some essential foodstuffs to the detriment of the health of the people. The implementation of the recommendations made for the improvement of existing conditions must be a matter of time and governed largely by financial considerations (see also this *Bulletin* 1937 Supp. p. 72* and 1938 Supp. p. 83*).

Training of Native Personnel—A notable advance in the training of non-European personnel was made when the systematic training of nine learner Sanitary Inspectors (Indian, African, and Goan) culminated in their examination under the auspices of the Royal Sanitary Institute: five satisfied the examiners. The training scheme is the first of its kind to be undertaken in East Africa. The training of *rural dispensers* was continued as usual.

Measures taken to spread the knowledge of hygiene and sanitation included lectures by Sanitary Inspectors to school-children and the general population; the distribution of pamphlets devoted to explaining the meaning of simple health precautions; lectures by Medical Officers, Health Exhibitions, etc.

The Annual Report of the Dental Surgeon is printed as an Appendix to the Annual Medical Report under review. It is stated that after four years of observation of the natives of Zanzibar Protectorate, it is safe to affirm that over 90 per cent. of them suffer from dental disease. The Report comments at some length on oral conditions in the Protectorate, discusses dental work carried out among school-children and supplies tabulated facts relating to the numbers of schools visited, pupils examined, etc.

Port Health Work—During the year 539 ships and 712 dhows entered the harbour and 1,531 immigrants landed. Routine services were carried out as usual and nothing unusual in respect of Port Health work is reported.

Aeroplane traffic accounted for the arrival and departure of 347 planes carrying 384 immigrants and 267 emigrants. All aircraft arrive from Kenya or Tanganyika: no quarantine restrictions of any kind are imposed and so far do not appear to be called for.

Hospitals, Dispensaries, etc.—The numbers and distribution of Hospitals and Dispensaries in the Protectorate may be conveniently set out in the following manner:—

Locality	Hospitals	Special Clinics	Dispensaries	Total
Zanzibar Island — Town District	6	2	2	10
Pemba Island — Town District	2	—	18	20
— — — District	3	—	—	3
— — — District	1	—	—	8
Totals	12	2	28	42

The above figures include one European hospital and a Mental Hospital in Zanzibar Town, a Poor Home and a Leper Colony in Zanzibar District and a Leper Colony in Pemba Island District.

At these institutions 4,673 in-patient were admitted during the year in patient cases treated totalled 121,347 and among them 449,370 attendances were recorded. Out patients dealt with numbered 219,396 and attendances at Dispensaries. Mention has already been made of the extension of medical facilities in the interests of women (see *Merchandise* above) and of the proportions of value throwing any light on the incidence of disease in the Protectorate are the returns compiled at Government Hospitals and Dispensaries. The following notes briefly summarize the principal references contained in the Report and returns to disease incidence during 1937.

Malaria patients treated at Government Hospital etc numbered 8,801 and of these 249 were in-patient (7 died) and 8,552 were out patients. The distribution of types of infection among in-patients reads *benign tertian* 28, *quartan* 1, *tertian* 123 and unclassified 97. The corresponding figures for out patients being 457, 22, 1,797 and 6,276 respectively. There were also 5 cases of *blackwater fever* two of these being treated as in-patients. At the Pathological Laboratories Zanzibar and Pemba the following blood films were examined and findings recorded —

Laboratory	Blood film	Positive findings			
		<i>P. vivax</i>	<i>P. falciparum</i>	<i>P. malariae</i>	Undefined
Zanzibar	9,378	253	1,252	26	533
Pemba	2,015	446	339	—	103

P. vivax and *P. falciparum* were found together in 22. Reference has been made in the section *Public Health* above of anti-malarial control measures and of the special survey completed in 1937.

No case of any of the dangerous infectious diseases was recorded (see this *Bulletin* 1938 Supp. p. 84*). During the year 8,805 anti-smallpox vaccinations were performed in Zanzibar and 1,918 in Pemba. One case of *relapsing fever* was reported but as *O. moubata* is not known to exist in Zanzibar or Pemba it is certain the disease must have been contracted outside the Protectorate. One fatal case of *cerebrospinal meningitis* was notified from Wete in Pemba.

Of the 2 cases of enteric fever notified 20 occurred in Zanzibar Town. At the Zanzibar Laboratory 18 out of the 113 samples of serum agglutinated *Bact. No. 2000*. Dysentery was responsible for 56 cases and of these 38 occurred in Zanzibar. (Hospital Returns record 61 cases of which 8 were amoebic, 24 bacillary and 31 unclassified.) Among 142 faecal specimens examined *B. et dysenteriae* Flexner was isolated in 26 and Sonne in 6.

During the year 214 patients were treated for tuberculosis (all forms) and of this total 182 were suffering from the pulmonary type of the disease. 45 of the 48 deaths were due to phthisis. New cases notified nearly all of the pulmonary type numbered 151 and of these 123 were in Zanzibar Island. The year's figures for the Walezo Tuberculosis Asylum were total treated 94, died 33, discharged 39. There were also 6454 cases of bronchitis and 204 of pneumonia.

New cases of leprosy notified numbered 28 and the total cases treated 137. The two Leper Colonies at Walezo in Zanzibar and Makondeni in Pemba are well patronized by lepers who enter and reside there voluntarily (see this Bulletin 1938 Supp. p. 84*).

Helminthic diseases—Hospital Returns show that 12,202 cases of ankylostomiasis were dealt with during the year. The view is expressed that there can be no doubt that nearly the whole population of the island of Zanzibar is infected with hookworm. In an attempt to discover to what extent the application of proved methods of control is applicable in Zanzibar Government is to provide sufficient latrine accommodation in a selected area and by the end of the year six boring machines were at work in the area under the charge of three African Sanitary Inspectors. Efforts are being made to popularize the use of latrines by constructing portable latrines and providing cement tops free of charge at a cost to Government of 4 shillings each complete latrine and if the experiment proves successful it is hoped to apply the principle to the whole Protectorate. Schistosomiasis is said to be widespread in Pemba but less evident in Zanzibar. Intestinal forms of the disease are rare. During the year 576 cases were treated. An investigation of the problem was undertaken by a research worker from the London School of Hygiene and Tropical Medicine and by the end of the year the snail carrier had been incriminated, and the fact ascertained that its distribution in the Protectorate is limited by certain definite factors. In the light of these discoveries it is hoped that measures may be devised for the complete eradication of the disease. At the two Laboratories the following findings were recorded following the examination of specimens of faeces and urine—

Item	Laboratory	
	Zanzibar	Pemba
Faecal specimens examined	6,328	863
Positive findings—		
Ankylostoma	2,508	408
Ascaris	483	29
Trichuris	94*	46
S. mansoni	5	—
Urine examined	499	813
Positive findings—		
Schistosoma	16	129

Venereal Diseases—During the year 1192 cases of syphilis 1465 of gonorrhoea 65 of soft chancre and 4168 of warts were treated. It is stated that the figures for gonorrhoea give no idea of the incidence for almost every adult has the disease (see this *Bulletin* 1938 Supp. p. 85*). At the Zanzibar Laboratory the Kahn test applied to 4210 samples of serum gave 681 positive and 592 doubtful reactions.

Other diseases referred to in the Report included the following. It is said that *filariasis* occupies a prominent position amongst diseases affecting natives. For *ulcers* 21,973 cases were dealt with. Among the 3354 *diseases of the eye* treated were 93 cases of *trachoma*. Cases of *influenza* numbered 1068 all were of a mild type and no deaths were reported.

Scientific—The Laboratories at Zanzibar and Pemba continued to function as heretofore and references to the work and findings recorded have been made under various headings in the preceding note. During the year the following paper was published—

VASSALLO (S. M.) Duodenal Ulcer in Zanzibar—*East African Med. J.* 1937 Vol. 14 No. 3

Financial—Total expenditure on Medical Department Services amounted to £48,204 a sum which represents 9.7 per cent of the total revenue of the Protectorate.
P. Granville Edgè

different States from 35.5 in Cojedes to 0.6 in the Federal District. The former figure would appear to be of doubtful accuracy for in the account of observations made in San Carlos a small town in Cojedes we read that the diagnosis malaria had been inserted on a large number of death certificates of cases of which the cause of death was completely unknown. For Venezuela as a whole the marked reduction which characterized malaria mortality recorded in 1936 and 1937 is explained by the fact that in those years malaria deaths certified by a doctor were alone taken into consideration.

The report gives details of observations made in places in 15 of the 22 States. A few of the surveys were fairly complete and the report describes the measures that have been adopted to control the disease. As examples of the diversity of malaria conditions may be cited observations made in Barcelona and Maracay. Barcelona, the capital of Anzoategui (pop. 11497) on the river Neverí, 3 kilometres from the sea suffers severely in certain years. The months of maximum prevalence are from October to April, which coincide with the seasonal prevalence of *A. albimanus*. Three-quarters of the cases are *falciparum* infections. In Maracay, an important agricultural and industrial town 445 metres above sea level, malaria is an important cause of mortality in certain years. There is a well marked five-year cycle. Here May to October are the months of maximum prevalence and *mix* infections preponderate. *A. pseudopunctipennis* is the anopheline most in evidence during the malaria season.

Attached to the Central Office of the Division of Malariology is a laboratory and a school of malariology. Thirteen doctors and 23 fifth-year students attended the first course. The staff of the Division during the year examined 68,531 persons, visited 22,071 breeding places, and classified 21,126 adult mosquitoes and 222,543 larvae.

[No. 2.

SUMMARY OF RECENT ABSTRACTS

II YELLOW FEVER*

Epidemiology

JAMES (p. 110) gives a table of 111 cases with 84 deaths in South America and Africa during the 6 months ending 31st March 1937 and a similar table (p. 486) of 349 cases with 297 deaths during the 9 months ending 30th September 1937. The latter is an increase over the numbers recorded in the previous year.

Flu (p. 116) thinks that an atypical usually unrecognized form of the disease exists endemically in Surinam and that it flares up in epidemic and typical form with the incursion of considerable numbers of susceptible persons. The evidence for this opinion is given. Only the existence of a comparatively innocuous virus and maintenance of the disease in atypical form during non-epidemic periods can explain why natives and whites who have lived long in yellow fever lands do not suffer severely during epidemics. This view is supported by further evidence —

PELTIER, DURIEX and MARTIN (p. 115) consider that an epidemic in French Guinea in 1932 supposed to be of influenza but with a mortality of 1,540 in 8,600 cases was probably actually due to yellow fever. Their evidence includes the results of protection tests preceded by a rise in the death rate among local Africans in Nigeria not being then suspected. In a survey in French Equatorial Africa STEFANOPOULO (p. 114) found that a number of sera gave positive protection tests. [The figures are as follows — Middle Congo 277 sera tested with 59 positive of which 104 with 19 positive were from children under 15. Gabon region 272 sera tested with 33 positive of which 95 with 10 positive were from children under 15. Tchad region 129 sera tested with 37 positive of which 115 with 36 positive were from children under 15.] These positive results in children indicate that the disease must still be present. Investigations added further support to the view that the test is sufficiently specific to be of value in determining the distribution of yellow fever

* The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1933 Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed (p. 10).

In the Lower Congo VAN DER BERGHE (p. 491) found 14 positive sera in 114 collected from children. JAMES (p. 487) records that in Kordofan 70 to 80 per cent. of the inhabitants show yellow fever immune bodies in the blood.

SOPER (p. 114) concludes that the reported incidence of yellow fever is no safe index of its occurrence in endemic zones and that there is a vast silent reservoir of infection in the interior of South America. It extends to many districts in which *Aedes aegypti* does not exist. HANSON (p. 487) reports an outbreak in Peru apparently of the jungle type with a high mortality. *Aedes* is absent from the infected area.

OHLEWICH (p. 488) shows how an epidemic was started in northern Chile by the introduction of a case into a hospital where mosquito nets were little used. The epidemic (of more than 100 cases) was controlled by anti-mosquito measures.

SOREL (p. 111) describes a missionary who had lived for 30 years in Africa, sometimes in the midst of epidemics of yellow fever. During this time he had never had any attack indicative of yellow fever. He then left and stayed for a year in Paris but within a month of returning to the French Sudan he contracted the infection and died of it.

Aetiology

DURIEUX (p. 495) states that the injection of patients' blood into the brains of mice affords a method of certain diagnosis on condition that the nature of the isolated virus is confirmed by protection tests with yellow fever immune serum. Thirteen strains were isolated in this manner. He considers that in human yellow fever under the influence of the bile in the serum, the virus loses its viscerotropic but preserves its neurotropic properties for longer periods. Certain strains are much more virulent than others. Virus was found to persist in the blood of yellow fever patients up to the 5th day of fever (See below vaccination).

SMITH (p. 496) found that mouse testis seems to be quite as suitable as mouse brain for the isolation of virus.

ROUBAUD, STEFANOPOULO and FINDLAY (p. 124) found that a culture virus kept for long periods either in mouse embryo tissue and then fowl embryo tissue or in the latter alone was not transmissible by the bites of mosquitoes.

WHITMAN (p. 122) titrated the virus present in *Aedes* at various intervals after infection. The virus content falls during the first week and then increases rapidly to a higher level than at first. Multiplication therefore takes place. (For this author's experimental work on *Aedes* larvae see later Research.)

Transmission

WHITMAN and ANTUNES (p. 490) found that *Aedes scapularis* and *Aedes fluviatilis* are efficient vectors. *Aedes nubilus*, *A. terreus*, *Mansonia jansoni*, *M. fasciolata*, *M. chrysotum* and *M. albicosta* failed to transmit but the virus was retained in their bodies for long periods. Certain races of *Psorophora ferox* may be capable of transmission. ROUBAUD, COLAS-BELCOUR and STEFANOPOULO (p. 117) show that *Aedes gemscutatus* is an efficient carrier.

WHITMAN and ANTUNES (p. 489) demonstrated the transmissibility of two strains of jungle yellow fever by *Aedes aegypti*. This is interesting in view of the fact that the virus seems rarely to be introduced into towns harbouring this mosquito possibly because patients in outlying

districts (jungle) are not brought into towns within the period of their infectivity (the first 3-4 days of illness). But that it may be seen in the small outbreak at Cambará Paraná recorded by WILCOTT *et al* see below (Prevention). The strains used were the M.A.J. and Suarez strains and the incubation period found was 14 or 15 days much longer than for the Asibi (urban) strain. This long incubation period may play a part in limiting the importation of jungle virus into towns since a greater proportion of infected insects would die before becoming infectious. Some of the rhesus monkeys infected showed delayed febrile response and at the time of fever virus had practically disappeared from the blood stream. If the human response is similar many cases brought to towns for treatment would be no longer infectious for local *Aedes* which would limit the frequency with which jungle virus might invade urban centres.

ARTURUS and WIRTHS (p 491) found that *Haemagogus janthinomys* retained the Asibi strain of virus for at least two weeks and *H. tritaeniorhynchus* the M.A.J. strain (of jungle fever virus) for 16 days. Transmission however was not produced.

VATHIS (p 117) compared strains of *Aedes aegypti* from widely different countries. Cross fertilization can be effected and the species is very homogeneous in all parts of the world. Three years previously Mathis had tried without avail to discover whether there were distinct races of *Aedes aegypti* comparable with what is known to exist in the case of *Anopheles maculipennis*. *Aedes aegypti* is therefore a serious potential danger as a carrier of yellow fever in any country.

THE BULLETIN DE L'OFFICE INTERNATIONAL D'HYGIÈNE PUBLIQUE (p 113) gives the *Aedes* index for various African countries. It is prevalent throughout East and West Africa. JAMES (p 486) shows that in a small epidemic in Accra there was a low *Aedes* index in houses but breeding was taking place freely in abandoned wells.

VACCALUM and FINDLAY (p 125) found that 22 out of 92 African monkeys showed immune bodies. In view of the essentially domestic character of *Aedes aegypti* under natural conditions other mosquitoes must be regarded as potential vectors. 175 cattle and 70 sheep from Kenya were examined, with 13 and 3 respectively positive. The possibility of their having been exposed to infection cannot be excluded. Certain wild rodents and animals in West Africa were entirely negative. But it is also possible that virucidal properties may appear in cattle under certain physiological conditions or as a result of bacterial or virus infections other than yellow fever since in Uganda where there are few human positive sera the proportion in cattle is high and in the Gold Coast the reverse is the case.

JAMES (p 111) quotes FINDLAY's observation that 20 out of 88 monkeys caught in endemic areas in Africa gave positive protection tests while the sera of monkeys from Kenya, India and Java were negative. The specificity of the protection test using cattle sera is doubtful.

Pathology

HOFFMANN (p 119) claims that the most reliable and quickest method of diagnosis in early epidemic cases in countries with latent endemic infection is the histological examination of post-mortem material. BARTER and BROCK (p 491) state that specific lesions can only be found in the liver. They also note that intranuclear inclusions in the liver cells when they can be demonstrated clinch the diagnosis.

occurred in patients inoculated with two of several pools of monkey sera used with the virus.

PELTIER, DURIEX JONCHÈRE and ARQUIÉ (p. 494) found that serum containing bile neutralized yellow fever virus completely in four hours, provided that the jaundice was total. Bile salts are necessary for this phenomenon. The virus is probably not killed but only coated. Virus treated in this way has been used for vaccination. The serum of patients with total jaundice may thus give positive protection tests. It appears that brain tissue is necessary for this phenomenon since if phosphatic suspension of infected mouse brain or virus present in Seitz filtrate are used, the bile destroys the virus completely.

SOREL (p. 111) quotes a patient who had been vaccinated against yellow fever by three inoculations in August-September 1934. She became ill on 2nd October 1936 and died of typical yellow fever on the sixth day. A specimen of her serum collected at the beginning of the attack was found to be no longer protective. It therefore appears to be necessary to vaccinate at intervals of 18 months or even every year. BIZIEX and DESROS (p. 117) report a patient who died of yellow fever although vaccinated 19 months previously with three doses of Laligret's vaccine.

Research

SOPER, BEEUWES, DAVIS and KERR (p. 496) show that antibody present in the serum of babies depends on its presence in the serum of the mothers. This initial immunity present at birth seems to be entirely passive and disappears usually within three months. The influence of maternal immunity on the results of protection tests in children may be disregarded after 12 and probably after 6 months.

SELLARDS and BENNETT (p. 123) showed that 20 per cent. suspensions of mouse brains infected with the French neurotropic strain in physiological saline containing 1 per cent. phenol lost virulence completely after being kept at 37°C. for six days. Nevertheless, used as a vaccine this gave some protection to mice: 21 out of 35 surviving, whereas 29 out of 31 controls died. Addition of cysteine to this vaccine augmented its efficiency probably by restoring some of its lost antigenic power.

WHITMAN and ANTUNES (p. 489) found that *Aedes aegypti* infected in the larval stage retained virus on emerging as adults especially if the concentration of virus in the fluid in which the larvae were placed was high, even if the larvae were transferred to clean water after a few hours contact with virus. Attempts to transmit virus through eggs were uniformly negative.

NICOLAU and BAFFET (p. 119) and STREFAKOPOULO, NAGAKO and WASSERMANN (p. 497) have investigated the susceptibility of various animals to yellow fever virus.

C II

TROPICAL DERMATOLOGY

A REVIEW OF RECENT ARTICLES I *

99

Blasomycosis—Once again the majority of publications have been concerned with chromoblastomycosis. CARRIÓ and PIMENTEL¹ describe the first case to be recognized in the Dominican Republic. The patient was a male native labourer aged 60 in whom the disease had started some 20 years earlier whilst he was working barefooted in a tuber plantation. At that time a small wart appeared on the right external malleolus. This gradually spread until a diffuse thick swelling involved the whole of the outer side of the foot. A superimposed tumour was well defined but had an irregular and polycyclic border. It extended from the external malleolus round the tendo Achillis nearly to the internal malleolus. The centre of this mass was slightly depressed and violaceous consisting of scarring and some scattered warts. Its edge was raised 8 mm above the surrounding skin and was lobulated and papillomatous with some slight scaling and crusting. A full description is given of the cultures and microscopical appearances of the organism. This was of the *Hormodendron pedrosoi* type but exhibited a slower rate of growth and unusual length of the conidia and a variability in the production of aerial mycelium. The case reported by GOMES² is interesting in several ways. A white Brazilian aged 51 cut his hand on the branch of a eucalyptus tree. This wound healed in a month under dressings with hydrogen peroxide but vesicles appeared in the scar eight days after apparent cure. These were sharply defined and gradually acquired a verrucous surface. X-rays demonstrated osteoporosis of the first and second phalanges of the left hand. Details are given of the first and experimental inoculation the author succeeded in infecting guinea pigs rats and rabbits. It is claimed that this constitutes the first experimental reproduction of the disease. The same fungus was isolated from the offending tree branch. In Java MÜLLER ESSED and HAZEBOEK³ detected the disease on the left buttock of a 60-year-old native. There was no history of antecedent trauma but this might be negated by the fact that three years had elapsed since the lesion had first been noticed. The fungus was proved to be *Trichosporon pedrosoi*. The article is well illustrated. MARTIN⁴ has published the

TABLE 1.—Clinical and Biologic Differentiation of *Coccidioides immitis* in vivo in and *Paracoccidioides brasiliensis* (North American South American and *Histoplasma*)

Disease	Parasite	Clinical Characteristics	Biologic Characteristics	Immunologic Characteristics	Pathologic Characteristics	Other Characteristics
Coccidioidomycosis (Pitt-Rivers disease, 1906) (Richardson and Chubb, 1934) (Richardson and Chubb, 1934)	<i>Coccidioides immitis</i>	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.
North American blastomycosis (Pitt-Rivers disease, 1906) (Richardson and Chubb, 1934)	<i>Blastomyces dermatitidis</i>	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.
Paracoccidioidomycosis (Pitt-Rivers disease, 1906) (Richardson and Chubb, 1934)	<i>Paracoccidioides brasiliensis</i>	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.
South American blastomycosis (Pitt-Rivers disease, 1906) (Richardson and Chubb, 1934)	<i>Blastomyces dermatitidis</i>	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.	Localized cutaneous lesions, with lesions of the face, neck, and chest, and with lesions of the respiratory system, may be localized or generalized, with or without dissemination.

results of his work on antigens. Seven species of *Cadophora americana* obtained from the United States were compared with specimens of *Phialophora verrucosa* procured from patients in Texas, Uruguay, North Carolina, Porto Rico and South America. The experiments were carried out on rabbits and it was found that one type of *Cadophora* isolated from wood pulp gave results very closely approximating to those obtained with *P. verrucosa*. The remaining six species differed very widely from these both antigenically and morphologically. The importance of a paper published by MOORE* lies chiefly in its extensive pathological work for the references to clinical features are but brief. It deals with blastomycosis, coccidioid granuloma and paracoccidioid granuloma and is a comparison of North American and South American and European types. The chief differences are most easily appreciated by a reference to the accompanying table which is reproduced from his well illustrated article.

Coccidioidosis—Studies of the metabolism of *Coccidioides immitis* (Stiles) are published by STEWART and MEYER*. The organism is resistant to desiccation but the chlamydospore develops under conditions of drying. It is apparently impossible to infect animals in the absence of this spore. It therefore seems probable that this resistance to drying is an important factor in the dissemination of the organism in the San Joaquin Valley of California. They have devised a synthetic medium which possesses selective properties of great value in the isolation of the organism from soil and clinical material. This consists of distilled water containing 1 per cent ammonium phosphate, 1 per cent sodium acetate, 0.2 per cent acid potassium phosphate, 0.2 per cent potassium phosphate and 0.01 per cent magnesium sulphate. There are no significant differences of metabolism shown between specimens grown in the above medium and those grown in a protein rich medium. Glucose is assimilated by *Coccidioides* and by blastomycetes. This change does not suppress the production of ammonia but even favours it, a fact which shows a great difference between the metabolism of these organisms and that of bacteria and certain protozoa. The authors lay great stress on the fact that fungi require their own types of media. Such should be chemically defined so that they can form a common denominator allowing exact correlation of results reported by investigators in different countries.

Maduromycosis—The fourth case to be reported from North America is described in great detail by HANAN and ZURETT*. The patient was a male Hindu who had been born near Delhi but who had lived in the United States for 18 years. In 1933 when aged 36 a splinter entered the dorsum of the left foot when he kicked a piece of old wood. The wound healed rapidly but six weeks after the accident swelling appeared at the site. This gradually increased but ulceration did not appear until two years later. This story is partially

confirmed by the fact that the man was in hospital in 1892 for bronchitis and no foot lesion was present at that time. On examination a mass measuring 4×5 cm. was found on the dorsum of the left foot. It felt like a multilocular cyst and was freely moveable except at one point where it was attached to the epithellum. At this point the skin was thickened, hyperpigmented and eczematous. The whole was excised and the mass was then found to consist of encapsulated cysts each measuring 5 mm. in diameter. Each contained a dark brown serous fluid with some black grains in the centre. These grains were turned red by nitric acid. Excellent pictures illustrate the pathological investigations, as a result of which it is claimed that a new species has been isolated. It is proposed to use the name *Mladurella lackawana* the descriptive adjective being borrowed from a locality near Buffalo. The mycelium is white or smoky gray with a white periphery in old cultures. The colony tends to be spherical with a central mycelial zone and a peripheral zone. Growth is successful only on Sabouraud's dextrose agar and glycerine agar when enriched with liver infusion. The hyphae vary in dimensions from 1 to 5 microns and are coarsely granular. Septums are rare in early cultures but definite fine septums with smoky gray mycelium appear in later cultures at room temperature. Chlamydospores appear early in the spore zone. There are nodular organs consisting of arthrospores with square-cut ends in the peripheral mycelium late at room temperature. The optimal medium is fresh liver or liver infusion—Sabouraud's dextrose agar. The optimal temperature is between 20° and 37°C . The organism does not liquefy gelatin, digests milk protein, does not ferment milk lactose and does not digest milk fat. Pigment formation is abundant but blackening of the medium is more pronounced at room temperature except on glycerine agar enriched with liver. There is little or no growth on fluid mediums. Animal inoculation gives negative results. The first case in which the disease has apparently been contracted in the Dutch East Indies is described by BOERS, KOUWENAAR and WOLFF*. Actually too it is only the fourth case to be reported in that area. The man was a Punjabi who had lived on the east coast of Sumatra for 20 years. The total history covered only 12 months. The fungus was of the black grain variety and closely approximated to the descriptions of *M. americana*. Treatment was successful after eight months intravenous injections of sodium iodide. In all, 50 were given each consisting of 25 cc. of a 10 per cent. solution.

Piedra—The black variety is common in Cochin China and SOUCHARD and NGUYEN VAN HUONG[†] found large numbers of Annamese to be affected. The nodosities are very black and very hard, measuring 1 to 2 mm. in length and 300 to 400 microns in diameter. Both shape and size were however somewhat irregular. Whilst it appears that the organism has not hitherto been detected in this part of the world it would seem to be identical with the Brazilian black piedra in all respects, clinically macroscopically microscopically and in culture.

Ringworm infections—GONAR¹⁰ has analysed 300 cases of scalp infection. All occurred in Egyptians two-thirds of them living in Cairo and the remainder in the neighbouring villages. There were 176 cases of favus all being caused by *A. schoenleini*; the most common incidence being between the ages of five and eight. There were 119 cases of *T. violaceum* infection usually occurring between the ages of five and ten; this disease was rather more common in the town whilst favus cases were more common in the country districts. All the *A. schoenleini* cases ran a shorter course than did those of favus by its absence pustules were chronic and the crater was remarkable lesions. There were four instances of infection by *M. canis* whilst *T. tonsurans* was only found on one occasion. Boys (179) outnumbered girls. A similar investigation has been carried out in Batavia by BOEDYN and VERBURGH who have studied the material obtained from 106 cases during 1936. They only succeeded in getting 42 positive cultures and of these but 10 were uncontaminated. These ten are described in great detail and at least two new species are claimed among them. One fungus which was found in crown lesions they propose to call *Pratomyces variabilis* (Boedyn and Verbunt) whilst some cases of *pedra* showed a fungus which they call *Piedra javanica* (Boedyn and Verbunt). Large drawings accompany these descriptions. Other cultures proved to be *Epidermophyton rubrum*, *E. interdigitale*, *Trichophyton plicatile*, *Favotrichophyton ochraceum* and *F. decipiens*. From the small amount of material available it would seem that epidermophyton infections head the list followed by *pedra*, pityriasis versicolor and microspora in that order. LEWIS MONTGOMERY and HOPPER¹¹ have studied *T. purpurum* (Bang) in great detail. The history geographical distribution microscopical and cultural characteristics are reviewed. They have studied 100 cases the average duration of infection being three years. As the disease is so resistant to treatment experimental inoculation of volunteers was not attempted. The feet were involved in 88 cases the hands in 39 trunk in 15 the inguinal region in 12 a curious gyrate eruption was found on the body in 4 and the face was attacked twice. In all, 68 patients showed nail infection. Some exacerbation occurred during the summer months but the clinical features always involved serious differential diagnosis from psoriasis arsenical dermatitis of the palms neurodermatitis eczema syzosis and erythema annulare centrifugum. Indeed diagnosis sometimes depended on the results of culture. On the palms and soles the skin was dull red slightly thickened and bore a branny trace of vesiculation. Fissuring of the patches occurred when they desquamated. The edge was always sharply defined but there was no involvement of the interdigital spaces and the joint areas of the hands. On the body the same dull red scaly appearance was presented but there was also some tendency to central resolution of the circinate

patches so that there was a superficial resemblance to *trinea circinata*. Sometimes the plaques were thicker and more heavily scaling, whilst in others the configuration was bizarre even suggesting *trinea imbricata*. The nails were opaque lustreless, friable yellowish, irregular and showed subungual hyperkeratosis. In spite of deep involvement of the nail the surrounding tissues were sometimes unaffected, the interdigital skin even being clean. A case of generalized infection with *T. rubrum* is described by GODAL¹³. The patient was a soldier who had just returned from Indo-China, having previously served in Madagascar and China. The disease was said to have been present for ten months. Practically the whole of the glabrous skin bore sharply defined large red plaques with slight flaking and vesiculation at the polycyclic edges. There was some lichenification, with folliculitis and scattered pustules. The nails and hair were unaffected. The same fungus has been studied by CATAXEI¹⁴ who obtained material from a native of Tonking the lesions being on the buttocks, flanks and umbilicus. The scales showed very numerous mycelial elements, sometimes moniliform. Cultures were at first smooth and white but the centre became heaped and downy after three weeks. At this time the colony had assumed a reddish purple colour except for the centre which remained whitish. Pathogenicity to guinea-pigs and monkeys was proved but the hair was not attacked in them. This organism corresponds with *T. rubrum* (Castellani 1909) and is placed in the second section of trichophyta in the classification of Langeron and Milobevitch. FRASER¹⁵ has investigated the viability of epidermophyta and trichophyta in an attempt to account for the disappointing results seen in the treatment of foot infections. The fungi remain viable in scales for over a year and *in vitro* they withstand cold better than heat. Attempts to infect dry scarified skin were always unsuccessful. The pH in the fourth interdigital space was found to be high and might possibly be caused by decomposition of sweat. The fungicidal properties of many chemicals and physical agents were reviewed. It is stressed that X-rays in safe doses, never kill fungi, which are also more resistant to ultra violet light than are bacteria. Perchloride of mercury and iodine seem to be the most efficient chemicals phenol dyes etc. being far behind them. Whilst it is true that viability in scales is persistent there is no direct proof that pathogenicity is retained. Most treatments also have a penetrative effect so that it is difficult to account for the therapeutic failures. It is concluded that greater attention must be paid to the soil, i.e. hygiene and ventilation of the feet are of supreme importance.

Least infections—*Dermatitis eutorulosa* is the name given by KESTEVEN¹⁶ to 13 cases which showed localised papulo-vesicular

and or exornated and weeping inflammatory condition of the skin due to invasion of the skin by *Euoriza excorians* Kesteven and causing more or less itching. The clinical diagnosis cannot be made with certainty but the presence of a sodden fringe to the patch with the presence of vesicles is suggestive. Between the toes the skin is markedly sodden and white but blisters are more common on the side of the foot. The organism has also been found in an acute red intertrigo of the groins in an indefinite vesicular eruption of the legs and arms and on the palms where the edges of the lesion are more definitely sodden and may even bear pustules as well as vesicles. It may cause a chronic paronychia which shows no crusting but a watery discharge. The author has succeeded in producing typical lesions on his own arm by inoculation of this yeast and has also recovered the organism from the resultant dermatitis. Treatment has proved efficient by the use of a 1 per cent solution of dihydroxyacetanilol in benzol by a 1 per cent solution of paradinitrophenol in water and by the free use of Tinct. Iodi. A full description of the organism is included the author concluding with a criticism of the vague and muddling nomenclatures and poor descriptions of fungi in general and of yeasts in particular.

Achromia — CASTELLANI¹⁷ describes this condition as seen in Central America and the West Indies. The moulds and fungi which have been described in these cases are regarded as non pathogenic by the author. (The variety of achromia seen in Cuba by PARDO-ASTELLO [see this *Bulletin* 1937 Vol. 34 p. 259] is different and is caused by fungi). The face and neck are most commonly attacked. The patches which may be as large as half a crown, are at first slightly wrinkled and scaly later becoming smooth. There is complete loss of pigment so that the areas appear to be yellow or pale yellow when they occur in negroes. There are no subjective symptoms whatever and the discs seldom coalesce. They are very persistent but sometimes do repigment. The differential diagnosis from a case of tinea flava in which the fungus has disappeared is practically impossible. All treatment including antmycotic remedies is useless. Some disguise can be obtained by the use of an appropriate dilution of potassium permanganate.

Mycosis fungoides — WILSON¹⁸ has treated four cases of this disease by means of injections of ethyl chaulmoograte as first suggested by LUNHOLDT in the *Acta Derm Ven* during September 1936. The treatment is long and tedious requiring exact determination of the dosage in each case. Three cc have even been injected twice a week for as long as 12 months. Although there is cessation of itching after the third or fourth injection there is no suggestion that cure has ever been attained.

Xeroderma pigmentosum — The disease has been seen in five children out of a family of six by BURNET¹⁹ et al. The parents are young natives

- ¹⁷ CASTELLANI (Aldo) *Achromia Flava Amycetica* (Pseudotinea Flava) Vol. 41 No. 19 pp 309-310 With 1 fig. *J Trop Med & Hyg* 1938 Oct. 1

of Tunis. Although there was no previous family history of the disease it is noteworthy that the parents are cousins. The two eldest children both girls died at the ages of 7 and 6 years. Since then the other children have been kept indoors—these are now aged 5 years, 3 years and 14 months. The first signs developed at the ages of 12, 9 and 6 months respectively. The sixth and youngest child died of diarrhoea at the age of three months, at which date no skin changes had appeared. All the cases are typical. In another Tunisian family of five children, two sisters now aged 20 and 16 suffer from xeroderma pigmentosum which first started at the age of four years in both. These have been described by CHATELLIER²⁰. Twenty five cases of this disease (including all the above) have now been detected in Tunis.

Mango dermatitis.—One of the most interesting papers has been contributed by KIRBY SMITH²¹. Cases of this affection have been noted since 1832 but so far they have not been mentioned in any text-book. The mango a member of the Anacardiaceae as is the poison ivy is very sensitive to cold so that its distribution in the United States is restricted to Florida. A world-wide questionnaire revealed the fact that the dermatitis has been seen and recognized occasionally in India, Mexico, Brazil, the Philippines and Colombia. The hands, neck and face particularly the lips, are the sites of election. Stomatitis may also be present and an acute gastro-enteritis often completes the picture. Six to twenty four hours after contact with the fruit usually of course direct eating, there appear vesiculation and oedema of the face and lips. Burning and itching are always present and in some cases the effects are so severe that prostration ensues, but no deaths have ever been noted. It is generally believed that the substance of the fruit is innocuous, but it is undoubtedly true that the peel, resin from the stem or sap itself can be causative. Tests show that the irritant is non-protein, non-volatile and is destroyed by exposure to 56°C. for five minutes. It is soluble in ether, chloroform, alcohol, etc. Oxidation has apparently destroyed it in the older exposed resin-like sap. Thirty-five volunteers underwent tests and five of them gave positive reactions. The author has succeeded in collecting 68 positive reports in all, most of them coming from Florida.

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

PRECIS OF ABSTRACTS IN THIS SECTION

In the section which follows CHANG (p 107) reports on the clinical findings and treatment of cases of relapsing fever. In Changsha the disease is louse borne and is common among dealers in old clothes and rare in children. An explanation for this is offered. SERGENT (p 108) records failure of vaccination for nine months and may produce a state of racial premonition for two years. MOISE (p 109) considers that *O. savignyi* is the vector in Abyssinia and AVANESSOV (p 109) incriminates ticks of the genus *Ornithodoros* species as yet not identified in Afghanistan while WHEELER (p 109) shows that *O. hermsi* is a vector in California. An obscure case of spirochaetal infection in Kentucky is described by PALMER (p 109). FENG and CHUNG (p 110) record the results of the incubation of infected ticks at various temperatures. JOYEY and SALTER (p 110) were successful in producing infection in rats fed on the brains and viscera of previously infected animals thus demonstrating the possibility of alimentary infection while L ABBATE and MANNINO (p 111) consider that Mannino became infected through a spurt of blood from a patient with relapsing fever which entered his nostril accidentally. CHUNG and FENG (p 111) failed to infect splenectomized squirrels by means of infected bedbugs (*Cimex lectularius*). True positive reactions to Kolmer's Wassermann Kahn and Kline tests were not given by patients with relapsing fever unless there was concurrent syphilis in a series of 238 specimens investigated by TSUN and CHUNG (p 111). BRUSSIN and STERNBERG (p 112) show that if mice infected with *S. recurrentis* are given an injection of neosalvarsan there follows a very marked production of antibodies. They record experiments on these lines in splenectomized animals and in those in which the R.E. system is blocked. In their second paper (p 113) these authors show that the earlier salvarsan was given the slower was the development of antibodies and that the killed spirochaetes apparently acted as vaccines.

CHANG (Shih lu) Relapsing Fever in Changsha. A Report of 41 Cases.
—*Chinese Med J* 1938. Aug Vol. 54 No 2 pp 163-172
[15 refs.]

A study of 41 cases (4 fatal) of relapsing fever during the four years 1933-36 in the province of Changsha. 41 per cent of the cases occurred amongst dealers in old clothes etc. which is not surprising in view of the fact that the disease is louse-borne. No case was observed in children below nine years old and the comparative rarity of the disease in children seems to be owing to the fact that they seldom crush the lice on the skin which is necessary in order to produce infection. Fever anorexia headache body aches and constipation are the most common symptoms and the onset is nearly always acute. Jaundice and enlargement of the liver and spleen are often observed. A high leucocytosis and also intense jaundice and liver enlargement are considered signs of poor prognosis. In 28 cases 11 had a positive Wassermann and 4 a positive Kahn test. On re-examination, 5 out of 6 of the former had become negative. 1 of the latter remained positive.

Thirty two cases were treated with 0.15 to 0.3 gm. neosalvarsan but the smaller dose is considered sufficient. Five patients showed a bad reaction and 3 died. Nine cases were treated with 2 to 3 cc. of acetylarsan. Glucose given intravenously immediately before the arsenic treatment is said to have reduced untoward reactions.

Relapses occurred in three cases, of which one might have been due to reinfection. E Hindle

CLELAND (J. B.) A Death from Relapsing Fever in Australia.—*Med Jl Australia* 1938. May 7. 25th Year. Vol. 1. No. 19. pp. 820-821.

The record of the case of an Indian seaman who died in Adelaide in 1921. The enlarged spleen was kept in the museum and has now been re-examined and found to contain spirochaetes. E. H.

SERGEANT (André) Fièvre récurrente à *Spirochaeta hispanica* en Algérie. Transmission par le rhinophale du chien. Prémunition. Sérum de convalescents. Relapsing Fever caused by *Spirochaeta hispanica* in Algeria. Transmission by the Dog Tick, *Rhipicephalus*. Prémunition. Convalescent Serum.—*Ann. Inst. Pasteur* 1938. Sept. Vol. 61. No. 3. pp. 217-254. With 14 figs. [21 refs.]

A valuable résumé of observations on Algerian relapsing fever prepared in memory of the late André Sergeant.

Most of the results have been previously reviewed in this *Bulletin* but some further details are included.

Attempts at vaccination by means of dead spirochaetes, killed either by cold or exposure to bile gave negative results. Treatment of infected guinea-pigs by the serum of refractory animals produced disappearance of the spirochaetes when pig serum was injected, and when the organisms reappeared they were less numerous than in control guinea-pigs. Donkey serum had no effect. Novarsenobenzol was found to have no curative effect on this infection except in toxic doses.

The latter half of the paper is concerned with latent infection and "premunition". The duration of the latent infection was tested by killing guinea-pigs at various intervals after the first attack, and injecting emulsions of the brain into normal guinea-pigs. The results show that infection can persist up to nine months after the original attack and also confers a "racial premunition" which can last for at least two years in the guinea-pig. This is accompanied by a "specific premunition" which is less intense than the racial premunition but, when present causes the partial or complete suppression of any attacks resulting from reinoculation.

Finally details are given of the therapeutic use of convalescent serum in guinea-pigs and the author advocates its use for the treatment of human infections [see this *Bulletin* 1936 Vol. 33 p. 696]. E. H.

MOSE (R. M. Regolo) Ricerche epidemiologiche e sperimentali sulla trasmissione e patologia della febbre recorrente in Somalia (1932-1937) [Relapsing Fever in Somalia, 1932-37].—*Ann. di Med. Ver. e Colon* 1938. July-Aug. Vol. 44. No. 7-8. pp. 315-327. With 2 plates, 7 charts & 4 figs.

Ornithodoros moubata has been regarded as the transmitter of relapsing fever in Abyssinia and Somaliland, but the author after a

fairly extensive examination has concluded that *O. savignyi* is present in large numbers whereas *O. moubata* is relatively quite scarce and that as far as concerns relapsing fever it is the former *O. savignyi* which is of epidemiological importance
H H S

AVANTSOV (G A) [Case of Spirochaetosis transmitted by Ticks in Afghanistan.]—*Med Parasit & Parasitic Dis* Moscow 1938 Vol. 7 No 1 [In Russian pp 88-94 With 2 figs. French summary p 94]

In view of the absence of any previous records of relapsing fever transmitted by ticks in Afghanistan the author reports a number of cases in Europeans and Natives and describes the symptoms observed. These cases were associated with the finding of ticks of the genus *Ornithodoros* the species of which has not yet been identified. Treatment with neosalvarsan was found to be effective only during the first days of the attack but some cases proved to be refractory. In Afghanistan the incidence of tick fever is seasonal with two peaks—at the beginning of summer and at the end of autumn

WHEELER (Charles M) Progress of Spirochaete Infection in the Developmental Stages of the Host Tick, *Ornithodoros hermsi* Wheeler—*Amer J Trop Med* 1938 July Vol 18, No 4 pp 413-419 With 3 charts. [10 refs]

Details of experiments on the transmission of a Californian strain of spirochaetal relapsing fever by *Ornithodoros hermsi*

The larvae hatching from eggs laid by infected ticks five from Big Bear Lake and two from Lake Tahoe were tested for the inheritance of infection by feeding both these larvae and the successive nymphal stages on white mice. Out of 672 larvae tested only 2 produced infection but even this low percentage (0.29) is apparently sufficient to ensure its persistence

In a further series of experiments clean larval ticks were fed on infected mice and subsequently the later developmental stages of the ticks were fed on normal mice and from 35 to 48 per cent were found to transmit the infection. Moreover clean larvae from a female taken at Lake Tahoe were infected with a strain of relapsing fever originating from a tick at Big Bear Lake
E H

PALMER (Lee) Spirochaetal Blood Stream Infection of Undetermined Type Report of a Case.—*Southern Med J* 1938, May Vol 31 No. 5, pp 530-534 With 10 figs.

Details of a case of obscure spirochaetal infection in a 3-year-old boy in Louisville Kentucky. The spirochaetes were found in the patient's blood by dark ground examination and also in a rat that had been inoculated 10 days previously with some of his blood.

The spirochaetes are said to be sluggishly motile slender about 15 μ in length with three to five spirals, and were found on 12 to 14 occasions. The patient had 27 to 30 attacks of fever going up to 105-106°F each lasting 2 to 10 days with a 2 to 7-day interval between the bouts. The attacks were accompanied by the development of a rash resembling German measles, secondary lues or rose-spots but

except for this and malnutrition physical examinations were entirely negative.

The condition failed to respond to 18 intravenous 0.2 gm. doses of neocarsphenamine 12 doses of Mapharsen 0.015 gm. stavarsol, 15 injections of bismuth, and potassium iodide extending over a 10 months illness. Five months after the onset he developed pericarditis with effusion.

E H

FENG (LAN-CHOU) & CHUNG (HUEL-LAN) The Effect of Temperature on the Development of *Spirochaeta duttoni* in *Ornithodoros moubata* — *Chinese Med J* 1938 Mar Supp No 2 pp 555-562.

A continuation of the authors previous paper on this subject [see this *Bulletin* 1937 Vol. 34 p 353] concerning the development of *Spirochaeta duttoni* in *Ornithodoros moubata*.

When the ticks were kept at 5° to 8°C. immediately after the infective meal the spirochaetes remained alive in the stomach up to 63 days and only a very small number passed through the stomach wall and reached the other organs of the body. By the 81st day all spirochaetes had disappeared from the ticks, and incubation at 25° to 30°C. did not restore their infectivity or bring about a reappearance of spirochaetes.

When the ticks were first incubated at 25° to 30°C. for about two months to ensure a well established infection, and then kept at 5° to 8°C. the spirochaetes did not disappear for at least 60 days, and the ticks produced infection when fed on susceptible animals.

The dissections of ticks kept at 25° to 30°C. up to 197 days after infection showed that spirochaetes invariably disappeared from the stomach contents by the 12th day, but remained present in the salivary glands, the reservoirs of the coxal glands and the nerve ganglia which seem to be the best sites for their development. Spirochaetes were also found in the genital glands and occasionally in the Malpighian tubules.

E H

JOYEUX (Ch.) & SAUTET (J) Importance de la voie digestive pour la transmission du *Spirochaeta duttoni* [The Importance of the Alimentary Canal in the Transmission of *Spirochaeta duttoni*] — *Bull Soc Path Exot* 1938 Apr 6 Vol. 31 No 4 pp 279-281

Using a strain of *S. duttoni* from Brazzaville, the authors have fed normal rats with infected tissues with the object of testing the possibility of this method of transmission.

Infection was produced in rats by feeding them with the brains of rats infected respectively 15 and 21 days previously by inoculation, but when the brains (24) of rats that had been infected six months previously were used, no infection was produced by feeding. The ingestion of the viscera of infected rats also gave positive results.

The infections produced by feeding had a longer incubation period (10-14 days) than when infection was produced by *Ornithodoros* and also the febrile reaction was much less severe, without relapses.

L ABRATE (G) & MANNINO (S) Sopra un caso di febbre ricorrente stabilitasi per contagio diretto [A Case of Relapsing Fever contracted by Direct Contagion.]—*Arch Ital Sci Med Colon e Parassit* 1938 Aug Vol. 19 No 8. pp 486-489

One of the authors (Mannino) was taking blood from the finger of a patient at Gondar Abyssinia and during the process a few drops (possibly from a small artery) spurted into his nostril. The blood contained numerous spirochaetes in every field.

On the eighth day Mannino became feverish and the following day suffered from vomiting diarrhoea occipital headache and generalized pains his temperature being 40°C. A blood examination on the third day of fever showed scattered spirochaetes small delicate and feebly stained very different from those seen in the original case and resembling the metacyclic forms described by LEISMAN in *O. moubata*.

Mannino is convinced that no opportunity for infection by vermin could have occurred and the district in which he lived is not an endemic area. His symptoms were the same as those of his patient and according to BRumpt are characteristic of the tick borne type. The authors therefore consider that the infection was acquired from the blood entering his nostril, and that it may have been facilitated by an unhealthy state of the mucous membrane due to rhinitis a little time previously. They discuss and do not reject the hypothesis that the spirochaetes thus directly transmitted might have undergone metacyclic development in his blood as they would have done in the body of a tick. C IV

CHUNG (Hui-Lan) & FENG (Lan-Chou) Studies on the Development of the Chinese Strain of *Spirochaeta recurrentis* in *Cimex lectularius*—*Chinese Med J* 1938 Mar Supp No 2. pp 563-577

Bedbugs (*Cimex lectularius*) were fed on splenectomized squirrels heavily infected with a Chinese strain of *Spirochaeta recurrentis* and subsequently examined for the persistence of spirochaetes.

The gastric juice of the bedbug seems to have an adverse effect on *S. recurrentis* for most of the spirochaetes were dead in 24 hours and only occasionally a few survived for two days.

Spirochaetes may be found in the legs and coelomic fluid within one and a half hours of an infective meal but they often succumb without further development and the longest period they were found to survive was twelve days. On one occasion a single spirochaete was found in the nerve ganglia but the Malpighian tubules and salivary glands were invariably negative.

Three splenectomized normal squirrels were each bitten by more than 60 bedbugs containing spirochaetes without being infected. Moreover the eggs and nymphs derived from infected bedbugs contained no spirochaetes and were not infectious. E H

Ts UN (Tung) & CHUNG (Hnei Lan) The Kolmer's Wassermann, Kahn and Kline Tests in Relapsing Fever—*Chinese Med J* 1938 Mar Supp No 2 pp 315-324 [14 refs]

A total of 238 specimens of sera from 88 cases of Chinese relapsing fever at the Peiping Union Medical College were subjected to various

tests 102 to Kolmer's Wassermann Kahn and Kline tests simultaneously 18 to the first two of these tests 114 to Kolmer's Wassermann and Kline tests and 4 to Kolmer's Wassermann test alone. The results show that the sera of seven patients gave positive reactions considered to be due to relapsing fever but only in a transient and irregular manner. Sera of 29 cases in which concurrent syphilitic infection was present were consistently positive.

Although 7.95 per cent. of the relapsing fever patients gave false positive reactions with these various tests the transient and irregular appearance of these reactions readily distinguished them from the positive reactions observed in syphilis. E H

BRUSSIN (A M) & STERNBERG (E J) Ueber die Bedeutung des retikuloendothelialen Apparates bei Infektionskrankheiten. XV Die immunisatorische Funktion des Retikuloendothelial systems beim Rückfallfieber [The Significance of the Reticuloendothelial System in Infectious Diseases. XV The Immunizing Function of the Reticulo-Endothelial System in Relapsing Fever]—*Giorn di Bacteriol e Immunol* 1938 July Vol. 21 No 1 pp 46-62. With 1 chart. [31 refs.] English summary (4 lines.)

An account of experiments supporting the view that the reticuloendothelial system is the source of antibodies against *Spirochaeta recurrentis* and *Trypanosoma equiperdum*. Quantitative estimations were made of the titre of the immune bodies in the blood of infected mice with the R.E.S. intact and in others with this system blocked.

Advantage was taken of the fact that when mice infected with *S. recurrentis* are injected with neosalvarsan, the destruction of the spirochaetes in the tissues is followed by a very marked production of antibodies. Accordingly, normal mice and others splenectomized one day previously, were each injected with a dose of 0.5 cc. of a 1:400 solution of neosalvarsan per gramme body weight, followed 30 to 60 minutes later by an intraperitoneal inoculation of 0.02 cc. blood containing 1-2 spirochaetes (*S. duttoni*) per field. The titre of antibodies against the spirochaetes in these mice was estimated by means of the adhesion test (depending on the thrombo-cytobarin content) and in the case of normal mice the titre rose to 3,800 by the sixth day and after reaching 4,000 on the eighth fell to about 1,000 on the tenth day and then to a level of about 200. In the case of the splenectomized mice however the titre only rose to a maximum of about 300 by the tenth day and then dropped to below 100. Similar results were obtained with splenectomized mice that in addition had had the R.E.S. blocked by injections of sugar of iron, but in this series the dose of neosalvarsan was increased to 0.5 cc. of a 1:100 solution per gramme body weight.

The immunizing function of the spleen, however, is gradually replaced by the compensatory action of the remaining reticuloendothelial tissue, the rate at which this occurs depending on the nature of the antigen.

By injection with neosalvarsan previous to the inoculation of the organisms it is possible to immunize an animal against the spirochaetes of relapsing fever without the development of a latent infection by diminishing this previous dose of neosalvarsan, however although infection is not prevented, the course of the disease can be varied since the duration of the latent period is lengthened.

In mice the antibody formation against spirochaetes is much stronger than against trypanosomes. The authors' experiments support the view that it is only by making comparative quantitative estimations of the antibody titre in animals that had received a previous injection of neosalvarsan that it is possible to follow the differences between normal splenectomized, and splenectomized and blockaded animals respectively. If the infectious had been allowed to develop normally, it would not have been possible to observe the differences in antibody formation. E. H.

BRUSIN (A. M.) & STERNBERG (E. J.) Ueber den Einfluss der Salvarsanpräparate auf die Antikörperbildung beim Rückfallfieber [The Effect of Salvarsan Preparations on Antibody Production in Relapsing Fever]—*Giorr. di Batterio' e Immunol.* 1938. Aug. Vol. 21. No. 2. pp. 207-225. With 2 charts. [19 refs.]

Working with relapsing fever infection in mice the authors studied the development of antibodies by the thromboeytobarru reaction. They found that the earlier salvarsan was given, the slower was the development of antibodies. The spirochaetes that were killed by the salvarsan apparently acted as vaccines, but their immunizing power did not seem to differ from that of spirochaetes succumbing to the natural defences of the body. No evidence was obtained to suggest that salvarsan stimulated the antibody-forming mechanism, and its chief value therefore lies in its power of destroying the spirochaetes directly. G. S. Wilson.

LEPTOSPIROSIS

PRECIS OF ABSTRACTS IN THIS SECTION

DAS GUPTA (p. 114) records five further cases in Calcutta occurring sporadically and not associated with any common conditions. Infection in rats is rare in Calcutta. The organisms isolated belonged serologically to the *L. icterohaemorrhagiae* group. VAUCEL (p. 114) summarizes observations in Indo-China, describing the well marked serological types found. GLOTZER (p. 115) records infection by *L. icterohaemorrhagiae* in a fish cutter in New York and raises the question of the inclusion of this disease among those counted as occupational hazards. He stresses the importance of bearing in mind Weil's disease in waterfront cities. KAUFMAN (p. 115) shows the general agreement in the serological reactions of strains of leptospira of Weil's disease and the distinctive differences between them and *L. canicola*. ESSEVELD and MOCHTAR (p. 115) describe *L. parva* isolated from field rats in Java. It differs from all the strains with which it was compared and is not definitely pathogenic for guinea-pigs. A single rat strain in Java was found to be identical with the "Salinam" strain which causes leptospirosis in Sumatra. JOHNSON (p. 116) describes eight cases of mild disease in Queensland caused by the Pomona type of leptospira, which is serologically distinct from *L. icterohaemorrhagiae*. The epidemic occurred probably as a result

of heavy rain, as a consequence of which rural workers are brought into contact with mud and water which if infected, may retain the living organism for a considerable period. WALCH SORGDRAGER, BOHLANDER and SCHÜFFNER (p. 116) describe the peculiarities of the disease in three districts of Queensland. In Ingham two strains were found, Ballico (a new strain) and "Zanoni," and in Pomona a hitherto undescribed strain. The authors propose the name *L. australis B* for the Zanoni strain until it is decided whether or not it belongs to the Salunem group. SEFTON (p. 117) describes the appearance of acute yellow atrophy in the liver of a patient in Brazil. *L. icterohaemorrhagiae* was obtained in preparations of the liver and it may be that from a similar case NOGUCHI isolated his "*L. icteroides*." VAN DER WALLE (p. 117) found positive reactions to *L. icterohaemorrhagiae* in 15 and to *L. canicola* in 29 of 100 dogs in Antwerp.

C II

DAS GUPTA (B M.) *Leptospirosis in India.*—*Indian Med Gaz* 1938, Aug. Vol. 73 No. 8, pp. 449-453. [11 refs.]

A description of five more cases (three fatal) of leptospirosis in Calcutta, from one of which the causal organism was isolated the remaining four being diagnosed by agglutination and other tests.

Including one previously described (see this *Bulletin* 1938 Vol. 35 p. 129) six cases have been seen within the past eight months. The infecting organism belongs to the same serological group as the typical *L. icterohaemorrhagiae* but the two strains isolated could be differentiated by protection tests.

The most curious feature of these cases is their epidemiology for they occurred sporadically in different quarters of the city and were not associated with river bathing, polluted water or any particular occupation. Moreover the incidence of this infection in the rat population of Calcutta is extremely low. KNOWLES in 1928 found none infected out of 180 rats examined and Knowles and Das Gupta (1932) 2 out of 183. Recently 162 rats (mainly *Neotoma bengalensis*) were examined, and in addition twenty rat sera were tested for agglutination reaction with human strains, with completely negative results.

VAUCHEL (M.) *Contribution à l'étude des leptospiroses. Résultats acquis en Indochine* [A Contribution to the Study of Leptospiroses. Results acquired in Indo-China].—*Arch. Insts Pasteur d'Indochine* 1937 Oct. Vol. 7 No. 28, pp. 157-178. With 7 charts. [73 refs.]

A useful summary of observations on leptospiral infections in Indo-China, from which the author concludes that it is not practicable to divide them into different species on the results of agglutination reactions.

On the other hand there are well marked serological types which all seem to belong to the *L. icterohaemorrhagiae* group. These types seem comparatively rare in Europe (*L. icterohaemorrhagiae*, *L. grippotyphosa* and *L. canicola*) and similarly only three have been noted in Japan (*L. icterohaemorrhagiae*, *L. excrucians* and *L. abdominalis*). The three Japanese types are all found in the Netherlands Indies, the Malay archipelago and Indo-China but in these countries other

types are found which may possibly be intermediate forms. Of especial interest are the two strains Hebler and Tuyen-Quang isolated in Tonking which are very well marked and distinct types [see this *Bulletin* 1937 Vol. 34 p 706]

An extensive bibliography of the subject is given including a section devoted to leptospiroses in Indo-China. E H

GLOTZER (Solomon) Well's Disease Report of a Case in a Fish Worker—*Jl Amer Med Assoc* 1938 June 25 Vol. 110 No 26 pp 2143-2145

The record of a typical case of infection with *S* (*Leptospira*) *icterohaemorrhagiae* in a fish cutter in New York City. This is the twenty first reported case in the U S A and the second among fish workers. The author raises the question of its inclusion in the list of diseases accepted as occupational hazards for the disease is obviously liable to occur in types of work in which the individual is exposed to contact with rat excreta.

Weil's disease must also be considered in the differential diagnosis of jaundice especially in a waterfront city such as New York where rat infestation is present. E H

KAUFMANN (Otto) Vergleichende serologische Untersuchungen mit verschiedenen Stämmen der *Spirochaeta icterogenes* und mit der *Spirochaeta canicola* [A Comparative Serological Investigation of Various Strains of *Spirochaeta icterogenes* (*L. icterohaemorrhagiae*) and *S* (*L.*) *canicola*].—*Ztschr f Immunitätsf u Experim Therap* 1938. July 8 Vol. 93 No 3/4 pp 354-367 With 1 chart [28 refs.]

The author examined the serological reactions of 45 positive Weil sera preserved at the Hamburg Hygienic State Institute to three Weil strains—U Lisbon, and R104—and a strain of *L. canicola*. Complement fixation agglutination and flocculation tests were performed with each serum and the results confirm the view that although Weil strains show considerable variation there is a general agreement in their serological reactions. *L. canicola* on the other hand possesses well-marked distinctive characters separating it from *L. icterohaemorrhagiae*. E H

ESSEVELD (H.) & MOCHTAR (A.) Over het voorkomen van een nieuw leptospira type (*L. javanica*) en het Salnem-type bij veldratten op Java. [A New Leptospira type (*L. javanica*) and the "Salnem-Type" in Field Rats of Java].—*Geneesk Tijdschr v Nederl Indië* 1938. June 21 Vol. 78 No 25 pp 1513-1522. [29 refs.] German summary [Summary appears also in *Bulletin of Hygiene*]

SARDJITO Mochtar and WIRASMO were able to cultivate leptospirae from 21 per cent of field rats caught in mid Java. Twelve of those leptospira strains are now made the subject of comparative serological test by the agglutination lysis technique. High titre sera of nine known strains were used Wijnberg (*L. icterohaemorrhagiae* from Holland) Swart Tachmat Salnem Roesel (*L. canicola*) Moscow (*L. grippotyphosa*) Hebdomadis (Japan 7-day fever) Pomona (Australian) and Ballico (Australian). Eleven out of the twelve belonged to one type and differed from all of the test strains. They

were not definitely pathogenic for guinea-pigs and the strain was named *L. jaranica*. It has not yet been possible to compare this strain with *L. akirami* which however is markedly virulent for guinea-pigs and has as its reservoir an *Apodemus*-species not a rat species. Apparently the field rats in the vicinity of Batavia have also been found to be infected with *L. jaranica* and even cats have shown spontaneously acquired infection. It remains to determine whether this new organism is pathogenic for man in view of the importance of wet rice culture for Java.

The remaining 12th strain, R.A.148, was identified with the Salmem patient strain the cause of leptospirosis in Sumatra. It is obviously desirable that investigation as to the existence of this leptospirosis in Java should be made and also whether the field rats of Sumatra are infected.

JOHNSON (D. W.) Mild Leptospirosis in Southern Queensland—a Classification of the Infecting Leptospira, and a Report of Eight Further Cases of the Disease.—*Med. Jt. Australia* 1938. May 7. 25th Year. Vol. 1. No. 19. pp. 805-813. With 6 figs.

A clinical description of eight cases of mild leptospirosis in Southern Queensland, caused by the Pomona type of leptospira which is serologically distinct from *L. icterohaemorrhagiae* and seems to be a new type. The outstanding clinical features were fever prostration, severe headache and generalized muscular pains. Delirium and conjunctival congestion were also noted in several cases. The duration of the fever was 3 to 8 days. Jaundice was not observed and there were no deaths. Two patients suffered from pain and swelling in the joints—one had a typhus-like rash and another became temporarily blind some two weeks after apparent recovery.

The epidemic at Beaudesert is considered to have arisen as a result of heavy rain as all 7 cases developed 7 to 15 days from the last day on which this occurred. The other case, at Pomona similarly, occurred 10 days after very heavy rain. For a few days after a heavy fall the rural population would be working in close association with mud and water. The water from a creek in this neighbourhood, with a pH of 7.1 was mixed with pathogenic leptospires of the Pomona type and the organisms persisted in the water for 33 days at room temperature (6°-24°C).

WALCH SORGDRAGER (B.) BOHLANDER (L.) & SCHUFFNER (W. A. P.) Over leptospirosis in Australië en eenige opmerkingen over de oorsprong van de daar geïsoleerde stammen. [Leptospirosis in Australia. Remarks on the strains isolated there].—*Geneesk. Tijdschr. v. Nederl. Indië* 1938. Sept. 20. Vol. 78. No. 38. pp. 2299-2308. English summary. (Summary appears also in *Bulletin of Hygiene*.)

Cases of leptospirosis were reported from three districts Ingham, Pomona and Brisbane all in Queensland. The disease presents certain peculiarities in these districts. In Ingham it is found mostly among cane-cutters—the severity varies in some cases quite mild, in others severe and even fatal—jaundice does not occur in all. Two strains of leptospira were found. Ballico—a new strain, and "Zanoul," possibly distinct from, though showing certain co-reactions with, the Salmem group. Both were found in local rats. In Pomona,

a hitherto undescribed strain was isolated it sets up a mild fever lasting for a week and cases are seen every year. In Brisbane of three cases recorded one—ending fatally—was contracted in N. Queensland the other two were sewer workers in the town and clinically were typical instances of *icterohaemorrhagiae* infections.

The authors discuss some of the difficulties in classifying the Zanoni strain and until a decision is reached as to whether it belongs to the Salmem group or not they propose the name *L. australis* B. H. H. S.

SEFTON (Basil) *Espirochetose ictero-hemorrhagica* Subsidio aos estudos feitos no Brasil [A Case of Weil's Disease]—*Brasil Medico* 1938 Apr 16 Vol 52 No 16 pp 379-384 With 1 fig [66 refs.] [Summary appears also in *Bulletin of Hygiene*]

A man of 19 years of age when first seen by the author was suffering from headache loss of appetite dyspepsia slow pulse and was slightly jaundiced. Nine days later when again seen he was deeply jaundiced vomiting very weak and prostrated and clutching at his head. Death took place a few hours afterwards. At autopsy the liver showed the lesions of acute yellow atrophy. *L. icterohaemorrhagiae* was obtained in preparations and smears from the liver. [The interest of this case lies in the fact that it was probably in such a case as this that Noguchi first isolated his *L. icteroides* and was thus led to regard the organism as the cause of yellow fever] H. H. S.

VAN DER WALLE (N.) *Recherches sur l'existence d'infections à leptospires chez les chiens à Anvers*. [Investigations into the Presence of Leptospiral Infections in the Dogs of Antwerp]—*C. R. Soc Biol* 1938 Vol 128 No 21 pp 804-806

The results of the author's examination of the blood of 100 dogs in Antwerp are shown in the following table —

No of sera examined	Negative	Positive	Species of <i>Leptospira</i>	
			<i>L. ictero-haemorrhagiae</i>	<i>L. canicola</i>
Male 62	31	31	7	24
Female 38	25	13	8	5
Total 100	56	44	15	29

Cultures were made from the kidneys of these animals. 13 were contaminated 88 remained sterile and only one tube showed a culture of leptospira after an incubation period of about three weeks. This organism had a low virulence for guinea-pigs and in its serological reactions agreed with *L. canicola*. The serum of the dog from which this strain was isolated showed no signs of illness but its serum produced lysis of *L. canicola* in dilutions of 1:300 and *L. ictero-haemorrhagiae* in dilutions of 1:10. E. H.

BLACKWATER FEVER.

PRECIS OF ABSTRACTS IN THIS SECTION

FAIRLEY (p. 118) gives a résumé of the present state of knowledge of the visceral, plasma, biliary and faecal and urinary pigments in blackwater fever with special mention of pseudomethaemoglobin. FAIRLEY and BROMFIELD (p. 120) show that this pigment was found in the fluid from a pancreatic cyst and demonstrated on a Hartbridge reversion spectroscope. It can therefore be found outside the vascular system when blood escapes into a cavity is haemolysed and subsequently mixed with plasma or serous exudate. They describe methods of producing it artificially.

FOY and KORDI (p. 121) in Greece confirm the occurrence of pseudomethaemoglobin in the plasma and serum of blackwater fever patients, as described by FAIRLEY. Methaemoglobin is found in the urine but never in the serum in Greece. They discuss anuria and show that plasma albumin, globulin and fibrin fall within normal limits. The same authors (p. 122) found methaemoglobin, but not pseudomethaemoglobin, in the blood of a patient with cyanosis resulting from plasmoquine. The methaemoglobin was intracorpuscular and never appeared in the serum which contrasts with the pseudomethaemoglobin of blackwater fever which is always free in the serum.

JORDAN (p. 123) concluded, from an investigation of a patient with nocturnal haemoglobinuria, that the haemolysis was due to an abnormal state of the red cells. The remission of these appeared to be periodic.

HUBER, FLORAND LÉVRE and VÉRET (p. 123) describe a boy of 4 years with the extremely rare condition of the passage of myohaematin in the urine associated with slight fever jaundice and pains in the legs. There was no appreciable destruction of red cells.

PARISI (p. 124) saw 5 patients with blackwater fever in a total of 1,800 European soldiers treated for malaria in one year in East Africa. All had *falciparum* infections and recovered under treatment by atabrin (presumably the monomate). TRAPANI ANGLIERI (p. 124) treated a patient with *Synthesan* intravenously after the method of Ascoli. The patient recovered.

C II

FAIRLEY (N. Hamilton). Blood Pigment Metabolism in Blackwater Fever.—Reprinted from *Festschrift Bernhard Voeltz* ... 80 Geburtstag von seinen Freunden u. Schülern Hamburg 1937 pp. 123-130 [20 refs.]

In this short review the author deals with the phenomena resulting from intravascular haemolysis in blackwater fever but, as he points out, the mechanism by which the haemolysis is produced still remains to be solved.

After summarizing briefly the chief phenomena—clinical and pathological—associated with intravascular haemolysis, Fairley considers in turn the various pigments—visceral, plasma, biliary and faecal, and urinary—found in blackwater fever. There is nothing new in the article but it gives an excellent résumé of the present state of knowledge.

Visceral pigments—These consist of malarial pigment or haemozoin and haemoxydren. The former, which is similar to if not identical

with haematin is found in the cells of the reticulo-endothelial system and occurs as brownish black granules or clumps of black pigment and does not give the Prussian blue reaction. In blackwater fever it is found in small amounts but apart from malaria it is seen in the liver in only one other disease—schistosomiasis—in which disease it is formed from partly digested blood regurgitated into the portal vein by the worms. Haemosiderin occurs normally as a fine brown pigment in the parenchyma cells of the liver, spleen and kidneys—it is greatly increased in amount in blackwater fever and other diseases in which blood destruction is considerable. It contains 17 per cent of iron and gives the Prussian blue reaction.

Plasma pigments.—These are oxyhaemoglobin, pseudomethaemoglobin and bilirubin. The existence of oxyhaemoglobinaemia in blackwater fever has been recognized by the reviewer and his colleagues and by numerous other observers for many years. In view of the massive blood destruction in blackwater, the amount of haemoglobin free in the plasma is very small as compared with diseases like *Babes* infection. The explanation of this phenomenon is still obscure.

Methaemoglobin was first recorded in the blood of blackwater fever cases by BARRATT & YORKE (1909) and has since been observed by a number of workers. FAIRLEY and BROMFIELD (1934) [this *Bulletin* 1935 Vol. 32 p. 210] reported a new pigment closely allied to methaemoglobin in the plasma of a patient with blackwater and in 1937 found that it was present in all the more severe cases investigated in Macedonia [this *Bulletin* 1937 Vol. 34 p. 841]. They showed that this pigment had been erroneously regarded as methaemoglobin by all previous workers and named it pseudomethaemoglobin. The new pigment originates from extracorporeal haemoglobin; its maximum concentration is attained later than that of oxyhaemoglobin and in fatal cases its concentration often rises progressively until death. Pseudomethaemoglobin cannot function as a respiratory pigment; it is never found within the red corpuscles nor in the urine.

It was found experimentally that human plasma (normal as well as blackwater) converts extracorporeal haemoglobin into pseudomethaemoglobin and it was also found that when methaemoglobin, sulphaemoglobin, haematin, or an alkaline solution of a pure haemin was incubated with plasma at 40°C. pseudomethaemoglobin was formed. As a result of these observations Fairley and Bromfield concluded—

That there are two stages in the formation of pseudo-methaemoglobin in man: firstly the production of globin and haematin or haem from extracorporeal blood pigment, and, secondly the combination of haematin or haem with some nitrogen-containing substance in the plasma to form a compound—pseudo-methaemoglobin—which on reduction with sodium hydrosulphite gives a haemochromogen having a different spectrum to globin haemochromogen. The nature of the nitrogen-containing constituent is still being investigated.

Hyperbilirubinaemia occurs in all severe cases of blackwater and may persist after haemoglobinaemia has disappeared.

Biliary and faecal pigments.—Clinically, there is abundant evidence that an increased quantity of bile reaches the duodenum in blackwater fever since the stools are of bilious type and bilious vomiting is characteristic. This pleocholia is of course a direct consequence of the increase of haemobilirubin resulting from intravascular haemolysis. Fairley and Bromfield (1934) examined the bilirubin content of

blackwater fever bile and recorded values up to 4,900 units (2.45 per cent). These results tally with the experimental observations of Barratt and Yorke (1914) [this *Bulletin* 1915 Vol. 5 p. 254] who found that for 3 to 4 hours following the intravenous injection of rabbits with their own haemoglobin, the amount of pigment in the bile was increased by four to six times.

Urinary pigments.—Those of special interest are oxyhaemoglobin, methaemoglobin urobilin and a brown pigment found as a deposit in blackwater urine and generally regarded as acid haematin. The last is responsible for blockage of the renal tubules—it requires further investigation for it has not the solubilities of artificially produced acid haematin and owing to its insolubility is very difficult to investigate spectroscopically. The quantity of oxyhaemoglobin in the urine varies considerably in different cases, but according to Yorke and his colleagues even in the most severe cases of blackwater fever never more than 10 per cent. of the extra-corpuseular haemoglobin is excreted in this way. Physiologists think that extracorpuseular haemoglobin is filtered through the glomerulus of the kidney but Yorke and NAUSS (1911) consider that haemoglobin is secreted by the epithelial cells of the convoluted tubules, which are damaged in the process and undergo degenerative changes.

Methaemoglobin is responsible for the black discolouration of blackwater fever urine and its incidence varies with the reaction of the urine and the interval between the excretion of the urine and its examination.

IV Yorke

FAIRLEY (N. Hamilton) & BROMFIELD (R. J.) I. Pseudo-Methaemoglobin—its Demonstration in Pancreatic Cyst Fluid. II. Artificial Production of Pseudo-Methaemoglobin. [Demonstration.]—*Trans. Roy Soc Trop Med & Hyg* 1938. Jan. 25. Vol. 31. No. 4 pp. 374-376

Pseudomethaemoglobin, occurring naturally in pancreatic cyst fluid, as well as that produced artificially was demonstrated on a Hartridge reversion spectroscope.

The pancreatic cyst yielded over 3 litres of dark brown turbid fluid, which was just alkaline to litmus and contained albumin and diastase but no bile salts or pigments. The benzidine test was positive and an occasional red cell and leucocyte were found in the deposit. The authors have previously shown that pseudomethaemoglobin is produced in severe intravascular haemolysis—the present finding shows that it may also be produced outside the vascular system when blood escapes into a cavity—is haemolysed and subsequently mixed with plasma or serous exudate.

Pseudomethaemoglobin was produced artificially—

(a) By incubating solutions of oxyhaemoglobin with plasma derived from certain animal species. When one volume of a strong solution of oxyhaemoglobin obtained from man or the following monkeys—*Macacus rhesus* *M. usus* or *Cercopithecus aethiops*—was incubated at 40°C with three volumes of human or monkey plasma, pseudomethaemoglobin was produced within two or three days. When, however, solutions of haemoglobin were incubated with plasma from the rabbit, guinea-pig or rat pseudomethaemoglobin was not produced, although methaemoglobin sometimes appeared. Control solutions of

oxyhaemoglobin from all species readily produced methaemoglobin when incubated alone for 12 to 24 hours.

(b) By adding alkaline haematin to plasma derived from certain animal species. Alkaline haematin was prepared by adding pure haem to water made alkaline with two or three drops of a 10 per cent solution of sodium hydroxide. This was then added to plasma from man *Macacus* spp *Cercopithecus* sp and from certain other animals e.g. rabbit and guinea-pig. With human and monkey plasma pseudo-methaemoglobin was immediately produced but this was not the case with the plasma from other animals.

There can be little doubt that pseudomethaemoglobin is a by-product of haemoglobin katabolism and is formed both *in vivo* and *in vitro* by the union of haematin with some protein or other nitrogenous constituent of human and simian plasma. H J

FOX (HENRY) & KONDI (ATHENA) Spectrographic Analysis of Pigments in Serum and Urine of Blackwater Fever—*Trans Roy Soc Trop Med & Hyg* 1938 June 25 Vol. 32, No 1 pp 49-65 With 6 figs. [26 refs.]

In view of the discovery by FAIRLEY and BROMFIELD of a new pigment (pseudomethaemoglobin) in the plasma and serum of blackwater fever patients the authors have made a spectrographic analysis of all cases of this disease entering the Refugee Hospital during 1936 and 1937 they have also re-examined spectrograms taken in 1934 and 1938 and are able to confirm the existence of a pigment having its absorption maximum in the red at 622 and 624 $m\mu$. The present paper is concerned entirely with the qualitative aspect of the work in the visible region of the spectrum. The extinct coefficient of pseudomethaemoglobin cannot be obtained at present, since no known concentration of this pigment has yet been made and consequently no accurate qualitative work is possible. Some idea of a relative concentration of the pigment in different bloods is, however, obtainable by spectroscopic dilution and this method has been used in the present work.

The authors give the following extended summary of their results and conclusions —

1 Pseudo-methaemoglobin has been confirmed as a new pigment present in the vast majority of cases of blackwater fever in Greece.

" 2 This pigment has its absorption maximum of the band in the red at a point that varies between 622 and 624 $m\mu$, thus occupying a position intermediate between sulphaemoglobin (618 $m\mu$) and methaemoglobin (630 $m\mu$).

" 3 To represent the series of changes that are taking place in cases of blackwater fever spectrograms are given showing the absorption band of blood containing (a) pseudo-methaemoglobin, oxyhaemoglobin and bilirubin (b) pseudo-methaemoglobin and bilirubin.

4 To show the shift in the band of the three pigments spectrograms are given comparing the absorption maximum of the band in the red of pseudo-methaemoglobin, methaemoglobin and sulphaemoglobin.

" 5 A spectrogram of urine in a case of blackwater fever containing methaemoglobin is given to emphasize that methaemoglobin with its absorption band at 630 $m\mu$ is the pigment present in urine.

6 The presence of methaemoglobin in urine is not directly related to the presence of pseudo-methaemoglobin in blood.

7 Methaemoglobin in the urine is present in the bladder as shown by catheterization, carried out four hourly thus indicating that the formation of methaemoglobin in urine takes place higher up in the renal system than

the urinary bladder. Methaemoglobin when present in the urine is converted into sulphhaemoglobin on the addition of 10 per cent. yellow ammonium sulphide.

" 8 Methaemoglobin has been found to occur in urine when pH varies between 5 and 9 as taken potentiometrically.

9 Urines which contain no methaemoglobin when passed do not develop it on standing at laboratory temperatures for long periods (up to two weeks).

10 Considerable difficulty was found in correlating the degree of anuria with the amount of blood destruction and the pH of the urine and it is suggested that colligative changes in the blood, incident upon the liberation of large amounts of haemoglobin, may not be an unimportant factor in the genesis of anuria, in addition to the blockage of the renal tubules with haemoglobin. Estimations of the depression in the freezing point of serum (Δ) from anuric cases of blackwater fever would tend to support this view.

11 Estimation of plasma albumin, globulin and fibrin in blackwater fever indicate that these fall within normal range although the averages differ from normal averages, being somewhat lower in the case of total proteins and albumin, and raised in the globulin and fibrin. The $\frac{A}{G}$ ratio was sometimes markedly below normal.

12 Methaemoglobin has never been found in blackwater serum in Greece.

13 The magnitude and suddenness of the haemolysis is not the only factor determining the concentration of pseudo-methaemoglobin in blood, as shown by cases where great haemolysis has taken place yet the concentration of pseudo-methaemoglobin is often less than in cases when the haemolysis has been considerably lighter.

IV 3

FOX (Henry) & KOXDI (Athena). A Note on Intracorpustular Methaemoglobin in Plasmoehlin Toxicity—*Ann Trop Med & Parasit* 1938 Oct. 12 Vol 32 No 3. pp. 249-256 With 2 plates.

In view of the constant occurrence of pseudomethaemoglobin in blackwater fever in Macedonia, the authors have inquired whether the pigment found in cases of plasmoquine intoxication, and in the black water said to follow the administration of plasmoquine was methaemoglobin or pseudomethaemoglobin.

The cyanosis characteristic of plasmoquine poisoning has always been attributed to the presence of intracorpustular methaemoglobin, giving rise to a prominent absorption band in the region of the spectrum above 600 m μ . As however a similar band in blackwater fever had been erroneously described as methaemoglobin, it seemed desirable to ascertain the exact nature of the substance which produces the absorption band in the red in cases of plasmoquine poisoning.

The authors state that they have rarely seen an unquestioned case of cyanosis accompanied by the presence of abnormal pigments in the blood-stream in cases treated with normal doses of atabrin and plasmoquine [atabrin 0.3 gm. plus plasmoquine 0.03 gm. daily for five days]. Recently however such a case was encountered—the patient developed marked cyanosis, and abnormal pigments were found in the blood stream. Full details of the case are given and also the following summary of the observations—

1 Methaemoglobin, and not pseudo-methaemoglobin, has been found spectroscopically to be the pigment present in the circulating blood in cases of plasmoehlin toxicity.

2. This methaemoglobin is intracorpuseular and never appears at any time in the serum. This is in sharp contrast to the pseudo-methaemoglobin that occurs in blackwater fever which is always free in the serum.

3. Whether in cases of blackwater fever said to be provoked by plasmochin the methaemoglobin is present free in the serum as a consequence of the haemolysis, is at the moment impossible to say. It is not impossible that once the methaemoglobin has been liberated from the red cell it may be converted into pseudo-methaemoglobin.

4. The supernatant fluid from the lysed cells of the case of plasmochin toxicity incubated with serum at 37°C. formed pseudo-methaemoglobin, but this is not unusual since weak solution of haemoglobin incubated with serum will also form pseudo-methaemoglobin.

JORDAN (F. L. J.) Etudes sur l'hémogloburine [Studies in Haemoglobinuria.]—*Acta Med Scandinavica* 1938 Vol 95 No 2-4 pp 319-340 With 1 chart [59 refs.]

The author has studied two typical cases of haemoglobinuria *ex frigore* and a case with an atypical haemoglobinuria resembling in many respects the nocturnal haemoglobinuria of ENVERING. The last case was that of a girl of 25 years of age who had suffered from many attacks since December 1928. The urines passed after midnight and during the early morning were chiefly affected. The attacks were never precipitated by cold as in the case of haemoglobinuria *ex frigore*. There was no evidence of syphilis and the Wassermann and other reactions were negative.

In the case of nocturnal haemoglobinuria examination of the serum of the patient showed nothing abnormal and the haemolysis appeared to be due to an abnormal state of the red cells themselves. In both classes of case the haemolysis is activated by carbonic acid. In the case of nocturnal haemoglobinuria the sensibilization of the erythrocytes appeared to be the subject of periodic oscillations. Cholesterol had no effect on the haemolysis.

HUBER (Julien) FLORAND (J.) LIÈVRE (J. A.) & NÉRET Crises myopathiques paroxystiques avec hémogloburine [Paroxysmal Myopathic Crises with Haemoglobinuria.]—*Bull et Mém Soc Méd Hôp de Paris* 1938 May 9 54th Year 3rd Ser No 15 pp 725-728

A detailed clinical account is given of the case of a boy four years old who was brought to the author's clinic with a painful spasm of the muscles of the legs associated with fever. The child was perfectly well until 30th January 1938 when after a short walk he appeared to be fatigued and to have lost his appetite. The following morning he complained of pains in the right foot. On 1st February the pains had extended all over the right leg and the child walked with difficulty. On 2nd February both legs were involved and the child was unable to walk, and on 3rd February he passed urine containing haemoglobin. When first seen by the authors on 4th February the temperature was 38.3°C the pulse 160 and there was slight jaundice. The lower portion of the body and especially the legs were very hyperaesthetic, and the child could not raise the heels from the bed. The muscles of the legs and the lumbar region were rigid, in a state of contraction, and very painful. The condition gradually disappeared and by the end of February he was apparently well.

This condition which is extremely rare in man is fairly common in horses. The pigment appearing in the urine is of muscular origin and is known as myohaematin. In the present case there was no appreciable destruction of red cells, the red cell resistance was normal the Donath and Landsteiner reaction was negative as was also Ehrlich's test. In all, only 4 or 5 human cases have been recorded. IV 1

PARISI (Ennio) Sull'emoglobinuria nei malarici e il suo trattamento terapeutico con atebirin [Blackwater Fever treated by Atebrin].—*Giorn. Ital. di Clin. Trop.* 1937 Sept. 30 Vol. 1 N. S. No. 9 pp. 270-71 273-6 278-80

Five cases are reported occurring in Italian Somaliland among European soldiers. In every one *P. falciparum* was seen in the blood all had taken quinine but not always very regularly. One stated that he had taken 0.4 gm. (6 grains) daily of the hydrochloride since his coming to the country. These five were the only cases seen among 1,800 malarial patients during the twelve months December 1935-November 1936 and the author suggests that an individual predisposition should be postulated, or "some other element which up to the present has escaped our observation [neither suggestion is very helpful]. All these patients were given atebirin with good result [The dosage employed is not stated but in the course of his preliminary remarks the author mentions that the musonate injected intra-muscularly thrice daily in doses of 12.5 cgm. in 3 cc. water has been recommended in the absence of any other statement it is to be presumed that this was the plan he adopted.] H H S

TRAPANI-ANGILERI (Rocco) Un caso di febbre litorale-emoglobinurica da malaria trattato con la cura di Maurizio Ascoli. [Case of Malarial Haemoglobinuria treated by Ascoli's Method].—*Riv. Sanitaria Siciliana* 1937 Oct. 15 Vol. 25 No. 20 pp. 1178-80 1183 [41 refs.]

A peasant aged 18 who had always lived in a malarious locality and who had suffered from attacks of malaria in the past had irregular fever for a week during which he was treated with small doses of quinine. He suddenly became acutely ill with a temperature of 104.9°F vomiting and diarrhoea. He became intensely jaundiced and passed blood-stained urine. He was given 1 gm. of quinine a day for four days and at the same time Ascoli's method of treatment was begun. After the first intravenous injection of *Serravallo's* the haemoglobinuria ceased after the third injection the temperature fell to normal. Recovery was uninterrupted. All the injections were well tolerated though there was a transitory pallor of the skin after the injection of each of the two final largest doses of the series. The conditions in which the patient was treated did not permit of a very thorough study of the case. N IV

MALARIA.

PRÉCIS OF ABSTRACTS IN THIS SECTION

WILSON (p 126) reports his findings in the non-immune and partially immune communities of Tanganyika Territory. Control becomes necessary where large numbers of non-immunes are present in endemic areas in townships estates and most undertakings of a temporary character. Treatment should not be indiscriminate and should not interfere with the development of immunity in endemic areas. The significance of parasites in the blood is discussed.

The MALARIA ADVISORY BOARD of the FEDERATED MALAY STATES (p 128) gives the reasons for the apparent increase in malaria in recent years. The results of tests of a number of drugs are given. Totaquina Type II is effective and cheaper than quinine hydrochloride. An anopheline survey is reported.

SCHÜFFNER (p 129) discusses the value of the spleen rate and the necessity for blood examinations in a correct assessment of malaria and immunity. This is a translation of an old paper published in Dutch in 1919.

RUSSELL (p 130) in the Gold Coast found that 55.5 per cent. of 600 infants up to 1 year of age showed parasites at a single examination. She therefore administers quinine as a routine to all children brought for treatment.

RUSSELL, MENON and RAMACHANDRA RAO (p 131) show the state of malaria in an area of the Madras Presidency which was not malarious before the inauguration of an irrigation scheme.

GENEVRAY TOUMANOFF and HOANG-TICH TRY (p 131) describe the epidemiological features of an area south west of Tonking where both mountainous and low-lying districts are severely infected. NGUYEN DINH HAO (p 132) shows that although Hanoi is practically free from malaria, endemic foci of *falciparum* infections exist in surrounding villages.

MEUNIER (p 132) discusses epidemics on board ship and urges the necessity for preventive treatment of crews of boats touching at West African ports.

BLAIR (p 133) in Southern Rhodesia found 8 patients with *P. ovale* infection in a limited area where *vivax* and *malariae* infections were also found. The latter two infections are rare since *falciparum* accounts for 96.9 per cent of the total cases. ZIEMAN (p 133) considers that *P. ovale* should be regarded not as a separate species but as a particular form of *P. vivax*. He describes *P. falciparum* subsp. *P. perniciosum* seen in the Cameroons.

EKBLOM (p 134) in Sweden recognizes three races of *A. maculipennis typicus* which occurs inland *messae* the most common, and *atroparvus* which is confined to the coasts. No relation can be found between their distribution and the former incidence of malaria. WEYER (p 134) in Germany also notes that *atroparvus* occurs where the salinity of water is high.

DE MEILLOV (p 135) reports that *A. gambiae* though normally breeding in sunlit pools may in the absence of these breed in completely shaded water for instance in underground cisterns until the rains provide the normal conditions. There is some reason to consider *A. coustani* var. *tenebrosus* a vector of malaria.

CALLOT and RISTORCELLI (p 136) found *A. sergenti* larvae for the first time in a district of Tunis. A description is given. COLLIGNON

(p. 136) in Algiers found *A. maculipennis* and *A. hispaniola* to be very prevalent. LANGERON (p. 136) found *A. claviger* and *A. hispaniola* breeding in the Atlas mountains as high as 8,200 feet. *Vivax* epidemics occur in villages in this area. WALKER (p. 137) found infection of *A. gambiae* and *A. funealis* larvae with a fungus, *Coelomyces africanus* in Freetown. This causes a high larval mortality and may infect pupae and adults.

WEATHERSHEI & HASSELL (p. 137) describes the staining of larvae which persists to the adult stage and may be useful in studying the dispersion of all forms.

STRICKLAND (p. 137) describes a method of preventing the breeding of *A. ludlowi* by preventing the access of sea water to the coastal lagoons in Bengal and Orissa.

KITCHEN (p. 138) examined the reticulocytes in *vivax* infection and found the percentage infected to be much greater than that of adult red cells. Spontaneous termination of the infection took place while the reticulocyte count remained high.

HINGST (p. 138) points out that as sporulation of *P. vivax* takes place in restricted areas of the viscera or bone marrow the percentages of infected reticulocytes and mature red cells in the peripheral blood are not reliable criteria of the conditions where sporulation occurs.

GARCIA (p. 138) found infected red cells in sections of the umbilical veins of the foetuses of two pregnant women who died of malaria. Infected red cells were found in the heart blood (in section) and bone marrow of one of them.

SACK (p. 139) reports instances of long incubation periods in *vivax* infections, one of almost a year.

MAYNE and YOUNG (p. 139) found an apparent antagonism between *P. vivax* and *P. malariae* when both infections are present. In 9 of 12 such cases *vivax* was dominant. Probably more instances of mixed infections occur in nature than are found.

MILAM and KISCH (p. 140) treated 35 patients suffering from general paresis with *P. knowlesi* with 29 responses. The course is usually moderate but severe reactions may occur.

The article by HENRY to which the abstract (p. 141) refers gives recent results obtained by the use of his reaction.

BRISQLESE (p. 141) notes that occipital headache, liver tenderness and circulatory disturbance are found in relapsing fever and may serve to differentiate it from malaria if blood examination is not possible. TADDIA (p. 141) records 3 cases of simultaneous subtertian malaria and relapsing fever. Severe headache during the fever was the principal complaint and the general condition was bad, with severe anaemia.

DESROS and ABILLY (p. 142) describe the characters of acute and chronic nephritis of malarial origin. An increase in the blood urea was frequently found in 28 patients undergoing courses of therapeutic malaria. Renal function should therefore be watched. Quinine is never contra-indicated in these cases.

C IV

COLONIAL DEVELOPMENT FUND (MALARIAL RESEARCH SCHOLARSHIP)

Report of the Malaria Unit, Mombi, 1938 [WILSON (D. Bagster)] — 34 pp. With 5 maps & 9 figs. on 6 plates. 1938. Dar es Salaam Govt. Printer [3s.]

This valuable report is concerned for the most part with a study of malaria in communities in the Northern Province of Tanganyika.

Territory which are either non immune or only partially immune to the disease. Prolonged observations were carried out at Moshi School with a population of 380 of which there are 328 Chagga and 34 Pare. These are non immune hill people of Kilimanjaro. The school is situated at a height of 3 800 feet at the extreme upper edge of the domestic anopheline zone and it is improbable that there is any appreciable amount of malaria transmission. Infection is probably acquired by visits to Moshi town.

Spleen examinations at various parts of the inhabited zone of Kilimanjaro and house searches for anophelines at the end of the rainy season justified the conclusion that there is no endemic malaria in most of this area. No *Anopheles* were caught in houses at over 3 000 feet. In contrast to this Kahe a community of mixed tribes on a river about 2 000 feet above sea level has a spleen rate of 98 per cent.

Information is given of malaria incidence on the sugar estate of Arusha Chini and of the seasonal incidence of malaria among the nomadic pastoral Masai. There is a detailed account of the prevalence of malaria in the township of Moshi and of the measures that have been taken there for the control of the disease. Malaria on estates is the subject of another informative section of the report.

In addition to those previously reported, the following species of *Anopheles* have been found in the Northern Province *gambians*, *nili pretoriensis pharoensis lesoni* and *funestus* var. *reticulorum*. The first three have never been found in houses. *A. pharoensis* was repeatedly caught at Arusha Chini twenty-seven gland dissections were negative. The existence of three members of the *funestus* group *funestus lesoni* and *reticulorum* is of no great practical importance as their breeding places are identical. At Arusha Chini the relative numbers of *gambiae* and *funestus* vary considerably, *funestus* breeding predominates when the furrows are overgrown *gambiae* when there is less vegetation in the furrows. Sporozoite rates for the year varied from 1.4 to 2.3 much lower rates than are found on the coast. The possibility that different biological races may explain different infectivity rates has been studied with special attention to the length of wing of *A. gambiae*. There was no significant difference in infectivity between individuals of greater and lesser wing length but the proportion of long winged individuals increases with a rise in atmospheric humidity. In three localities the higher the infectivity the larger was the proportion of long winged insects.

In his general conclusions the author stresses the need for specialists both European and native being available for malaria control. The value of the regular searching of selected houses for adult mosquitoes as affording an index of the residual anopheline population in controlled areas is underlined. Where malaria is seasonal monthly catches in the off-season and weekly catches in the anopheline season are sufficient.

The only available method of malaria control is anopheline control a method far too expensive to be recommended unless there are strong grounds on which to base the recommendation. The aggregation in a sufficiently endemic locality of a large number of non-immunes necessitates control. It is necessary in townships in most undertakings of a temporary character such as railway construction, on estates which employ a considerable number of non-immune labourers and on railways. With regard to railways which pass through some of the most malarious country in the Territory control

should be established at important stopping places, especially at Mombasa where passengers have to wait during the night for the trains. On the trains themselves the proofing of compartments is advocated. Control is also required in the event of settling non-immune communities in endemic areas. Rapid increase of population in the malaria-free mountain zones may lead to settlement on land in the plains where malaria would become hyperendemic.

With regard to the diagnosis of malaria the examination of blood films, apart from its clinical value helps in the determination of the need for anopheline control. Some interesting remarks are made as to the interpretation of the results of blood examinations of Africans. The finding of a few parasites in a non-immune person means that he is suffering from malaria not so in an immune person. An immune person may suffer from a heavy infection if he moves to a new place but its significance will not be the same as that of a similar infection in a non-immune. The counting of parasites to 100 or 200 leucocytes is of great value.

In treatment, distinction must be made between immune and non-immune Africans. The presence of a few parasites in an adult who has been brought up in a hyperendemic area calls for no treatment. The indiscriminate distribution of quinine in hyperendemic areas should be discouraged. Non-immunes who go from non-endemic to endemic places require special attention. Schoolboys and prisoners are examples. Mosquito nets should be provided. A special record of such persons should be kept so that they may receive particular attention if attacked. Infants in hyperendemic areas require some protection but no measures should be taken to prevent their acquiring immunity. Weekly parasite counts were made on a group of 20 infants at Arusha Chini. Whenever the parasite count rose to 10,000 per cmm. they were given the equivalent of a 10 gram adult dose of quinine on each of two days. This reduced the parasite count greatly but hardly ever to nil. None of these children has been dangerously ill and the constant presence of parasites would seem to indicate that the development of immunity was not being interfered with.

Norman White

FEDERATED MALAY STATES. Annual Report of the Malaria Advisory Board for the Year 1937 (KINGSBURY (A. Neave) Chairman)—19 pp. With 4 charts. 1938 Kuala Lumpur F.M.S. Govt. Press

The number of admissions for malaria to Government and estate hospitals is admittedly an imperfect indication of malarial conditions in any given year but it is the only one available in the Federated Malay States as in many other places. The estate populations vary with the prosperity of the rubber industry. The prejudice of the kampong population against hospitalization is gradually declining. During 1937 the total number of malaria cases admitted to hospital numbered 35 483. If the number of hospitalized cases in 1933 be represented by 100 the corresponding ratios for the four succeeding years are 97, 138, 118 and 154. Factors referred to above played an unknown part in the apparent considerable increase of malaria prevalence. meteorological conditions and the immigration of large numbers of non immune labourers also contributed. The replanting of rubber was undertaken on a much larger scale than in the two preceding

years an operation that on certain estates was associated with a marked increase in anopheline breeding. Increased prevalence was least marked in Perak and most in evidence in Pahang where the number of cases treated in estate hospitals increased from 598 in 1936 to 1,393 in the year under review. Seven cases of blackwater fever were reported four of which were from Pahang. The case mortality rate was 2.2 per cent. as in 1936. As usual February and March were the months of lowest incidence the April to June peaks in the malaria curves of the four States approximated to those of the previous year. The main increase in the 1937 prevalence occurred from August onward.

Further work on testing remedies for malaria was carried out. Totaquina Type II was found as effective as quinine its cost is only half that of quinine hydrochloride. A remedy called

Malarene a proprietary preparation (not the standardized cinchona product prepared in Madras which bears the same name) was tried on 32 patients and found to be much less effective than quinine. A small sample of another proprietary preparation Homaline I was tried on five patients without success. Paludex (quinine and sodium di sulphonate of cupreous oxyquinoline) of which favourable reports have been published from the Belgian Congo is being tried on a series of cases. Paludex alone does not control the parasites and fever of local strains of *P. falciparum* it appeared to have less effect than quinine on *falciparum* gametocytes. Paludex plus quinine appeared to be no more effective than quinine alone.

The year's work has shown that 0.3 gm. of atebuin weekly suffices for the effective control of clinical malaria.

The anopheline survey of part of the Selangor coast area continued. In Rantau Panjang the percentages of total anophelines caught in a human bait trap and cattle sheds respectively were *A. barbirostris* 15 and 1. *A. hyrcanus* var *sinensis* 29 and 69. *A. sundicus* 51 and 5. Both *barbirostris* and *sundicus* appear to have a marked preference for human blood.

Investigations of anti malarial larvicide oils continued.

Where drains are liable to be attacked by acid water cement Fondu has given satisfactory results. In such places where new drains are required glazed channels are inset in the inverts.

Experimental control of *A. maculatus* breeding by shading has not yet proved very successful.

N IV

SCHÖFFNER (W. A. P.) Two Subjects relating to the Epidemiology of Malaria.—*Jl Malaria Inst of India* 1938. Sept. Vol. 1 No 3 pp. 221-256. With 6 diagrams. [28 refs.]

This paper was originally published in 1919 in Dutch [see this *Bulletin* 1920 Vol. 16 p. 317] it was accompanied by an English translation which though inadequate and not free from ambiguity enabled the student of malaria unacquainted with the Dutch language to realize that a classical contribution to the literature of his subject had been made. The Malaria Institute of India has rendered a valuable service to English readers by republishing an excellent translation of the original paper. There can be but very few contributions to the epidemiology of malaria written 20 years ago that have retained their freshness and up-to-dateness as this has done. It still affords stimulating reading.

An adequate summary of the paper would require much space. It should suffice to remind the reader of its nature and scope. It is based largely on observations which the author carried out for two years in Mandailing an intensely malarious locality in the Netherlands East Indies where the average individual was being infected at least four times a year where the disease had been rampant for several generations at least where malaria transmission occurred all the year round and where the total mortality approximated 45 per thousand of the sickly population, a rate but very little less than the birth rate. As a contrast to these conditions the findings of Dr and Mrs. SWELLENGREBEL in Sundatar (Sumatra) [see this *Bulletin* 1920 Vol. 16 p. 318] during an epidemic of malaria in villages that had previously suffered but little if at all from that disease are discussed.

The first part of the paper deals with the importance of determining the spleen rate and the limits of its usefulness. This includes a discussion of the correlation between splenomegaly and the presence of malaria parasites in the blood the deductions that may be drawn from the age distribution of splenomegaly as to the indigenous nature of the disease the density of infection or the number of times each individual is likely to be infected in a given area in a given time in relation to splenomegaly. The determination of the spleen rate is of great value if the examination is carried out according to fixed rules if the degree of splenic enlargement is recorded and if adults are included in the survey. It also facilitates the interpretation of other data. As a simple method of orientation in new surroundings and as an indicator of changes in malarial conditions the method has no equal but blood examinations are also indispensable.

The second and perhaps the most valuable part of the paper is concerned with observations regarding immunity arising from a study of the parasite content of the blood in a malarious population. The parasite picture in an acute epidemic is contrasted with the parasite picture under chronic endemic conditions. Most if not all, of the deductions and interpretations are now current in malaria literature but they have never since been better presented. N IV

RUSSELL (Beatrice A S) Incidence of Malaria among African Children.—*Trans Roy Soc. Trop Med & Hyg* 1938 Aug 25 Vol. 32 No. 2 pp. 237-242.

The writer of this paper has had twelve years experience of medical work among the women and children of the Gold Coast. She has found that malaria is excessively prevalent among infants during the first year of life though the symptoms and clinical signs are frequently ill-defined. This excessive prevalence led her to adopt the practice of giving quinine to all children brought for treatment. During three months in 1937 the blood of 600 infants without selection, aged from 11 days to 1 year who were brought to the clinic in Kumasi, Ashanti, for the first time was examined. Though but a single examination was made of each child 55.5 per cent. were found infected. There was a palpable spleen in 41.3 per cent. Only 12.6 per cent. had temperatures of 100°F or over. Anaemia judged by pallor of mucosae or polychromatophilia and anisocytosis, was noted in 23 per cent. The highest infection rate, 73 per cent. was in the 3 to 6 months age group.

in the less than 3 months age group it was 36 per cent. The writer considers that the results of this investigation justify the routine administration of quinine which she has adopted. N IV

RUSSELL (Paul F) MENON (M Kumara) & RAMACHANDRA RAO (T)
Epidemiology of Malaria in Pattukkottai Taluk, Tanjore District,
Madras Presidency, India.—*Jl Malaria Inst of India* 1938
Sept Vol 1 No 3. pp 285-326 With 6 graphs 1 fig & 1
map

Pattukkottai is a revenue division in the southern part of the Tanjore District extending southward to Palk Strait which separates it from the north west extremity of Ceylon. It covers an area of 434 000 acres and has a population of 279 000. There are 474 villages there are only 4 towns with populations exceeding 5 000. It is a dry level tract devoid of hills. It was not malarious prior to the inauguration of an irrigation scheme part of the Mettur-Cauvery project in 1933. Increased value of land and crops is being paid for in malaria. The observations recorded in this preliminary report extended from July 1936 to March 1938. It is a well documented report.

Twelve species of *Anopheles* were collected—*aconitus annularis barbrostris culicifacies hyrcanus* var *nigerrimus jamezi pallidus stephensi subpictus tessellatus vagus* and *varuna*. *A. culicifacies* is the only effective carrier (13,335 dissections made) but not an energetic one. the oöcyst index was 0.07 per cent (5 676 guts examined) and the sporozoite index of 6 483 glands dissected was 0.08 per cent. Though a house frequenter only 0.25 per cent. gave a positive human precipitin reaction. It breeds in irrigation water. There is an absence of drainage canals for irrigation water and irrigation has very markedly raised the subsoil water level.

Four thousand five hundred spleen examinations and blood smear examinations were made in 40 villages. For the taluk as a whole the spleen index is over 40 per cent. the parasite index over 30 per cent and the gametocyte index over 13 per cent. The spleen index and the parasite index for boys 39.7 and 32.3 per cent. were significantly greater than for girls 30.3 and 21.9. More than half of the children with spleens palpable only on deep inspiration harboured malaria parasites. About two-thirds of the infections were *falciparum* and somewhat less than a quarter *vivax*. A slightly greater percentage of *falciparum* infected children had palpable spleens than had *vivax* infected children. It is possible that malaria may be transmitted in any month of the year but there is evidence of a malaria season extending from July to January when the chances of contracting infection are considerably greater than in the remaining five months of the year. Tonking Region of Calcareous Ridges in the South-West].—
Rev Méd Française d'Extrême-Orient. 1938 Mar Vol 16
No 3 pp 161-169 [12 refs.]

In Tonking and in the basin of the Red River generally there are five more or less well-defined regions in which physiographic conditions vary considerably variations which influence the anopheline fauna and

An adequate summary of the paper would require much space. It should suffice to remind the reader of its nature and scope. It is based largely on observations which the author carried out for two years in Mandailing an intensely malarious locality in the Netherlands East Indies where the average individual was being infected at least four times a year where the disease had been rampant for several generations at least where the total mortality approximated 45 per year round and where the malarial transmission occurred all the thousand of the sickly population, a rate but very little less than the birth rate. As a contrast to these conditions the findings of Dr and Mrs SWELLENGREBEL in Sundatar (Sumatra) [see this Bulletin 1920 Vol. 16 p. 318] during an epidemic of malaria in villages that had previously suffered but little if at all from that disease are discussed.

The first part of the paper deals with the importance of determining the spleen rate and the limits of its usefulness. This includes a discussion of the correlation between splenomegaly and the presence of malaria parasites in the blood the deductions that may be drawn from the age distribution of splenomegaly as to the indigenous nature of the disease the density of infection or the number of times each individual is likely to be infected in a given area in a given time in relation to splenomegaly. The determination of the spleen rate is of great value if the examination is carried out according to fixed rules, if the degree of splenic enlargement is recorded and if adults are included in the survey. It also facilitates the interpretation of other data. As a simple method of orientation in new surroundings and as an indicator of changes in malaria conditions, the method has no equal but blood examinations are also indispensable.

The second and perhaps the most valuable part of the paper is concerned with observations regarding immunity arising from a study of the parasite content of the blood in a malarious population. The parasite picture in an acute epidemic is contrasted with the parasite picture under chronic endemic conditions. Most if not all of the deductions and interpretations are now current in malaria literature but they have never since been better presented. N 17

RUSSELL (Beatrice A. S.) Incidents of Malaria among African Children.—*Trans Roy Soc Trop Med. & Hyg* 1938. Aug 25 Vol 32. No. 2. pp. 237-242.

The writer of this paper has had twelve years experience of medical work among the women and children of the Gold Coast. She has found that malaria is excessively prevalent among infants during the first year of life though the symptoms and clinical signs are frequently ill-defined. This excessive prevalence led her to adopt the practice of giving quinine to all children brought for treatment. During three months in 1937 the blood of 600 infants without selection, aged from 11 days to 1 year who were brought to the clinic in Kumasi Ashanti, for the first time, was examined. Though but a single examination was made of each child 55.5 per cent. were found infected. There was a palpable spleen in 41.5 per cent. Only 12.6 per cent. had temperatures of 100°F or over. Anaemia judged by pallor of mucosae or polychromatophilia and anisocytosis, was noted in 23 per cent. The highest infection rate, 73 per cent. was in the 3 to 6 months age group.

in the less than 3 months age group it was 36 per cent. The writer considers that the results of this investigation justify the routine administration of quinine which she has adopted. N W

RUSSELL (Paul F) MENON (M Kumara) & RAMACHANDRA RAO (T)
Epidemiology of Malaria in Pattukkottai Taluk, Tanjore District,
Madras Presidency, India.—*Jl Malaria Inst of India* 1938.
Sept Vol 1 No. 3 pp 235-326 With 6 graphs 1 fig & 1
map

Pattukkottai is a revenue division in the southern part of the Tanjore District extending southward to Palk Strait which separates it from the north west extremity of Ceylon. It covers an area of 434 000 acres and has a population of 279 000. There are 474 villages there are only 4 towns with populations exceeding 5 000. It is a dry level tract devoid of hills. It was not malarious prior to the inauguration of an irrigation scheme part of the Mettur-Cauvery project in 1933. Increased value of land and crops is being paid for in malaria. The observations recorded in this preliminary report extended from July 1936 to March 1938. It is a well documented report.

Twelve species of *Anopheles* were collected —*aconitus annularis barbirostris culicifacies hyrcanus* var *nigerrimus jamesi pallidus stephensi subpiculus tessellatus vagus* and *varuna*. *A. culicifacies* is the only effective carrier (13,335 dissections made) but not an energetic one. The oöcyst index was 0.07 per cent. (5 676 guts examined) and the sporozoite index of 6 483 glands dissected was 0.08 per cent. Though a house frequenter only 0.25 per cent gave a positive human precipitin reaction. It breeds in irrigation water. There is an absence of drainage canals for irrigation water and irrigation has very markedly raised the subsoil water level.

Four thousand five hundred spleen examinations and blood smear examinations were made in 40 villages. For the taluk as a whole the spleen index is over 40 per cent the parasite index over 30 per cent and the gametocyte index over 13 per cent. The spleen index and the parasite index for boys 39.7 and 32.3 per cent were significantly greater than for girls 30.3 and 21.9. GENEVRAI (J) TOUMANOFF (C.) & HOANG-TICH TRY Contribution à l'étude du paludisme au Tonkin. (Sites des récifs calcaires de la région du Sud-Ouest.) [Contribution to the Study of Malaria in Tonking Region of Calcareous Ridges in the South-West.]—*Rev Méd Française d'Extrême-Orient* 1938. Mar Vol. 16 No 3 pp 161-169 [12 refs]

In Tonking and in the basin of the Red River generally there are five more or less well-defined regions in which physiographic conditions vary considerably variations which influence the anopheline fauna and

malaria incidence alike. These are the sea coastal region the deltaic region the middle region with rounded hills, the upper mountainous region and the high mountain region above 600 metres. Yet another area with special malaria characteristics is the subject of this report. It lies to the south-west of Tonking and includes parts of the provinces of Hoa Binh and Ninh-Binh. It consists of a series of calcareous ridges rising from land that is little if anything above sea-level and which formerly rose from the sea. None of them exceeds 800 metres in height. In places rounded hills with gentle slope alternate with the characteristic calcareous ridges. The old alluvial soil is fertile and rice-fields and coffee plantations are the source of the wealth of this corner of Tonking. There are agricultural communities of some importance. There are numerous streamlets and collections of standing water favourable for anopheline breeding.

Epidemiological data were collected in three communities. The splenic index varied from 56 to 83 per cent, the parasite index from 28 to 68 per cent. *P. vivax malayensis* and *falciparum* were all found, *falciparum* greatly preponderating. Malaria is in fact as severely prevalent in this low-lying area as in the high mountainous region and it is with difficulty that Annamite labour can be acclimatized to the conditions. All the anophelines found in the mountainous region were found here too *aconitus barberostrius fuliginosus hyrcanus* var *sinensis jeyporiensis* var *tonkinensis hartwegi hocki maculatus maculipalpis minimus philippinensis tessellatus* and *vagus A. minimus jeyporiensis* and *aconitus* together formed more than 50 per cent of the total number caught. The two former are the two chief vectors of Tonking. As in the high regions *A. minimus* was most prevalent during the dry season though larvae were numerous also during the rains May to September. *A. jeyporiensis maculatus* and to a less degree *aconitus* are also dry season mosquitoes. For some reason unknown *A. vagus* was relatively rare. One specimen of *A. aconitus* was found infected, out of 358 dissected in the dry weather. zoophile tendencies explain the normal unimportance of this species as a vector. The infection rate of *A. minimus* for all seasons was 6.45 per cent. an infection rate higher than that found in many parts of the mountainous region. N IV

NGUYEN DINH HAO. Note sur le paludisme à Hanoi et les environs. [Malaria in Hanoi and Neighbourhood.]—*Bull. Soc. Méd.-Chirurg. Indochine* 1937 Dec. Vol. 15 No. 10 pp 1191-1195.

Hanoi is practically free from indigenous malaria but in the outskirts of the town are several endemic foci, the most important of which is the *Banc de sable* a group of villages housing upwards of 20 000 people. Here malaria is contracted with frequency the majority being *falciparum* infections. N IV

MEUNIER (R.) Au sujet des "épidémies nautiques" de paludisme. [Malaria Epidemics on Board-Ship.]—*Bull. Office Internat. d'Hyg. Publique* 1933. July Vol. 30 No. 7 pp 1563-1565

A cargo boat loaded with ground-nuts left Ziguinchor on the 19th October. When she touched at Gibraltar on the 31st of October there were cases of fever on board. On the 3rd of November she was forced to put into Algiers as 13 of a total strength of 17 officers and

crew were down with fever. Blood examination revealed *P. falciparum* in 12 cases. In two of these cases *falciparum* was associated with *malariae*. There were no deaths though six of the cases were very severe attacks. The author urges the necessity for serious preventive malarial treatment for the crews of boats touching at West African ports between May and January. N W

BLAIR (D. M.) Infections with *Plasmodium ovale* Stephens in Southern Rhodesia.—*Trans Roy Soc Trop Med & Hyg* 1938 Aug 25 Vol. 32, No. 2. pp 229-236 With 3 charts & 24 figs.

The examination of a large number of blood films in connexion with a trypanosomiasis inquiry revealed eight cases of infection with *P. ovale*. All the cases were in people from a limited area on the Umtati River between the confluence of the Umtati and Ingondomo Rivers and Robb's Drift. The parasite as figured and described conforms in all respects with the original description of STEPHEN and OWENS. Measurements of red cells in one case show that *ovale* infection causes but very slight enlargement much less than does *vivax*. It is interesting to note that in the area in which these cases were found a few cases of *vivax* and *malariae* infection were also seen. Both these species are rare in Southern Rhodesia where *falciparum* was found in 96.9 per cent. of the positive blood films examined in Government laboratories.

ZIEMANN (Hans) Zum Problem der Bildung verschiedener Rassen Varietäten oder Spezies bei den Malaria parasiten. [The Problem of the Development of Different Races, Varieties or Species of Malaria Parasites.]—*Zent f Bakt I Abt Orig* 1938. Oct. 17 Vol. 142. No 7/8. pp 366-373 [26 refs.]

This paper is an expanded version of a lecture given by the author at the International Malaria Congress at Amsterdam, September 1938. He accepts the three species of malaria parasites *P. vivax*, *P. malariae* and *P. falciparum* as definite and the transformation of one species into another can be ruled out. Some workers have regarded *P. tenue* and *P. ovale* as separate species. The author has earlier viewed these as particular forms of *P. vivax* or *P. falciparum* with which they were always found. The species nature of *P. tenue* is generally denied but *P. ovale* finds more support among malarialogists as a definite species. As far as the author is aware there is no region where *P. ovale* is found exclusively and he decides against the species nature of this parasite quoting in support the reversal to *P. vivax* type when inoculation experiments were performed with the so-called *P. ovale*. The *P. camarensis* of the author also named *P. vivax* var. *minutum* Emm has recently been identified with *P. vivax*. Different strains of *P. vivax* are accepted by the author for example the Dutch and Madagascar strains, and the absence of such differentiation in the case of *P. malariae* is noteworthy. Attention is drawn to some of the findings of earlier workers with *P. falciparum* whose descriptions agree apparently with those for pigmentless forms described by RAFFAELE and JAMES.

Different forms showing alteration in the life-cycle have been isolated from *P. falciparum* by various workers. From his observations in 1896 the author designated such a form as *P. falciparum* var. *perniciosum* and in his view it should now be called *P. falciparum* subsp.

P. perniciosum. Such forms in freshly infested patients showed a marked virulence. He points out that if definite species varieties or strains are to be separated a standard technique, which he outlines must be followed and consideration must be given to the general picture including morphology immunobiological reactions and clinical findings. The author describes his findings in regard to the suggested subsp *P. perniciosum* seen in the Cameroons. The appearance of schizonts and half-moon forms in the peripheral blood, character of pigment colour of infected red cells number of merozoites, absence of crescents size of ripe oöcysts resistance to quinine and clinical manifestations with special reference to blackwater fever are dealt with. Support for his views is adduced from a recent description of an Ethiopian variety of *P. falciparum*. Further examples of definite differentiation of the species *P. falciparum* are cited from the literature.

[STEPHENS (1922) described what he considered to be a new species of malarial parasite and proposed the name *P. ovale*. Later he confirmed the description of it from another source. YORKE & OWEN (1930) showed that the morphological features of this parasite remain constant when infection is carried on by blood inoculation. JAMES *et al.* (1932) transmitted it through *Anopheles maculipennis* without any changes in character. They considered *P. ovale* without doubt a separate species. In 1933 the same authors write after marshalling all the facts that there is in reality no disputable question concerning the nomenclature of *P. ovale*.]

J. D. Fulton.

EKBLOM (Tore). Les races suédoises de l'*Anopheles maculipennis* et leur rôle épidémiologique. [Deuxième communication.] [Races of *A. maculipennis* in Sweden.]—*Bull. Soc. Path. Exot.* 1933. July 6. Vol. 31 No. 7 pp. 647-655 With 3 figs.

This is a re-investigation of the races of *Anopheles maculipennis* occurring in Sweden in the light of the changes in nomenclature that have been made since the publication of an earlier communication [see this *Bulletin* 1935 Vol. 32 p. 812]. The author now recognizes three races (i) *A. typicus* which occurs only inland and usually in low-lying country. This race extends its range farthest to the north. (ii) *A. messiae* which is the most common and widely distributed form. (iii) *A. atroparvus* (called *labronckiae* in the earlier paper) which is the most restricted form, confined to the coasts. This distribution is attributed in part to the greater salinity of the water in part to the higher temperature. No relation can be established between the present distribution of these races and the former incidence of malaria in Sweden.

V. B. Wigglesworth.

WEYER (Fr.) Die geographische Verbreitung der Rassen von *Anopheles maculipennis* in Deutschland. [The Geographical Distribution of the Races of *A. maculipennis* in Germany.]—*Ztschr. f. Parasitenk.* 1933 Oct. 17 Vol. 10 No. 4 pp. 457-463 With 6 figs. [25 refs.]

The author gives a full account of the distribution of races of *Anopheles maculipennis* in Germany including the relative abundance of the races in many of the localities.

In Germany *atroparvus* is exclusively coastal and often limited to a zone only a few miles wide but it also occurs away from the coast in spots where natural waters have a rather high salt content. The relation of larva to salinity is not a simple one. The only other races found are *messeae* and *typicus* the latter rare.

The paper includes a large number of measurements of salinity (particularly of water in which *atroparvus* breeds) and descriptions with photographs of breeding places which are typical of different races. Information on breeding places of *A. claviger* (*bifurcatus*) is included.

VERI (F) & GRATCHI (I) Distribuzione delle razze anofeliniche nelle zone malariche della provincia di Ravenna [Distribution of Anophelines in Ravenna].—*Riv. di Malarologia* Sez. I 1938. Vol. 17 No 4 pp 242-261 With 1 map & 2 figs. [24 refs.] English summary (9 lines)

DE MEILLON (Botha) A Note on *Anopheles gambiae* Giles and *Anopheles coustani* var *tenebrosus* Donitz from Southern Africa.—*South African Med. J.* 1938. Sept. 10 Vol. 12. No 17 pp 648-650

(a) *Anopheles gambiae* as a domestic breeder

A. gambiae is well known in Africa as a breeder in sunlit pools. In this short paper the author reports the finding of larvae in the island of Mozambique in rainwater stored in total darkness in two large closed, concrete underground cisterns and one larva in water kept in a barrel in a house.

At the time of the author's two-day visit there were only two open pools on this small built-up island, both were brackish and contained no larvae.

In Kenya SYMES has recently reported the finding of the larvae of *A. funestus* in almost similar domestic situations.

The author concludes that in the island of Mozambique *A. gambiae* in the absence of normal breeding places resorts to these completely shaded underground cisterns. He suggests that the species is thus kept alive until the arrival of the rains and the preferred breeding places are again available.

(b) *Anopheles coustani* var *tenebrosus* as a possible vector of human malaria.

This mosquito is common in the marshy coastal regions of Natal, Zululand and Portuguese East Africa where the following observations were made.

Precipitin tests on blood meals of female *tenebrosus* taken from a cattle shed occupied at night by 14 cows and several natives showed bovine reactions only. A solitary *A. funestus* was taken in the cattle shed but in a hut nearby *A. funestus* and *A. gambiae* were plentiful. Precipitin tests on these malaria vectors showed no bovine reaction. Men living in the open and in a tent near the breeding places of *tenebrosus* were constantly bitten by this mosquito mainly between 6 and 7 p.m. Female *tenebrosus* fed readily in the laboratory on a human volunteer though none became infected.

The author's main conclusions are that *A. funestus* and *A. gambiae* failed to locate the men in the cattle shed because of the overpowering presence of the cattle that *tenebrosus* though zoophilic will attack

man in the absence of cattle and that the evidence so far that *Leucoborus* is not a vector of malaria is inconclusive. He suspects that as this variety is common in the winter months when the normal vectors are inactive *Leucoborus* may play a part in the propagation of winter malaria.

CALLOT (J) & RISTORCELLI (A.) Localité nouvelle pour *Anopheles (myzomyia) sergenti* Theobald, 1907 [New Locality for *Anopheles sergenti*.]—*Arch Inst Pasteur de Tunis* 1938, Mar Vol. 27 No. 1 pp. 105-107 With 4 figs.

This reports the finding of *A. sergenti* breeding in the oasis of Mansoura, six kilometres from Kebili in Tunisia the first occasion on which this relatively rare, but widely distributed, North African species has been reported from this locality. The larvae were found in a small shallow swamp under palm trees and were therefore relatively shaded for a great part of the day. The swamp contained an alga, *Cladophora fruticosa* and a reed *Phragmites communis* and was edged with *Limonium delicatulum*. Attention is called to characteristics easily recognized serving to distinguish the larva of *A. sergenti* from those of *multicolor* and *hispaniola* which are much more common in Tunisia: a palmate hair on the first abdominal segment and a very distinct palmate hair on the metathorax. The palmate hairs of the abdomen are remarkably long and slender. The adult females are easily identified by the wide white band on the palps.

SEW (P) On Some Physico-Chemical and Vegetation Factors of the Breeding Places of *Anopheles sudanicus* Rodenw.—*Jl Malaria Inst. of India* 1938, Sept Vol. 1 No. 3, pp. 257-260.

WALKER (A J) Fungal Infections of Mosquitoes, especially of *Anopheles costalis*—*Ann Trop Med & Parasit* 1938 Oct. 12 Vol. 32. No 3 pp 231-244 With 2 diagrams & 2 plates. [14 refs.]

The author reviews previous work on fungal infections in mosquito larvae and describes a new species which is not rare in Sierra Leone in *Anopheles* species.

Fungi here described as *Codomyces africanus* are rather often to be found in larvae less often in pupae and adults of *Anopheles gambiae* [referred to as *A. costalis* in the title] and *funedus* in and near Freetown. The organism causes a very high mortality in larvae, when a light infection occurs in an adult female the fungus is confined to the ovaries and eggs do not develop.

The fungus (fungi?) gives rise to four types of sporangia. It is not clearly established that they belong to a single species of organism and on the mycological side much more work appears to be desirable.

WEATHERSHEE (Albert A.) & HASSELL (Philip G) Mosquito Studies. On the Recovery of Stain in Adults developing from Anopheline Larvae stained in Vitro.—*Amer J Trop Med* 1938 Sept Vol. 18 No 5 pp 531-543

The authors put larvae of mosquitoes in dilute stains. This colours some of the internal organs and the dye persists through the pupal into the adult stage. This might be a valuable method of studying the dispersion of larvae pupae or adults.

A number of microscopic stains have been tried and the result is said to be highly satisfactory. With certain stains the colour in the underlying tissues may be seen in a living adult sometimes it can only be found by dissections. The most satisfactory stains are Giemsa's, Wright's methylene blue and Congo Red. They are used very dilute for a long period. For instance Giemsa stock solution is diluted 1/250 and larvae left in it 3 days every adult was unmistakably stained and one remained so 39 days after emergence. The larval mortality with these stains was not great. P A Buxton

STRICKLAND (C.) Malaria in Relation to the Coastal Lagoons of Bengal and Orissa.—*Indian Med Gaz* 1938 July Vol. 73 No 7 pp. 399-402. With 2 maps & 4 figs. on 1 plate.

The author describes lagoon formation shallow expanses of water shut off at times of low water from the river or sea-currents by a bank while they are flooded over at times of high water. As examples Chilka Lake on the coast of Orissa and a lagoon at Chatrapur are described. If these coastal lagoons contain water rendered brackish by communication with the sea *A. ludlowi* may breed in abundance and severe malaria result. If on the other hand they be banded up receiving only fresh water the resultant expanse of shallow sweet water supporting dense aquatic vegetation does not breed malaria carrying anophelines.

KITCHEN (S F) The Infection of Reticulocytes by *Plasmodium vivax*
—*Amer J Trop Med* 1939, July Vol. 18 No 4 pp. 347-
359 With 2 charts. [12 refs.]

The observations recorded in this paper were made on two patients inoculated for therapeutic purposes by mosquitoes infected with *P. vivax*. Neither case had any antimalarial medication. One patient after an incubation period of 12 days, had daily paroxysms for 54 days, 28 of which were accompanied by chills. Reticulocyte smears were examined daily from the 7th day of the disease. The second patient, after an incubation period of 13 days had 44 paroxysms during 46 days, with 20 rigors. Reticulocyte smears were examined from the 6th day of illness till the 4th day after the last paroxysm. The reticulocyte preparations were made by the dry slide method using Wright's stain (Grubler) in place of brilliant cresyl blue. The smears were made within an hour of the termination of the chill or if there were no rigor during the elevation of the temperature. Total red cell counts, haemoglobin estimations and total parasite counts were also made. Reticulocytes and parasitized cells were enumerated, and the age of the parasite and the type of cell infected whether reticulocyte, mature erythrocyte or an erythrocyte containing Schüffner's dots were noted. The percentage of reticulocytes infected was much greater than that of adult red cells. In about three-quarters of the observations the actual number of infected reticulocytes exceeded the number of infected adult red cells. Multiple infections were more numerous in reticulocytes. In both these untreated cases there was a marked increase in the number of reticulocytes above normal limits during the latter part of the infections. anaemia is inevitable in uninterrupted infections of two weeks duration. The infections terminated spontaneously while the reticulocyte counts remained at very high levels. A IV

HIGGS (H E) Erythrocyte Susceptibility to *Plasmodium vivax*
Grassi and Feletti, 1890.—*Amer J Trop Med* 1939, July
Vol. 18 No 4 pp. 361-372 With 3 graphs.

This paper combats the theory originally put forward by EASTON that the red cells are susceptible to invasion by malaria parasites only during the reticulocyte stage. The author points out that sporulation of *P. vivax* takes place largely in restricted areas of the viscera or bone marrow. It follows therefore that the percentages of infected reticulocytes and mature red cells in the peripheral blood are not reliable criteria of the conditions where sporulation occurs. Multiple infection of red cells is not frequently observed except in infections with certain strains of *P. vivax*. In these strains the author believes that amitotic division of the parasites is responsible for this multiple infection. A IV

GARCIA (Eusebio Y) Can Malaria be contracted In Utero?—*Jl Philippine Islands Med Assoc.* 1938 Mar Vol. 18, No 3.
pp. 141-146. With 8 figs on 4 plates.

The post-mortem findings of two cases are recorded. A woman six months pregnant died of cerebral malaria. Her blood immediately before death contained numerous ring forms, some old trophozoites and a few schizonts of *P. falciparum*. The post-mortem examination

was made two hours after death. Sections of the placenta showed an enormous number of infected red cells in the intervillous spaces some 90 per cent of the red cells were infected. A few infected red cells were seen in the vein of the cord. The second case was that of a woman four months pregnant who also died of cerebral malaria. Sections of the cord showed infected red cells in the umbilical vein. Sections of the foetal heart showed a large number of infected red cells in the heart chambers and in the myocardial vessels. Numerous phagocytes laden with pigment were also seen in these sections. Similar findings resulted from the examination of the bone-marrow of the femur and the femoral vessels. Reference is made to the literature concerning possible congenital infection in malaria [See also this *Bulletin* 1933 Vol 30 pp 474-475 1934 Vol 31 pp 419 427 689 1935 Vol 32 pp 125 126 408 838 1936 Vol 33 pp 225 229 264 783] N II

SACK (Georg) Beitrag zur Malaria mit langer Inkubationszeit [Malaria with Long Incubation Period.]—*Arch f Schiffs u Trop Hyg* 1933 Nov Vol. 42. No 11 pp 503-506 [11 refs]

The author records the history of a boy (F H) of 16 years of age who went from Germany for a holiday in Italy along with a party of boys. They arrived in Terranova Sardinia on 3rd August 1935. There the boy was severely bitten by insects in the night as he was sleeping in the open. He felt seedy the next day but was quite fit on the following day and was not again sick. Another boy of the party fell sick on the same day with vomiting and fever and was under treatment for 12 days and joined the party later. The boys returned home on 28th August 1935. Eight to ten days after the return one boy of the party G was attacked with malaria in Saarbrücken. The author's patient remained well till the summer of 1936. In July he became ill and on the 29th had an attack of fever and examination of his blood showed the presence of *Plasmodium vivax*. The febrile attacks were severe. He was treated with atehrin and plasmoquine in the usual way and three months afterwards the spleen which was considerably enlarged during the attack was no longer palpable. He had no relapse. The author discusses fully the views held regarding prolongation of the incubation period of malaria and refers to JAMES's work on the occurrence of sporozoites in the reticulo-endothelial system. He inclines to the view that the prolongation in his case was due to the small number of parasites introduced at the time of infection.

MAYNE (Bruce) & YOUNG (Martin D) Antagonism between Species of Malaria Parasites in Induced Mixed Infections. (Preliminary Note).—*Public Health Rep* 1933, July 29 Vol. 53 No 30 pp 1289-1291

In the State Hospital Columbia SC tertian malaria is used in the treatment of white paretics and quartan in the treatment of Negroes many of whom are immune to tertian. The two species combined were used in the treatment of 16 white and 4 Negro paretic patients. Intravenous injection of 5 to 10 cc of blood was the method of

DEANOS (E. H.) & ABELY (Paul) Le syndrome rénal d'origine paludéenne [Renal Syndrome of Malarial Origin.]—*Rev Méd. et Hyg Trop* 1938 July-Aug Vol. 30 No 4 pp 207-223. [23 refs.]

In the course of several sojourns in Senegal the Sudan and the Ivory Coast the first named author has frequently seen cases of acute and of chronic nephritis of malarial origin. The acute forms are of sudden onset and characterized by high temperature generalized pains most marked in the lumbo-sacral region facial oedema, cerebral symptoms such as convulsions or aphasia occasionally slight dilatation of the pupils, often slight yellowish discoloration of the conjunctivae never vomiting but sometimes regurgitation of acid liquid and very occasionally ascites. The urine is scanty albuminuria is generally slight but occasionally reaches 1.50 gm. Esbach. Most cases react favourably to theobromine associated with small doses of quinine.

The chronic forms are insidious in onset. There is a history of attacks of fever which have been more frequent prior to the appearance of nephritic symptoms. Theobromine-quinine generally effects an improvement though its action is much slower than in the acute cases. Six illustrative cases are described.

The second part of the paper discusses the nature of these cases in the light of observations of patients submitted to malaria therapy with *P. vivax*. In these cases it was not uncommon to find that the blood urea rose as the malaria progressed. Thus in the first observation quoted the blood urea at the time of the 4th febrile attack was 0.35 gm. at the time of the 9th attack it had risen to 0.75 gm. This phenomenon was not quite constant but it occurred with great frequency among the 28 observations recorded. It is important for the doctor treating cases of malaria to watch the renal functions of his patient and more particularly the urea content of the blood. The neurologist should also pay attention to these matters before submitting his patient to malaria therapy. Quinine is never contra indicated in these cases. It acts favourably on the malaria as well as on the renal condition to which the malaria has given rise.

HELMINTHIASIS PRÉCIS OF ABSTRACTS IN THIS SECTION

143

- GAUST *et al* (p 144) estimated the numbers of protozoan cysts and helminth eggs in faeces by various methods. Direct counting in iodine solution of known volumes of the material and the centrifugal flotation method using zinc sulphate solution of specific gravity 1.180 gave the highest readings. HSÜ and CROW (p 144) give the numbers of helminths (chiefly nematodes) found in 809 autopsies in Peiping. MARSEILLE (p 145) in Batavia found that compared with an investigation carried out by FLE in 1918 the incidence of ankylostomiasis has lessened but that of ascariis and trichurias is unchanged.
- SCHAPIRO, CROSBY and SICKLER (p 146) checked the Bachman intracutaneous skin test for trichiniasis against the post mortem examination of 30 per cent of patients so tested finding a close correlation between the two [see also this *Bulletin* 1928 Vol. 25 pp 470 963 and 1929 Vol. 26 p 551]. ROTH (p 146) found the site of election of adult *Trichinella* in the guinea pig to be near the junction of the small and large intestines and JENSEN and ROTH (p 147) show that larvae actively bore into striped muscle fibres. ROTH (p 147) examined various muscles of guinea pigs fed with larvae in definite numbers. Twenty per cent of the larvae were found in the masseters diaphragm and legs.
- BACHMAN (p 147) considers that in some worm infections there is produced a localized immunity both humoral and cellular. Absence of eosinophilia in the peripheral blood in the later stages of experimental trichinella infection of pigs may be due to the accumulation of these cells in the intestinal mucosa. [The reader may refer here to BLACKLOCK and GORDON's experiments on metazoan immunity carried out a decade ago. See this *Bulletin* 1927 Vol. 24 p 881 and 1928 Vol. 25 p 252.] CULBERTSON and KAPLAN (p 148) recognize passive immunity conferred upon mice by specific immune serum from rabbits. The antibody appears to act against ingested maturing larvae in the intestines.
- ITYENGAR (p 148) shows that in Travancore *Mf. malayi* is more widely prevalent than *Mf. bancrofti* and is a rural infection. It is transmitted by *Mansonioides annulifera* which depends for larval development on the waterplant *Pistia stratiotes*. The elimination of this plant is an effective measure of control.
- POYNTON and HODGKIN (p 149) give the percentages in which elephantiasis and microfilariae in the blood were found in a community in the Federated Malay States. The endemic infection is with *Mf. malayi*. They discuss the relationship between the probable spread of lymphangitis which is apt to occur at monthly intervals. They also discuss elephantiasis intradermal tests and the prevention of filariasis.
- GALLIARD (p 150) reports that larvae of *M. bancrofti* reached the infective stage in *Aedes aegypti*. YAO WU and SUN (p 150) found various forms of *Mf. bancrofti* in 28 sandflies dissected at different periods after infective feeds. Complete metamorphosis was not obtained probably owing to the early death of the sandflies.
- O'CONNOR and KNOTT (p 151) describe the pathological appearance in an excised varicose groin gland. These did not support their former conclusions that parturition in the adults is simultaneous and occurs about noon.

KNOTT (p 152) has had success in the treatment of elephantiasis of the leg by pressure first by means of a bandage boot and later when the condition has improved, by a supporting legging. It is not necessary to remove these during an attack of lymphangitis. For the acute inflammation which often follows surgical interference in elephantiasis CHAREUP (p 153) has used septasine with success.

YEN (p 154) gives the results of a study of the development of the larvae of *Dirofilaria immitis* in various species of Anopheles, Culex and Aedes. It was completed most frequently in the anophelines. KUBO (p 155) found a seasonal as well as a daily periodicity in *Mf immitis* in two dogs in Peiping.

ANDERSON and LEUCHER (p 155) report the first autochthonous case of cutaneous onchocerciasis in Tunisia.

SOUTHWELL and HIRSCHNER (p 155) detail observations made on the development of guinea-worm larvae in *Cyclops vernalis* under laboratory conditions.

WRIGHT (p 155) considers that the eggs of *Hapaticola hepatica* seen in the faeces of 16 persons in Panama were present through contamination. DAENGSVANG and TANSURAT (p. 156) give frog, fish and eel hosts of *Gnathostoma spinigerum*. FRICKERS (p 156) gives the incidence of various helminths (of which *Ancylostoma caninum* was the most common) in 400 dogs destroyed in Surinam. C IV

FAUST (Ernest Cartoll) D'ANTONI (Joseph S.) ODOM (Ada) MILLER (Max J.) PERES (Charles) SAWITZ (Will) THOMEN (Luis F.) TOBIE (John) & WALKER (J. Henry). A Critical Study of Clinical Laboratory Techniques for the Diagnosis of Protozoan Cysts and Helminth Eggs in Faeces. I. Preliminary Communication.—*Amer J Trop Med* 1938. Mar. Vol. 18. No. 2. pp 169-183. With 1 fig.

With a view to the accurate estimation of the number of protozoan cysts and helminth eggs in any faecal specimen, accurate quantitative determinations were carried out by a number of different methods. These included direct counting in iodine solution of known volumes of a specially prepared homogeneous emulsion of the material; direct counting in haematoxylin-stained fixed films of known volumes of the emulsion; counting in the deposit after 24 to 48 hours sedimentation; counting of a centrifuged deposit and counting by the direct centrifugal floatation method, using zinc sulphate solution (sp.g. 1.180) as the diluting fluid. The highest readings were obtained by the first and last of these methods, the first being slightly better than the centrifugal floatation method. It is especially noted that the zinc sulphate solution is equally suitable for floating protozoan cysts and helminth eggs and with its use concentrations of as high as a thousand-fold may be obtained. Further work on the subject is in progress and the authors expect to be in a position to recommend a simplified practical method for clinical laboratory diagnosis of parasites in faeces. C VI Weyron.

Hsu (H. F.) & Chow (C. Y.) Studies on Human Intestinal Helminths in 809 Autopsy Cases.—Reprinted from *Bull Fan Mem Inst Biol., Zool. Ser.* 1938. Aug. 20. Vol. 8. No. 3. pp. 245-273. [10 refs.]

These autopsies were made in Peiping from 1921 to 1938 and 78.1 per cent. of the persons had lived in North China.

It is pointed out that parasites may be lost before the death of seriously ill persons so the figures of parasitism here given may be lower than they were during life. There were 549 males and 260 females. As regards a number of them faecal examination had been made during life. Our laboratory has been using the direct smear method for the routine stool examination for helminth ova. Usually two samples of stools of different days are required for examination and two smears are made from each sample. Where and when indicated examinations are repeated and the floatation or other methods are also resorted to. [The particular cases unplied have not been traced.]

Ascaris was present in 312 (38 per cent) of autopsies during life. Stool examinations had been made in 149 of them and in 44 no ova had been found so that the examination detected only 70.4 per cent of infected persons. In 3 the worms were immature in 30 there were only male worms in 11 one or more mature females were present as many as 10 males and 6 females in one instance the total ascaris bag was 1,260 the highest number 36 and a footnote adds that the local record is now 63. Enterobius was found in 109 (13.5 per cent) with a total collection of 1,560 and a maximum of 575 in one patient. The percentage of infection in both sexes being the same 13.4 per cent. Trichuris was found in 64 (7.9 per cent) the total collection was 161 from a girl of eleven being the maximum unisexual infection was present in 71.9 per cent. of persons (33.3 per cent. with female worms and 38.6 per cent. with males). *Ancylostoma duodenale* was present in 117 (14.4 per cent) 1,354 worms in all with a maximum of 522 (270 males and 252 females) in a man of 18 a soldier and not a local man (the local record was 77) of these persons 69 had stool examinations during life and in 44 of them no eggs were found in 12 of the 25 negatives only male worms were found in the others males and 1 to 7 females where recorded the sexes of the worms were—males 632 females 690. *Necator americanus* was found in 22 (2.8 per cent) with a total of 164 worms and a maximum of 31 in a man who lived north of Peiping and had never been elsewhere. Stool examination disclosed only 44.4 per cent of the infections of the 22 cases missed, 8 were unisexual parasitisms 4 with males and 4 with females. The total collection was 164 worms 79 males and 85 females. Taking the hookworm cases together there were 127 on 72 of them stool examinations had been made and no ova were found in 45 so only 37.5 per cent of them were detected in the laboratory during life. One visitor to the district had 8 *Fasciolopsis buski* not discovered in the laboratory 4 had *Taenia saginata* one being diagnosed in the laboratory one had *T. solium* but his stool had not been examined during life. Clayton Lane

MARSEILLE (A.) Over het voorkomen van dierlijke darmparasieten bij de bevolking van een stadskampong te Batavia [The Incidence of Intestinal Parasites in a Native Quarter of Batavia.]—*Genoosk Tijdschr. v. Nederl. Indië* 1938. Sept. 27 Vol. 78 No. 39 pp. 2371-2375 English summary

The presence of intestinal animal parasites in the population of a native quarter in Batavia was investigated [But the total examined was small.] The figures obtained have been compared as far as possible with the results obtained in 1918 under similar conditions by FLU. Conclusions from this comparison should be drawn with some reserve as the research technique differs.

It appears that

1. The density of ancylostoma has lessened.
2. The density of *Entamoeba histolytica* need not be decreased.
3. The density of ascaris and trichocephalus remains unchanged.

On the strength of the fact that the density of ascaris and trichocephalus did not undergo any change it has been concluded that the direct as well as the indirect "faecal contact" has remained the same in the native homes in Batavia during the last twenty years, but that a change for the better can be observed as regards the special conditions necessary to cause ancylostoma infection.

SCHAPIRO (Mark M.) CROSBY (Benjamin L.) & SICKLER (Margaret M.)
The Correlation of Clinical Diagnosis and Post mortem Findings in Trichinosis.—*Jl Lab & Clin Med* 1938 Apr Vol 23 No 7 pp 681-687

"In a study apparently the first of its kind, on the diagnostic value of the Bachman intracutaneous skin test for trichinosis as checked against the postmortem examination of 30 per cent. of the patients skin tested, the results show a close correlation between skin test findings and post mortem findings. The skin test may be somewhat more valuable as a negative diagnostic measure than as a purely positive measure.

In a series of 400 persons in whom a routine use of Bachman's intracutaneous skin test was made at the Gallinger Municipal Hospital, Washington, the percentage positive for trichinosis was 18.25. Of the 400 persons 116 came to necropsy, namely 27 positives (22.4 per cent.) and 89 negatives. Of the 27 positives, the larvae of 12 were shown by the microscope only, of 5 by the Baermann apparatus only while 7 were positive and 3 were negative to both. Of the 89 negatives, 1 was positive to the microscope only and one both to it and Baermann's test. The three cases positive to the skin test but negative on autopsy may be due to false positives or to infections not detected by and perhaps without presence of larvae in the 1 gramme of muscle used in the Baermann test. The two false negatives are perhaps due to loss of sensitivity in long-standing and slight infections. At all events the skin test is a valuable help in diagnosis. C. L.

HORAK (Archibald L.) & WOLF (A. A.) Trichinosis. Report of Trichinae in Vocal Cords of a Patient with Diphtheria.—*Jl Amer Med Assoc* 1938 Aug 20 Vol 111 No. 8 pp 701-702 With 1 fig [12 refs]

ROTH (Hans) On the Localization of Adult Trichinae in the Intestine.—*Jl Parasitology* 1938 June Vol 24 No 3 pp 225-231

The guinea pig was the experimental animal. The site of election was near the junction of large and small intestines including the caecum. With heavy infective doses this habitat became crowded out and worms were found above and below these limits. The adults lived in the small intestine for 30-37 (and in one case to 50) days in the caecum for 42 to 55 production of young beginning on the 6th to

8th day The long lived ones go on growing and may reach a length of 2.2 mm for males and 4.8 mm. for females while in heavy infections they may when sexually mature be dwarfed 0.6 mm. for males and 1.1 mm. for females

JENSEN (Vilhelm) & ROTH (Hans) Zur Einwanderung der Trichinenlarve in die quergestreifte Muskelfaser [On the Entry of Trichinella Larvae into Striped Muscle Fibres.]—*Acta Path et Microb Scandinavica* 1938 Supp 37 pp 259-271 With 6 figs. [18 refs.]

Trichinella larvae actively bore into striped muscle fibres and complete their further development in them. These conclusions follow from examinations of six guinea-pigs infected by mouth with 1,500 to 6,250 measles and killed from 9 to 17 days later
C L

ROTH (Hans) Experimental Studies on the Course of Trichina Infection in Guinea Pigs. I. The Minimum Dose of Trichina Larvae required to produce Infestation of the Muscles with an Account of the Potential Productiveness of the Female Trichina.—*Amer J Hyg* 1933 July Vol 28 No 1 pp 85-103 [21 refs.]

Male guinea-pigs of about the same weight were fed with trichinella larvae freed by artificial digestion in definite numbers and either with or without knowledge of the sex of each larva. Seven test muscles were then digested namely the masseters diaphragm upper portions of front legs and shanks of hind legs it having been found that in them is represented about 20 per cent of the infection. The number of larvae becoming encapsuled varied from 300 to 2,400 for each female larva swallowed with an average of 1,288 but the commonest numbers lay between 1,500 and 2,000

BACHMAN (George W) Factors Involved in Resistance to Worm Infections with Special Reference to Trichinosis.—*Rev Med Trop y Parasit Habana*. 1938 May-June Vol 4 No 3 pp 121-125 With 2 plates [Spanish version pp 127-131]

We may therefore conclude that in some worm infections there is a localized immunity produced by the accumulation of antibodies and cells of the reticulo-endothelial system of the host, which wards off the invasion of the worm and the resorption of its toxic products.

The effects of age and diet as reported by other investigators are considered in relation to natural immunity particularly as to the action of polymorphonuclear leucocytes macrophages granulocytes and fibroblasts. In acquired immunity in animals these same cells are more active and are in greater numbers. In pigs eosinophilia from repeated sublethal doses of trichinous meat has been marked after the first feeds (32 per cent.) accompanied by a high precipitin titre (1-6 000) after the others eosinophilia has rapidly lessened and precipitin has been absent. It is suggested that the absence of eosinophils may be due to their accumulation in the intestinal mucosa so that there is there a bar to penetration by the larvae.

CULBERTSON (James T.) & KAPLAN (Samuel S.) A Study upon Passive Immunity in Experimental Trichiniasis.—*Parasitology* 1938. June. Vol. 30 No 2. pp 156-166 [12 refs.]

Protection against infection with *Trichinella spiralis* is conferred upon mice by the passive transfer to them of a specific immune serum from rabbits. A smaller percentage of mice treated with the immune serum die, and fewer larvae invade the muscles of the treated mice than among control animals. The action of the antibody of the immune serum appears to be directed specifically against the ingested larvae which are maturing to adult worms in the intestine of the infected animals. The results obtained thus far indicate that an immune serum would have little therapeutic value in the later stages of the disease.

IYENGAR (M. O. T.) Studies on the Epidemiology of Filariasis in Travancore.—*Indian Med. Res. Memoirs Supplementary Series to Indian J. Med. Res.* 1938. July. Memoir No 30. pp iv+179. With 24 figs. (4 maps) & 12 plates. [56 refs.]

So far as they are held to be of interest to workers on filariasis, the results of Iyengar's work on the Bancroftian and Malayan infections [done from 1931 to 1934 in the State of Travancore, South India, and already reported to that State's Government] are here published.

Using about 12 cmm. of blood taken between 9 p.m. and midnight without conscious selection from 78,763 persons, microfilariæ were found in 10,031, namely *Mf. malayi* alone in 6,138, *Mf. bancrofti* alone in 3,829 and both parasites in 64. *Mf. malayi* has by far the wider prevalence; it is a rural infection mostly of sandy coastal areas, but found also in forest settlements or in areas close to forest and indeed it is suggested that originally it must have been a forest infection. Its present wide prevalence in Northern Travancore results from local conditions which suit the breathing and feeding of the immature stages of its insect hosts of the genus *Mansonioides*. These are so well figured in the monograph that the illustrations alone essentially tell the story with the floating waterplant *Pistia stratioides* as the knave.

There is shown female *Mf. annulifera* ovipositing on the underwater surface of a floating *Pistia* leaf and the egg clusters so formed; and there is the report that in nature it is only on these leaves that she will lay her eggs: there is the surface of a pond in which *Mansonioides* breeds so covered with floating vegetation, including *Pistia* that larvae and pupæ would have great difficulty in reaching open water to pass the tips of their breathing siphons or trumpets into open air; there are transverse sections of *Pistia* roots showing that they contain large air cavities; photographs of the strong barbed or hooked breathing siphon and trumpet of larva and pupa of *Mf. annulifera*; sections of *Pistia* roots pierced by these structures; and photographs of the roots under water with larvae and pupæ attached to them in this way. In natural conditions the removal of *Pistia* meant disappearance of larvae within 48 hours and in 1,046 ponds which had no *Pistia* in them there were no *Mansonioides* larvae.

The conditions most favourable for the feeding of larval *Mansonioides* are man-made: the steeping of coconut husks in water (an essential preliminary to coir making) which diffuses organic matter on which the larvae feed; and such steeping, *Mansonioides* breeding, and Malayan filariasis correspond in distribution.

The young stages of *Mansonoides* may then be attacked through their food or their air. The conditions which give them such satisfying food are part of the staple industry of that area if it were topped it would be an economic catastrophe. *Pistia* thrives best in stagnant fresh water with a low pH not subject to flooding and effective interference to counter these conditions is not promising. But the clearing away of the floating *Pistia* weed from tanks is possible and the strikingly valuable results which have followed this action in the Shertalai taluk of the State have been reported in the later work of Iyengar [this *Bulletin* 1937 Vol. 34 p 884] and of SWEET and PILLAI [this *Bulletin* 1938 Vol. 35 p 766].

In its figures its 62 tables and its 30 appendices the monograph covers its subject so fully that it must be the subject of constant future reference and the absence of indexes to these three constituents will be missed. A glance at the maps will show how *Mf. malayi* has rural and *Mf. bancrofti* an urban distribution but it will be less easy to find the short appendix which shows that when the former infection was in question the male genitalia were affected in 6 of 1760 persons whereas with the latter the numbers were 96 of 1045. Such a difference must imply some significant difference in habitat or host's reaction or both. The next step in research will surely be the discovery and description of the adult parasite and of the reticulo-endothelial changes which it induces. Workers in India in parts of which as is now clear the infection is so rife cannot afford to be anywhere but in the van of those who seek this knowledge.

BYNTON (J. Orde) & HODGKIN (E. P.) *Endemic Filariasis in the Federated Malay States.*—*Bull. Inst. Med. Res. Federated Malay States* 1933. No 1. 67 pp. With 4 figs & 1 coloured plate [Bibliography.] C. L.

In the Federated Malay States infection with *Mf. bancrofti* is sporadic apart from Singapore. The endemic infection is with *Mf. malayi*. The disease is confined to low lying areas beside rivers with naturally raised banks on these the villages are set with ricefield and swamp on the low land behind them. Where a whole population of 1,398 was examined the percentages of elephantiasis and of microfilariae in the blood were for males over 10 years 18.2 and 10.8 for females over 10 years 2.9 and 4.5 for children 0.3 and 3.3. The Malaysians know that those who work or live in the swamps are the most liable to elephantiasis tappers for instance start work in the dark and may be most extensively bitten then by the insect carriers belonging to the genus *Mansonoides*. The differences between *Mf. bancrofti* and *Mf. malayi* are recounted and the former has been found in immigrants who have been in the country up to 15 years and are unlikely to have been infected since they arrived. It is held as demonstrated by many workers that microfilariae have a life of between two and three months and as probable that the mother worm discharges a fresh batch of young about once a month thus maintaining in the blood a supply of embryos in which the proportion of young mature and old is effectively balanced. Such monthly birth though there is no proof of it at present is very probably so it is held the cause of the downward spreading lymphangitis apt to occur monthly and attributable to successive migrations of enormous numbers of the [sheathed] microfilariae through the walls of the lymphatics to the blood stream.

by which the walls become thickened and impassable with the result that the microfilariae die *in situ* and set up an intense local reaction." As to periodicity the ratio between the numbers of embryos in the blood at midday and midnight is said to be put in general by workers as 1 to 1 000 for *Mf bancrofti* and 1 to 20 for *Mf malayi* while in two cases examined by the writers it was as 1 to 5 [In 4 cases quoted by IYENGAR (see above) the ratio varied from 0 to 2.9 per cent of the night figures.] Of 322 cases of elephantiasis the condition was confined to the lower limbs in all but two in them the right hand and scrotum were involved the youngest ages at which it appeared were 6 and 7 Of 3 689 heavy thick films half an inch across 327 contained microfilariae but half of those that were positive showed 5 or fewer embryos so that, as is noted, all positives can hardly have been found. Intradermal tests were made with an antigen obtained by washing *Dirofilaria immitis* in saline drying pulverizing, extracting in normal saline with suitable filtering to ensure sterility Of 64 persons with elephantiasis the test was positive in 35 of 33 showing microfilariae in 16 of 116 from an endemic area in 33 and of 57 from a non-endemic area in 7 Prognosis is excellent the enforced leisure being conducive to ripe old age.

Clinical filariasis at the Pehang river has risen immediately in the year after severe flooding and this is attributed to delay in getting the padi fields under cultivation, but it is not stated whether the *Pistia* plants, on which *Mansonoides* larvae and pupae depend for air remain and live on these fields when the flood goes down. For prevention, the moving of dwellings away from swamps has been effective, the draining of swamps over large areas is often an economic possibility but the destruction or hand removal of *Pistia* round the dwellings of estate labourers at least so successful in Travancore, is not mentioned.

GALLIARD (Henn) Evolution complète de *Filaria bancrofti* chez *Aedes* (*Stegomyia*) *aegypti* [Complete Development of *F. bancrofti* in *Aedes aegypti*].—C. R. Soc. Biol. 1938. Vol. 128. No. 23 pp. 1111-1112.

In *Aedes aegypti* the larva of *Wuchereria bancrofti* has reached the infective stage.

The workers in whose hands *Mf bancrofti* has failed to develop at all or to infectivity are enumerated. Galliard reports that on feeding *Aedes aegypti* and *Aedes albopictus* on 8 carriers of *Mf bancrofti* and on two of *Mf malayi* he obtained success on one patient only and when fed on him, one *Aedes aegypti* out of 5 showed larvae in the thorax, head and labium after 9 days at 26°-28°C. The *Aedes aegypti* were all of the same brood.

YAO (Y. T.) WU (C. C.) & SUK (C. Jung) The Development of Microfilaria of *Wuchereria bancrofti* in Sandfly *Phlebotomus sergenti* var *mongolensis*. A Preliminary Report.—Chinese Med. J. 1938. Mar. Supp. No. 2. pp. 401-410 With 2 plates.

All of 8 sandflies caught in nature (4 *P. chinensis* 2 *P. sergenti* *mongolensis* and 2 of a new species) had microfilariae stated to be *Mf bancrofti* in their alimentary canal. As to experimental infections,

brought about by feedings on one of two persons the findings were these.

Fifty nine *P. sergenti* var *mongolensis* bred in the laboratory were allowed to feed on two filarial patients of unequal degrees of infection with the following results (1) 17 of them, dissected between 8 hours and 4½ days after the infective meal were found to harbour exsheathed microfilariae both in their abdominal cavities and in their thoracic muscles (2) 7 of them dissected between 8 hours and 10½ days after the infective feeding were found to harbour pre-sausage forms in their thoracic muscles (3) 3 of them, dissected between 3½ and 6½ days were found to harbor sausage forms and (4) 1 of them dissected 9½ days after the infective feeding was found to harbour post sausage form

Sandflies fed on the case having heavy filarial infection were found to die earlier than those fed on case having the lighter infection

The failure of the microfilariae to complete their metamorphosis in the present series of sandflies is thought to be due to the untimely death of the insects and to the unfavourable conditions for the development of the larvae under which the experiment was carried out, rather than to their inability to attain their full development in these insects

C L

O'CONNOR (F W) & KNOTT (James) Chylous Filarial Lymphatic Varix. A Clinical Pathological Report.—*Trans Roy Soc Trop Med & Hyg* 1938, June 25 Vol. 32 No 1 pp 125-128

This report found among Professor O'Connor's papers after his death was brought up to date by Dr KNOTT. It concerns a negro youth of 17 in whose night blood microfilariae were present.

He had a swelling in the left groin which had begun when he was six, and which had become painful five days ago. This was his first inflammatory attack. The swelling measured 5½ by 2½ in. collapsed on pressure disclosing nodes and tubes and filled on coughing or standing. Aspiration showed chylous fluid with some microfilariae. It was removed by Knott at 2.45 p.m. on 28th October 1935. A sharp lymphangitis appeared in May 1937 but he remained free from further attacks up to March 1938 the date of report. Other enlargements of cord epididymis and inguinal nodes persisted, and he still had microfilariae in the blood.

The clinical manifestations of chylous lymphatic varix are shown to be filarial in origin in that they are associated with advanced pathological changes in the neighbourhood of ten adult *W. bancrofti*. In previous reports (O'CONNOR and HULSE 1932 and O'CONNOR and HULSE, 1933) there was evidence that parturition of female *W. bancrofti* is simultaneous and occurs about noon. That development in utero is simultaneous is borne out by the present study but that parturition always occurs about noon is not upheld by the present findings although it seems to have been imminent at the time of operation. In some previous instances microfilariae, living or degenerating have been found in lymphatic glands in the neighbourhood of parent female *W. bancrofti* and where such parasites were present there was marked evidence of glandular disease in the present one although there is extensive evidence of varicosity of the sinuses the gland substance appears to be healthy the very enlargement of the sinuses may therefore facilitate the passage of embryos through otherwise undamaged glands. In filariasis (where there is great variation of pathological signs, not only in different persons but in different parts of limited portions of tissue from the same person) intensive study along the present lines seems indicated by observers in various countries on all kinds of filarial material that may be available

C L

treatment. There appears to have been no bacteriological examination and no search for microfilariae in the blood in any case. In a seventh case an opened hydrocele displayed what was held to be an adult filaria of undetermined species the wound did not heal by first intention and 12 days later the pus contained streptococci and staphylococci and septasine had no effect on the suppuration. [Septasine (benzyl-amino-benzene-sulphamide) is prepared in tablets of 0.5 gm. the dose *per os* being 4 to 8 tablets daily. Soluseptasine (see CHOPRA and DAS GUPTA this *Bulletin* 1938 Vol. 35 p 900) is prepared in 6 per cent solution, the dose being 10 to 20 cc intravenously or intra-muscularly daily.] C L

YEN (Chia-hsien) Studies on *Dirofilaria immitis* Leidy with Special Reference to the Susceptibility of Some Minnesota Species of Mosquitoes to the Infection.—*Jl Parasitology* 1938. June. Vol. 24 No. 3 pp 189-205 [13 refs.]

Mosquitoes were caught wild and fed on an infective dog in Minnesota with the following results —

Many larvae completed their development in *Anopheles maculipennis* and *A. punctipennis* a few did so in *Culex territans* *C. tarsalis* and *C. pipiens*. In other mosquitoes some larvae completed development and some died with pigment encapsulation. In *Aedes vexans* encapsulation may be deferred till the preinfective (second larval) stage, in *A. stimulans* and *A. cinereus* the larvae may get as far as the sausage stage, in *A. canadensis* not beyond that of microfilaria as to others, in *Theobaldia inornata* and *Taeniorhynchus perturbans* larvae reach the malpighian tubules and there die, and in *Aedes triseriatus* they never leave the gut. C L

Total number of microfilariae present in the peripheral blood of 2 dogs over the period of the whole day [See Kuro's abstract, p. 155.]

[Reproduced from the *Chinese Medical Journal* Supplement.]

KUBO (M) The Daily and Seasonal Periodicity of *Microfilaria immitis* in the Peripheral Blood of the Dog.—*Chinese Med J* 1938. Mar Supp No 2. pp 375-384 With 13 figs.

In two dogs examined in Peiping with its great seasonal differences in temperature there was a seasonal as well as a daily microfilarial periodicity

At fortnightly intervals there were made on each dog two-hourly examinations of three specimens each of 20 cmm blood got by a fresh wound in the ear, beginning at 11 a.m. and ending at 9 a.m. next day. The ebb of the microfilarial blood tide was more complete than it often is in *Dirofilaria* infection though this is perhaps more apparent than real the maximum numbers themselves being relatively low. Adding together the total number of microfilariae counted in these twelve two-hourly examinations there was a most marked seasonal difference (r Fig) the daily maximum (in August) being twenty times greater than in the winter (November to March) C L.

ANDERSON (C) & LEHUCHER (P) Note préliminaire sur le premier cas autochtone d'onchocercose cutanée observé en Tunisie [The First Autochthonous Case of Cutaneous Onchocerciasis in Tunisia a Preliminary Note].—*Bull Soc Path Exot* 1938 July 6 Vol 31 No 7 pp 655-658.

SOUTHWELL (T) & KIRSCHNER (A) Some Observations on Guinea-Worm Larvae.—*Ann Trop Med & Parasit* 1938. Aug 2 Vol 32. No 2. pp 193-196. [21 refs.]

The observations were carried out at room temperature 17°C. in February in Liverpool because then only was the material available.

Few cyclops could be got and as one or more were killed daily the stock failed before the larvae became infective this may have been due to *C. vernalis* being a non-optimum host though most of the larvae were found in it. In tap water cyclops died in 6 hours in pond water some died each day and the life span did not exceed 9 days for 4 days they were very active and became progressively less so. The larvae are eaten by cyclops as many as 20 in 15 minutes. If now one draws out the alimentary canal of the host larvae can be seen piercing the stomach wall and the larva's intestine until now clear and empty is seen to contain granular material which becomes denser as life in the host's body cavity goes on. Cyclops have remained alive and active with 10 12 and 15 larvae in them Up to 22 days there was no clear development then the tail became constricted off and began to wither away in the 6th week, the beginning of moult 1 while detachment of the cuticle at the tail end appears to be the signal for the start of moult 2. Here the material gave out C L.

WRIGHT (Harry E) Further Observation on the Incidence of *Hepaticola (Capillaria) hepatica* Ova in Human Feces.—*Amer J Trop Med* 1938. May Vol 18. No 3. pp 329-330

In New San Juan a Panama village, the eggs of *Hepaticola hepatica* were found in 16 of 194 faecal specimens examined. Ten were negative 10 days later an occasional egg was found in another. It is concluded that the eggs were due to contamination as suggested by FAUST and MARTINEZ from examinations on the same villages [see also this *Bulletin* 1931 Vol 28 p 208 209] C L.

DAENGSTANG (S) & TAKSURAT (P) A Contribution to the Knowledge of the Second Intermediate Hosts of *Gnathostoma spinigerum* OWEN, 1838.—*Ann. Trop. Med. & Parasit.* 1938. Aug. 2. Vol. 32. No. 2. pp 137-140. With 1 fig.

"Naturally encysted gnathostome larvae were discovered in 91.67 per cent. of frogs, *Rana rugulosa* Wiegmann in 80 per cent. of eels, *Monopterus albus* (Zuiewa) in 37.5 per cent. of *Ophiocephalus striatus* Bloch and in 30 per cent. of *Clarias batrachus* (Linnaeus)."

[The last two are freshwater fish.] The range of second intermediate hosts includes then frog, fish and eel. C. L.

FRICKERS (J) Het voorkomen van *Dipylidium caninum* (Linné 1758) *Toxocara canis* (Werner 1782) *Ancylostoma caninum* (Ercolani 1859) *Dirofilaria immitis* (Leydi 1856) en *Spirocera sanguinolenta* (Rudolphi 1816) bij den hond (*Canis familiaris*) in Suriname. [The Incidence of *Dipylidium caninum* and Other Helminthic Infestations in Dogs in Surinam.]—*Tijdschr. v. Diergeneesk.* 1938. Sept. 15. Vol. 65. No. 18. pp. 921-924. English summary (4 lines)

The author who is the Government veterinary surgeon of Paramaribo examined the intestines of four hundred dogs which had been destroyed in Surinam. A large proportion of them harboured worms. *Ancylostoma caninum* was the most common and was found in 363 or 90.8 per cent. even in the first months of life. *Spirocera sanguinolenta* came next in frequency 266 or 65 per cent., being infested the degree increasing with age from 22.2 per cent. below four months to 90 per cent. at 8 years and over. *Dirofilaria immitis* was present in 112 (28 per cent.) also increasing with age none was found in those under 4 months old, 2.4 per cent. from 4-6 months and 8 out of ten at 8 years of age. *Dipylidium caninum* was found in 45 only (11.25 per cent.) mostly at 4-5 months when 10 were positive out of 41 at other ages the percentage ranged between 3.7 and 12.6. Lastly *Toxocara canis* was found in 32, or 8 per cent. almost all in young animals, 12 out of 27 under four months but in one only of 68 at 18 months. H. H. S.

MISCELLANEOUS

MANSON, BAHR (Philip) The Action of Sulphanilamide on *Brucella abortus* Infections.—*Practitioner* 1938 June Vol. 140 No 6 pp 740-742. With 1 fig

The author describes three cases of abortus undulant fever. In each the serum agglutinated both *Br. abortus* and *Br. melitensis* and in two the intradermal test was positive. Treatment with sulphanilamide was commenced after about six weeks of illness in two and after four months in the third (whose principal sign of disease was acute orchitis). The dose was 1.5 gm. daily by the mouth and this was strikingly successful in reducing the fever and the enlargement of the spleen. A single relapse occurred in each of the first two patients which yielded to further sulphanilamide administered in the second case by deep subcutaneous injections of 5 cc. one each day for 6 days. The effect on the temperature was too striking to be coincidental. The small terminal bout of fever noted on cessation of sulphanilamide treatment need not be regarded as a definite relapse but as the natural termination of the infection. [See also this *Bulletin* 1938 Vol. 35 C IV p 828]

TRAUT (E. F.) & LOGAN (Catharine Elizabeth) Undulant Fever treated with Sulfanilamide.—*Jl Amer Med Assoc* 1938 Sept. 17 Vol. 111 No 12. pp 1092-1093 C IV

Two patients suffering from undulant fever were treated with sulphanilamide in 1937. The first was engaged in work which entailed the handling of both raw pork and beef. On admission to hospital after three weeks of fever his serum agglutinated the bovine and porcine forms of *Br. melitensis* up to 1 in 1,280 dilution. After the failure of stock brucella vaccines to influence the condition sulphanilamide was given for nine days with excellent results the temperature being reduced to normal after the second day. The second patient a woman of 69 had been ill for eight weeks and had become very anaemic finally developing jaundice and a stuporose condition. Her serum agglutinated *Br. melitensis* in 1 in 15,000 dilution. After a blood transfusion 30 grams of sulphanilamide (prontylin) was administered daily (it is not stated for how long) and within 48 hours she was free from fever. The cure in both patients is apparently permanent.

GEAR (James) Onyalai a Form of Purpura occurring in Tropical Africa. Report of Cases occurring in South Africa.—*South African Med Jl* 1938 Sept. 10 Vol. 12. No 17 pp 632-637 With 2 figs. C IV

Onyalai a disease of obscure origin and pathology engendering fear in the African native owing to its sudden onset and high fatality rate has been observed since F. C. WELLMAN first wrote of its occurrence in West Africa in 1904. In the present paper the author records seven cases occurring in South Africa three ended fatally and the post mortem findings are noted. Among the patients was one woman and the ages ranged between 20 and 40 years. The symptoms were

practically the same in all sudden onset with feeling of lassitude, then soreness of the tongue, gums and buccal mucosa with rapid formation of "blood blisters" and profuse hæmorrhage from the mouth, nose, and blood-filled blebs or petechiae on the surface of the body. passage of blood in urine and faeces also occurs. The blood-filled bullae vary in size from that of a pea to $1\frac{1}{2}$ inches in diameter. The eyes and face are suffused and swollen and the parotid glands are enlarged and tender. Treatment by hæmostatics is of little avail, the anaemia is profound and in fatal cases death takes place usually within a week. The best treatment which when it succeeds does so rapidly is intramuscular injection of 20 cc. citrated whole blood.

At autopsy all the organs and tissues show petechiae (in one of the author's cases a large cerebral hæmorrhage was the immediate cause of death) the spleen is a little enlarged and friable. An instructive table giving the results of laboratory investigations in the seven cases shows that in the average case there is but little change from the normal in the number of erythrocytes or leucocytes—in fatal cases, naturally there is a severe drop in the former—and the colour index varied from 0.85 to 0.68 in those who recovered. The bleeding time was prolonged, but coagulation time showed little if any departure from the normal. the chief characteristic was marked reduction to almost complete absence of platelets. In two cases examined megakaryocytes were present in normal numbers in the bone marrow and there would therefore, seem to be an inhibition of the normal maturation of platelets. Intravenous blood-transfusion is less efficient in treatment than smaller amounts intramuscularly which suggests a deficiency of some factor in normal whole blood which stimulates platelet formation and maturation when in contact with the tissues. [This is rather an alternative form of statement of what has been found than an explanation of the pathogeny.] Prior to the onset of illness the patients had generally been in good health and living on a liberal mixed diet. Further investigation of cases and experimental work are called for and will be awaited with interest.

H H S

HELLMAN (J.) Onyiah. [Correspondence.]—*South African Med J* 1938. Oct. 8. Vol. 12. No. 19. p. 742.

Referring to the above article, Dr Hellman tells of five cases of the same, or closely similar condition seen by him among Hottentots in the Kalkfontein area. [In the atlas, two places named Kalkfontein are mentioned, about 150 miles apart, one in Griqualand West, the other in Prieska.] Of these three were women between 55 and 65 years and two were men of 40–45 years. As in Dr Gear's cases the onset was sudden. Thinking the condition was scorbutic, Dr Hellman prescribed orange juice and an antiscorbutic diet, but unavailingly. autohæmotherapy—20 cc. injected intramuscularly—was followed by rapid recovery and two of the patients received only one injection. In three it had to be repeated, but only once it would appear from the report. So far none has had any return of the symptoms, though the first occurred more than three years before. [This communication deals purely with the clinical aspect, no laboratory examinations were carried out, so the author does not venture to offer any suggestions as to the pathogeny of the condition.]

H H S

SNELLING (John G.) *Thrombocytopenic Purpura. Three Case Reports.*
—*New Orleans Med & Surg J* 1938. Nov. Vol. 91 No 5
pp 231-235 [23 refs]

This article is of particular interest in that though no mention is made of the fact nor even any reference to the condition the disease described bears many very remarkable points of similarity to *onyxiasis*. Apart from the profuse haemorrhages in skin, and from mucous surfaces—mouth nose rectum etc.—the blood conditions show many points in common. Thus the cardinal hematologic findings in thrombocytopenic purpura are (1) Marked decrease in platelets (2) normal coagulation time (3) prolonged bleeding time (4) delayed contractility or non-retractile clot (5) positive constrictor test

Referring to Dr GEAR's article abstracted above we see that the first three of these are common to *onyxiasis* and to thrombocytopenic purpura the fourth and fifth are not mentioned. Other features common to both are the sudden onset and the splenic condition. On the other hand, of three cases detailed in Dr Snelling's paper two were children, 5 and 7 years of age the other was aged 20 years and all were females whereas in the few recorded cases of *onyxiasis* males predominated and the ages of the patients were usually between 20 and 40 years

The author reviews the literature of idiopathic purpura and discusses the use of snake venom in treatment and where that and transfusion of blood fail he has found splenectomy very successful. *Onyxiasis* runs, when fatal, too acute a course for trial of tentative remedies and as seen in Gear's article autohaemotherapy with comparatively small amounts (20 cc.) proved very effectual whereas transfusion of larger amounts did not [Further study of these two—if they are two—conditions might reveal findings of great importance and it would be of much interest to observe the effects of small injections of the patient's whole blood intramuscularly in cases of thrombocytopenic purpura. Cases of *onyxiasis* showed no relapse though one was kept under observation for three years (see HELMAN above)] H H S

DUTTON (L. O.) *Thrombopenic Purpura due to Food Allergy.*—*J. Amer. Med. Assoc.* 1938. Nov. 19 Vol. 111 No 21
pp 1920-1921

A further case of thrombocytopenia associated with symptoms resembling those of *onyxiasis* but not so severe as those seen in the latter is reported here for two reasons (1) In order that a dietetic origin may be looked for in *onyxiasis* cases (2) That a simpler treatment than splenectomy may be tried in thrombocytopenic purpura. If the results are beneficial, much good will have been done if the attempt is ineffectual no harm will have resulted and the distinction of the two diseases from one another may be established.

SQUIRE and MADISON nearly two years ago (January 1937) reported three cases of thrombocytopenic purpura associated with probably due to food allergy. The case recorded by the author is that of a white woman of 59 years who had suffered on and off for years from purpuric symptoms—ecchymoses petechial haemorrhages, epistaxis haematuria—with marked reduction of platelets down to 60 000 per *cmm*. The allergy appeared to be due to citrus fruits and when these were excluded no fresh spots were seen and the old ones cleared

completely in ten days and the platelet count rose to 240 000. When small amounts of citrus fruits were cautiously added to the diet fresh ecchymoses appeared in three days.

The author comments that at least an unknown percentage of persons suffering from this disease [thrombocytopenic purpura] might be relieved by a much simpler procedure than radical splenectomy and it is amazing that a shock organ could be so narrowly limited that only the cells responsible for the platelet formation in the bone marrow could be affected by an allergen.

H H S

MEDICAL AND SANITARY REPORTS

Kedah (1937)

Kedah a Malay State under British protection, lies on the west coast of the Malay Peninsula. It is bordered on the interior by Selang and Perak, and includes the island of Langkawi and a number of smaller islands to the south. The mainland is about 105 miles long and about 65 miles wide at its widest part. Its area, including the Langkawi group of islands, is about 3 649 sq miles

Vital Statistics.—The data relating to population births deaths etc., continue to be presented in great detail in a number of tabular statements (see comments below) As mentioned in the 1938 *Supplement* to this *Bulletin* deaths in early life appear to be a feature of Kedah mortality experience during the year under review approximately 50 per cent of the total deaths registered occurred at ages 0-20 years and no less than 45 per cent. in the 0-5 age-group alone. The principal facts for the State as a whole read as follows —

Race	Population	Births	Birth Rate	Deaths	Death Rate	Infant Deaths	I.M.R.
Malays	319,260	11,654	36.5	6,265	19.6	1,490	127
Chinese	83,472	3,743	43.8	1,914	22.4	503	133
Indians	56,402	2,007	35.6	1,407	24.9	432	215
Non Asiatics	631	7	11.1	1	1.6	—	—
Others	13,010	243	11.4	194	14.9	21	85
Totals	474,775	17,664	37.2	9,781	20.6	2,438	138

As regards *Estate Populations* the relevant data are set out in similar fashion for purposes of comparison, viz. —

(a) European Holdings

Race	Estate Population	Births	Birth Rate	Deaths	Death Rate	I.M.R.
Malays	5,756	69	12.0	21	3.6	203
Chinese	1,805	31	17.3	13	7.2	129
Indians	38,112	1,339	33.5	903	25.0	281
Javanese	61	—	—	—	—	—
Others	103	1	9.3	1	9.2	—
Totals	43,842	1,490	33.9	938	18.8	255

(b) Asiatic Holdings

Race	Estate Population	Births	Birth Rate	Deaths	Death Rate	I.M.R.
Malays	7,559	25	3.3	17	2.3	160
Chinese	3,091	15	4.9	9	2.9	6.7
Indians	2,287	23	12.2	29	11.4	107
Javanese	44	—	—	—	—	—
Others	80	—	—	—	—	—
Totals	13,061	63	5.2	62	3.88	273.8 (? see below)

With regard to the above data relating to population on Estates it should be added that though numerous tabulations of facts are supplied, some of the calculated rates appear to be incorrect and in other cases discrepancies are noted between different statements relating to similar facts. For example, in Table XXI.B the crude birth rate on Asiatic Holdings is given as 20.4 per 1,000 but the 68 births related to a population of 13 061 give a birth rate of 5.2 per 1 000. In Table XV.D dealing with Asiatic mortality data, the crude death rate is published at 16.5 per 1 000 but 52 deaths related to a population of 13 061 give a death rate of 3.9 per 1 000. Table XV.A gives the deaths on Asiatic Holdings as 23, but Table XVI records them as numbering 52. The infant mortality rates on Asiatic Estates do not appear to be convincing—three specific rates are quoted in Table XXI.B as 160, 107 and 6.7 respectively yet the gross rate for all nationalities is given as 273.8 per 1,000 births. As a matter of fact on the basis of data supplied in Table XV.A the specific rates for Malaya, Indians and Chinese are 200, 214 and 67 respectively and the rate for all communities 178 per 1 000 births. The Report observes "Figures for Asiatic Estates are known to be inaccurate." This remark is presumed to relate to the raw data supplied from these sources and not to the arithmetic applied to the facts for the calculation of rates.

The usual statement dealing with the health of *European Officials* seems to have been omitted from the Report under review.

Maternity and Child Welfare Work.—It is stated that though it is yet too early to seek the benefits resulting from the introduction of the *Kampong Midwifery Service* (see this *Bulletin* 1938 Supp. p. 189*) yet a most successful beginning has been made. The four locally trained midwives posted to kampongs will have an uphill fight before they completely overcome the conservatism of Malay women and succeed in combating the opposition of the old *bidans* but strenuous efforts are being made to surmount these and other difficulties. Four more midwives are to be posted to kampongs and four new pupils are to commence their training. In addition to the introduction of this service, with a view to the improvement of Midwifery practice the new *Midwives Enactment* aims at the control of midwifery by the establishment of a system of compulsory registration and organized supervision—so far the new law applies only to the three largest towns, viz. Alor Star, Sungai Patani, and Kulim.

The work of the Lady Medical Officer in charge of Maternity and Child Welfare has again proved of immense value—the record of the year's work reads as follows—

Item	Women's and Children's Clinics		
	General Hospital	Town Dispensary	Other Dispensaries
First Visits	891	2,102	—
Subsequent Visits	761	3,209	—
Injections (for Yaws)	2,107	—	294

School Hygiene—The provisional approval of Government has been obtained sanctioning the appointment of an additional Assistant Health Officer primarily intended for general health work in North

Kedah but concentrating his activities upon laying the foundations of a regular School Medical Inspection Service. During the year under review all Malay Vernacular Schools not visited in the preceding year were inspected. In the course of these visits opportunities were used for giving brief talks on health matters to school-children. Various recommendations were made with a view to improving the sanitary conveniences of school premises and for remedying minor defects. Three Chinese schools were visited and inspected at the request of the Registrar of Schools. Chinese schools are not subject to the routine visits paid by the Medical Department. Upwards of 5 000 school-children were examined in nine districts and 206 of them were found to have enlarged spleens. Spleen rates ranged from *nil* to 13.3.

As regards the volume of work dealt with in connexion with the School Medical Service it is noted that 39 Malay Vernacular Schools and 4 690 school-children were inspected. 3 non-Government Chinese Schools and 189 children were inspected. The principal defects recorded during the medical examination of school-children may be summarized as follows —

Defects	Percentage of defects recorded in —	
	Malay Vernacular Schools	Non-Government Chinese Schools
	Per cent.	Per cent.
Caries Class I	9.5	10.6
" " II	8.7	7.1
" " III	7.3	15.3
Scabies	5.0	4.7
Eye diseases	0.3	3.5
Enlarged spleen	4.1	1.2
Anaemia	1.0	2.4
Yaws	1.7	<i>nil</i>
Not vaccinated	2.1	5.0

Public Health Sanitation etc. — The various increases in Departmental staff necessitated by the reorganization of Medical Services (see this *Bulletin* 1938 Supp p. 190*) received the approval of Government. New services provided or contemplated are mentioned in appropriate sections of the present Summary. Malaria control work in the three principal towns continued along lines previously described. In rural areas where anti-larval measures are impracticable drug prophylaxis was continued.

In the nine Sanitary Board areas (see this *Bulletin* 1938 Supp p. 190*) little has been done to improve methods of *sewage disposal*. Considerable attention was devoted to the improvement of *water supplies* during the year. Schemes envisage the provision of filtered and chlorinated supplies to all the large towns and extension of supplies to rural dwellers. These schemes can only be developed with the gradualness of time. As regards *housing and town planning* it is stated that in the larger towns considerable demolition of old and insanitary houses was carried out during the year and that building layouts have been prepared for use in both large and small towns. Certain areas have been gazetted so that future building can be controlled.

Health conditions on estates mines etc. continued to receive attention and the Health Board Scheme applicable to such properties

functioned smoothly. All European Estates were visited at least once during the year but it is again noted that a large amount of extra work was entailed in the supervision of Asiatic Estates owing to the obstruction of the majority of owners. Improvement in housing conditions, sewage disposal, water supplies etc. on various estates is recorded.

Quarantine restrictions were applied against the arrival of passengers and various commodities from Siam on account of cholera. Railway passengers subjected to routine inspection at Padang Besar numbered 12,758.

Hospitals, Dispensaries etc.—A considerable amount of building and general activity featured the year under review. The new schemes of work envisage the provision of a Dental Clinic and Tuberculous Department at the General Hospital, Alor Star; provision of a Venereal Diseases Clinic as a branch of the Town Dispensary, Alor Star; new dispensaries in three areas; structural additions to various hospitals etc.

Further extension of the chain of *kampong* dispensaries will ensure that the whole of the rice-growing population in North Kedah will shortly be provided for. Similar provision for the remoter areas of Central and South Kedah are also under consideration.

The training of dressers has now been brought into line with the schemes of work followed in the Straits Settlements and Federated Malay States. One dresser is to attend the Pharmacy course at the Singapore College of Medicine and one Health Inspector is attending the course of study leading up to the Diploma of the Royal Sanitary Institute.

As regards the volume of work dealt with at medical institutions providing for the needs of the general public and Government Officials, the following details have been extracted —

Hospital	In-patients			Out-patients		
	Beds	Treated	Dead	New Cases	Re-vents	Totals
Alor Star	300	6,852	325	10,206	2,856	13,064
Sungei Patani	300	6,729	293	7,048	1,485	8,533
Baling	33	347	13	3,548	1,042	4,590
Kulim	210	4,878	230	9,299	2,444	11,843
Langkawi	70	498	23	3,230	801	3,731
Prison Sick Wards						
Alor Star	'	129	—	1,291	4,991	6,282
Sungei Patani		—	—	120	696	816
Totals	913	19,531	889	34,844	14,017	48,861

The Dispensary Records read —

8 Outdoor Dispensaries, Alor Star	31,301	14,819	46,120
1 " Dispensary Suk (Central Kedah)	3,447	364	3,811
1 " " Bandar Bahru (S. Kedah)	2,173	364	2,536
1 " " Padang Matrat (Langkawi)	770	46	816
4 Motor Travelling Dispensaries (1 each District)	20,793	2,738	23,531

The above details refer to State Hospitals. The medical requirements of the large labour forces on rubber *estates* are met by the Health Board organization hospitals maintained by the Health Board groups accommodate a total of 1063 beds. Each hospital has an outdoor dispensary. To Group Hospitals on European Estates 22 679 patients were admitted and 717 died the corresponding figure for hospitals on Asiatic Estates being 935 and 20 respectively. The notes which follow summarize the principal references to morbidity experience during 1937 taken from the Report under review.

No case of *cholera* or *plague* was reported. The cholera epidemic in Siam gave rise to considerable anxiety and special precautionary measures were taken (see *Quarantine* above). No anti plague measures have ever been enforced though rats are found in abundance in all centres of population.

Fifteen cases of *smallpox* were reported from South Kedah four of them terminating fatally. The first case (a Chinese woman newly arrived from China) all other cases occurred among Malays on a rubber estate) occurred on June 28th and the last on July 24th. A special vaccination campaign was instituted and 27 400 estate employees were vaccinated total vaccinations in the State numbered 41,333.

A prolonged epidemic of *measles* occurred chiefly on estates and among Indian labourers the infection was introduced by newly arrived Indian labourers. Notified cases numbered 1 443 and 26 deaths were ascribed to this cause. It is said that a considerably larger number of deaths occurred certified as due to broncho-pneumonia which should have been assigned to measles. One fatal case (an Indian) of *tropical typhus* was recorded.

No epidemic of *malaria* was recorded cases dealt with show an increase over the 1936 figures but fewer deaths were assigned to the disease the recorded facts being 7 007 cases and 580 deaths. On the other hand deaths ascribed to *fevers unspecified* numbered 3 494 so that this title becomes responsible for 36 per cent. of the total deaths in the State due to all causes. As regards malaria on estates 13 184 cases of malaria and unspecified fever and 67 deaths were recorded. The majority—12 545—of the cases occurred on European estates but while on European holdings deaths due to malaria constituted 6 per cent. of the total deaths due to all causes on Asiatic estates the corresponding ratio stood at 25 per cent. With regard to the data relating to Asiatic holdings the Report adds. It is impossible to consider these figures as of any value whatever for statistical purposes.

Of *enteric fever* 69 cases and 10 deaths were notified, and of *dysentery* and *diarrhoea* 520 cases with 370 deaths. It is also stated that in State hospitals 244 patients were treated for dysentery and 16 died and in Group Hospitals (estates populations) 312 patients were admitted and 33 died [*i.e.* a total of 556 in-patients alone treated for dysentery].

Mention has been made of the proposed establishment of a *Tuberculosis Department* at the General Hospital, Alor Star (see *Hospitals* above) and with this aim in view Dr P. T. K. NAYAR, one of the Assistant Medical Officers attended an intensive course of study of modern methods of treatment of tuberculosis at the Brompton Hospital, London. The scheme aims at the provision of a fully equipped and special ward and the establishment of an out patient clinic a modest beginning has already been made to provide these

special T.B. services. In patients at State Hospitals treated for *pulmonary tuberculosis* numbered 442 and 196 died for *other respiratory diseases* 694 cases and 71 deaths were recorded. To the Group Hospitals (estate populations) 473 patients were admitted suffering from *pneumonia* and 146 deaths were ascribed to this cause.

Other diseases—During the year in the State as a whole 301 deaths were registered as due to *ankylostomiasis* 647 cases were treated in State Hospitals with 13 deaths and 226 in Group Hospitals with 2 deaths. *Barbers* caused the deaths of 144 persons, 99 of these being Malays, 31 Chinese and 11 Indians no mention of the special investigation of lines of treatment is made (see this *Bulletin* 1938 Supp. p 193*) Kedah *lepers* continue to be accommodated and treated at the four institutions outside the State during the year 213 were under treatment 14 died and 16 absconded. In a special Appendix the new policy regarding the control of leprosy is discussed (see below *Scientific*) Deaths ascribed to *syphilis* numbered 29. A special *Veneral Diseases Clinic* is to be established in a room which is to be set aside for this purpose in the new Town Dispensary Alor Star. The new *Dental Clinic* (see this *Bulletin* 1938 Supp. p 190*) has functioned with success since its opening in October 1937 during the last three months of the year 215 new cases and 250 re-visits were recorded.

Scientific.—Each of the five State Hospitals has its own branch laboratory and during the year 43 728 specimens were examined. At the Central Laboratory Sengul Patani, 7 413 specimens were examined but findings are not recorded.

Three special Reports appear as Appendices to the Report under review viz

1 *A Health Survey of Langkawi Island* by Dr E. D. B. Wolff, who records the results of his examination of 2,800 persons, the sanitary condition of the island etc.

2 *The New Policy regarding the Control of Leprosy* which aims at abolition of the former system of compulsory isolation by means which will induce sufferers to seek treatment voluntarily etc.

3 *Report of a case of Hydrophobia* by Dr R. SIVARAMANDAM.

Financial—Total expenditure on Medical Department services during 1937 amounted to \$551,225

P. Granville Edg

Perlis (1937)

Perlis is the most northerly of the Malay States, lying on the west coast of the Malay Peninsula. It is bordered on the interior by Siam to the north and Kedah to the south, and has an area of about 316 sq. miles.

Vital Statistics—It is stated that the registration of births and deaths will eventually be carried out by an Assistant Medical Officer trained by the Senior Health Officer Kedah. The relevant vital statistics for 1937 are shown in the accompanying Table.

[The Table on page 49 entitled *Stillbirths according to Nationality and Sex* actually presents live births with these distinctions 105 stillbirths were recorded.]

There were 3 resident *European Officials*. *Asian Officials* resident numbered 360 with the same average number resident seven were invalided and two died.

Nationality	Population	Births	Birth rate	Deaths	Death rate	Infant Deaths	I.M.R.
Europeans	7	—	—	—	—	—	—
Eurasians	6	—	—	—	—	—	—
Chinese	6,224	257	41.3	173	27.8	37	144
Malays	43,497	1,474	33.9	725	16.7	142	96
Indians	977	23	23.5	23	23.5	3	130
Others (mostly Siamese)	1,992	39	19.6	44	22.1	7	179
Totals	52,703	1,783	34.0	965	18.3	189	105.4

The population of labourers and their dependents on *estates* totalled 436 distributed as to 361 Indians 74 Malays and a single Chinese. Fifteen births and six deaths—all Indians—were recorded.

Maternity and Child Welfare Work—One of the midwives trained at Alor Star for the newly created *Kampong* Midwifery Service (see p 162 *supra* and this *Bulletin* 1938 Supp p 194*) was duly posted to her *Lampong* in Perlis and another pupil midwife has commenced her course of training. During the year 13 deaths were registered as due to diseases of pregnancy childbirth and the puerperal state. The Hospital midwife attended 4 labour cases in the homes of patients. Vernacular Schools were medically examined by the Lady Medical Officer Kedah. Owing to the absence of leave during part of the year of the Assistant Medical Officer and of the Assistant Health Officer when attending a course of training in Kedah the volume of work accomplished was somewhat less than usual. Ten schools were inspected and 948 children medically examined. The principal findings being summarized as follows—*dental caries* 30.6 per cent. *enlarged spleens* 17.5 per cent. *anaemia* 17.2 per cent. Only 0.1 per cent. were affected with *yaws*. 37 children received N.A.B. injections for the disease.

Public Health Sanitation etc—The work of the Medical Department Perlis is supervised by the State Surgeon Kedah (Dr J. PORTELLY) who reports that the general health of the Perlis population during 1937 was good. Routine anti-malarial measures continued to be carried out and it is hoped by better control and by anti-larval and drug prophylaxis to reduce malaria incidence in the endemic areas in course of time. Methods of *sewage and refuse disposal* remain as previously described (see this *Bulletin* 1938 Supp p 194*). As regards *water supplies* these remain as described in the previous issue of the *Supplement* to this *Bulletin*. reference is again made to the proposed installation of a filter plant at Padang Besar (see this *Bulletin* 1938 Supp p 194*). Kaki Bukit still obtains its supply from sources liable to pollution. The provision of *safe supplies* can only be met by the removal of the illages to a new site and this matter is receiving the attention of the authorities. Additions and improvements to market stalls are reported shops street stalls and hawkers are inspected at regular intervals and licences issued only when prescribed sanitary standards are maintained. Steps are being taken to deal with unsatisfactory itinerant hawkers. *Hospitals Dispensaries etc*—New Buildings for the accommodation of certain members of Medical Department staff were completed and occupied and various additions made to existing

buildings during the year. The medical institutions provided for in-patient and out-patient treatments remain as previously described (see this *Bulletin* 1938 Supp. p. 194*). At the General Hospital Kangar 1,707 in-patients were dealt with and 89 deaths were recorded, 36 of these deaths occurring within 48 hours of admission. 806 of the patients were Chinese, 594 Indians and 268 Malays. Out-patients treated at this Hospital numbered 5,443 and of these 3,288 were Malays, 1,211 Indians and 687 were Chinese. [The racial proportions among in-patients and out-patients are striking. Among in-patients Chinese head the list with 47 per cent. while only 17 per cent. were Malays, but among out-patients the positions become reversed, Malays 60 per cent. Chinese 16 per cent.] The Outdoor Dispensary at Kaki Bukit dealt with 6,315 new cases and the Travelling Dispensary 411 cases (exclusive of those treated at Schools, Coolie Lines, etc.).

In common with usual experience *malaria* and *fevers unspecified* were responsible for the largest proportions of the total deaths registered in Perlis during 1937—no less than 41 per cent. of the deaths due to all causes appear under these two titles. Only 19 deaths were specifically assigned to *malaria* but 376 were due to *unspecified fevers*. Hospital in-patients treated for *malaria* numbered 457 and 10 died. Types of infection are not differentiated in the Hospital Returns, but among 4,872 blood-films examined at the Hospital Laboratory Kangar 1,912 contained *malaria* parasites the percentages and types being *benign tertian* 51.4 *subtertian* 38.5 *mixed infections* 9.8 and *quartan* 0.3 per cent. Larval surveys indicated *A. barboides* as the most prevalent type, followed in descending order by *A. hyrcanus* and *A. maculatus*.

Twelve cases of *cerebrospinal fever* (all Chinese and mostly mining coolies) were notified. Eleven of the cases occurred in Kaki Bukit and its suburbs, an insubstantial area where conditions are ideal for the spread of such a disease. Ten of the cases were treated in Hospital with 5 deaths. Prompt and energetic action succeeded in suppressing the outbreak. No case of *typhus* or *smallpox* was reported. 1,796 vaccinations were performed.

Rabies.—Seven persons were bitten by dogs actually rabid or suspected of being rabid: two were treated at Alor Star and three at Kangar Hospital. One refused treatment and died a month later and another reported at the Hospital a month after the bite and developed hydrophobia the day after admission and died. (This case is referred to in the Kedah Report above.) The brains of two dogs sent to the Institute for Medical Research, Kuala Lumpur were declared positive for *rabies*.

Ten deaths were ascribed to *enteric fever* in the State as a whole. Four cases of *typhoid fever* with one death and one fatal case of *paratyphoid* were treated in Hospital. Hospital patients treated for *dysentery* numbered 29 and 3 deaths were recorded. 14 of the patients were suffering from the amoebic type of the disease.

Forty-seven deaths were registered as due to *pulmonary tuberculosis*. Cases admitted to Hospital numbered 54 and of these 51 were pulmonary. 11 hospital deaths were recorded. Deaths due to *pneumonia* (all forms) in Perlis totalled 23. 44 cases with 15 deaths appear in the Hospital Returns.

Of the 4 Perlis *lepers* one was accommodated at the Pulau Jerejak Leper Settlement, Straits Settlements and three at Sungai Baloh, F.M.S.

Other diseases mentioned in the Hospital Returns include 82 cases of *ankylostomiasis* 107 of *influenza* 54 of *ulcers* and 32 of *chickenpox*. In the tabulated causes of death it is noted that 46 deaths are ascribed to *Demam Batok* a term which vaguely connotes *feverish cough*.

Scientific.—Of the 8,205 specimens examined at the Laboratory 4,872 were the blood films already mentioned under *malaria* in the preceding notes. As regards the remainder these included 1,740 faecal specimens 1,252 giving positive findings and 283 specimens of sputum of which 32 contained *Mycobacterium tuberculosis*.

Financial.—Expenditure on Medical Department services during 1937 amounted to £45,649 a sum which represents 6 per cent. of the total revenue or 7 per cent. of the total expenditure of the State during the year under review.

P. Granville Edge

Kelantan (1937)

The State of Kelantan is on the eastern side of the Malay Peninsula. On the north is the China Sea, on the south Pahang on the east Trengganu and the China Sea on the west Perak and Siamese Territory. The area is estimated at 5,720 sq miles, or rather less than that of Yorkshire.

Vital Statistics.—Births and deaths registration became compulsory only in July 1930. It is said that amongst Malays and other races registration is fairly complete but information is lacking regarding births and deaths occurring among inhabitants of the remote and hilly districts of Ulu Kelantan where many aboriginal tribes are to be found. The relevant facts for the year under review read as follows—

Race	Estimated Population	Births	Birth Rate	Deaths	Death Rate	Infant Deaths	I.M.R.
Europeans	80	2	25.0	3	37.5	1	?
Malays	354,844	9,733	24.6	8,278	17.7	1,099	112.9
Chinese	27,034	698	25.8	396	14.6	64	91.7
Indians	10,401	225	21.6	200	19.2	48	213.3
Eurasians	72	0	—	2	27.8	0	0
Others	7,947	183	19.2	106	13.3	9	58.8
Totals	400,378	10,811	27.0	8,983	17.4	1,221	112.04

Deaths are classified in the Report under review by race age groups and by principal causes.

Of European Officials there were 28 resident with the same average number resident no invalids or deaths were recorded. Of the 1,057 non-European Officials with the same average number resident it is noted that eleven were invalids and five died during the year. The total labour force with their dependents on *Estates* is returned as 6,135 but these are exclusive of *Estates* employing entirely Malay or Chinese labour 3,796 were Indians and their dependents and among this group 111 births and 109 deaths were recorded giving birth and death rates 29.7 and 29.2 respectively. There were 33 infant deaths so the infant mortality rate would be 297.2 per 1,000 registered births.

Maternity and Child Welfare Work.—There is no special Maternity Hospital in the State but maternity beds are available at the Kota Bharu Hospital where however in spite of every effort services are not so far popular among Malay women. During the year 187 deliveries were recorded at the Hospital and of these 122 were Indian women, 59 were Chinese, but only 1 was a Malay. Free facilities are provided for ante-natal treatment and delivery of women from *Estates*. Provision was made for the training of four Malay *midwives* but owing to the illiteracy of Malay women difficulty was experienced in obtaining suitable candidates with the result that only one was selected to commence the course of training (see this *Bulletin* 1938 Supp. p. 197*).

An *Infant Welfare Centre* was started in premises acquired in the market area of Kota Bharu the work being under the charge of a part time Assistant Lady Medical Officer assisted by an Infant Welfare Nurse. This undertaking has made a most successful beginning the clinic is popular and attendances have steadily increased month by month. The Health Nurse, after her daily work at the Clinic visits homes in Kota Bharu and in adjacent kampongs from which births have been reported. The record of the year's work shows that 1,343 visits were paid to newly born infants 1 497 visits were paid to women (858 of these to Malay women) and 1 173 to children (of the latter 703 were Malay children).

School Hygiene.—During the year 1 English and 42 Malay Vernacular Schools were inspected and 2,896 school-children medically examined. In towns the general sanitary condition of the schools is satisfactory and it is also said that in areas where anti malarial measures are efficiently carried out spleen rates are low. Among other findings it is said that minor *skin diseases* are common and the percentage among children examined was 21.8. *dental caries* is equally prevalent with 21.2 per cent. of the pupils examined, *anaemia* was present in 5 per cent. and *diseases of the eye* in 2.6 per cent. while 48 cases of active *yaws* were detected and referred for treatment. A list of pupils and their defects is given to the teachers in towns, necessary treatments are supplied at Hospitals and Dispensaries, and in rural areas by Travelling and Pack Dispensaries during the course of their weekly visits. Hygiene is taught in the schools by teachers.

Public Health Sanitation etc.—The lack of a satisfactory index of the general health of the State is again referred to (see this *Bulletin* 1938 Supp. p. 197*). For purposes of public health administration the State is divided into five Districts which cover the main centres of population. Anti-malarial work was carried out along lines previously described in the notified areas the zone of control in Kuala Krai was considerably extended. Additional work undertaken during the year included control measures in a Chinese rubber estate near Kuala Krai, the canalizing of the Sungai Krai the construction of earth drains and the replacement of roadside ditches by concrete drains. Frequent larval surveys were undertaken and regular mosquito surveys were continued.

The single bucket system of *sewage disposal* continues in use (see this *Bulletin* 1935 Supp. p. 180*). Considerable extension of the service is necessary for many houses in the towns and kampongs lack sanitary latrines and are still dependent upon primitive methods of

disposal of excreta Every effort is being made to bring about improvement where the erection of new houses and repairs to old ones are approved the construction of sanitary latrine accommodation is made compulsory Kota Bharu is still the only town in the State having piped water supplies but even here shallow wells inadequately protected are largely used In all premises licensed for the sale or manufacture of foods and drinks the use of piped supplies has been made compulsory In other towns in the State supplies are obtained from wells streams and rivers having regard to the fact that bowel diseases are almost universal provision of piped supplies is a sanitary necessity Matters concerned with housing and town planning continued to engage the attention of the responsible authorities defects are being remedied and improvements in existing conditions gradually effected The inspection of premises where foods and drinks are prepared or offered for sale was continued it is stated that On Estates subject to medical inspection the housing of labourers medical aid and all other matters concerned with the physical welfare of employees received considered attention

No provision exists for the training of sanitary personnel but it is noted that all the Sanitary Inspectors employed hold the Certificate of the Royal Sanitary Institute London

Port Health Work—Coasting steamers plying between Singapore and Bangkok call at Tumpat where the Chief Hospital Assistant at the Tumpat Dispensary acts as Deputy Health Officer and inspects all passengers during the year 175 steamers with 433 passengers called at the port but no case of infectious disease was recorded.

Hospitals Dispensaries etc—Hospitals maintained by the Medical Department remain as previously described except that it is necessary to add that certain extensions to existing buildings were completed during the year (see this *Bulletin* 1937 Supp p 192* and 1938 Supp p 198*) In addition to the Out-patient Departments established at all Hospitals there are Dispensaries at five centres 2 *Motor Travelling Dispensaries* 2 Outboard *Motor Prahu Dispensaries* and 2 *Pack Dispensaries* The volume of work dealt with by Hospitals and Dispensaries during the year may be set out as follows —

Institution	Admitted	Treated	Deaths	Out patients	Attendances
Hospitals	6,358	6,063	249	40,037	52,292
5 Dispensaries	—	—	—	41,063	66,500
6 Travelling Dispensaries	—	—	—	—	100,489

Information concerning disease incidence in the State is available only from the records maintained by Hospitals Dispensaries and Travelling Dispensaries reference to some of the diseases treated during the year is made in the notes which follow

Malaria is the principal disease and chief cause of death in the State—it is mainly prevalent in the foothills of Ulu Kelantan and is endemic on most of the rubber estates lying along the banks of the Kelantan River During the year under review there was a marked increase in the number of malaria cases admitted to hospitals attributed in part to the Japanese Iron Mine at Temangan where

one of them employed by the Nippon Mining Company, Dungun. The volume of maternity work dealt with at various centres can conveniently be set down in the following manner —

Centre	Maternity Cases Conducted.					Maternal Deaths
	Malays	Chinese	Indians	Others	Total	
Kuala Trengganu Hosp Town Clinic (Japanese Midwife)	13	84	4	1	102	1
Besut (Malay Midwife)	61	37	1	2	101	0
Dungun (Indian Midwife)	50	4	1	0	55	0
Kemaman (Chinese Midwife)	1*	19	0	0	31	0
	2	57	1	1	61	0
Total	125	201	7	4	330	1

Of the 175 women who made 307 attendances for ante-natal examination at these centres 114 were Malays, 52 were Chinese, 8 were Indians and 3 were members of other races.

At the Kuala Trengganu Town Clinic 69 patients attended for ante-natal treatment, 225 infants under one year of age and 1,117 children between the ages of one and twelve years also attended for treatment. It is hoped to build up gradually child welfare services in the districts with the assistance of local midwives. It is interesting to note that infant mortality rates are high in the south and much lower in the north of the State while highly malarious inland districts show lower rates than urban areas. Malaria would not therefore seem to be the major factor in the problem of infant mortality—in inland districts where money is scarce breast feeding is the practice but in the towns sophisticated foods replace the natural method.

School Hygiene.—Twenty-three Government Schools and ten Private Schools were inspected during the year and 2,148 children medically examined, which means that 85 per cent. of the children on the registers were dealt with. Of the total children examined 1,232 were in Kuala Trengganu schools. Pupils showing enlarged spleens formed 3 per cent. of the total examined. Spleen rates for coastal towns ranged from 0.8 per cent. to 27.4 per cent. and for inland areas between 2.8 per cent. and 42.9 per cent. Signs of yaws were noted in 3.8 per cent. of the children examined, mostly tertiary lesions of the hands and feet. Dental caries was noted in 50 per cent. of the children. A great number of the pupils are said to be infected with worms in faecal specimens of 116 pupils in Kuala Trengganu 111 were positive with ova.

Public Health Sanitation, etc.—There are now Town Boards at ten places (see this Bulletin 1938 Supp. p. 202*). During the year the Medical Officer was appointed Health Officer, Kuala Trengganu. Assistant Health Officers were appointed at Chukai and Dungun and in smaller places Dressers act as Health Inspectors. It is said that the larger towns are free from malaria and that anti-malaria measures are most needed where such are most difficult to implement. Mosquito surveys were carried out by Health Inspectors in various areas. As regards sewage disposal a "double pail" system was inaugurated in Kuala Trengganu superseding the former system, and

in Kuala Dungun and Chukai the conservancy systems were extended elsewhere conditions remain unchanged (see this *Bulletin* 1937 Supp p 196*) Disposal of refuse is by controlled tipping in the larger towns and by burning and burying in the villages. The position in respect to water supplies remains as previously described (see this *Bulletin* 1937 Supp p 196*) In the crowded parts of Kuala Trengganu water sold by bullock cart is obtained from wells potentially dangerous.

Housing and Town Planning matters continue to engage the attention of the Town Boards and progressive improvement is reported. With regard to *labour conditions* three mines have small hospitals and employ dressers and a fourth has a large hospital and dispensary and employs a qualified Indian sanitary inspector and staff of coolies. Health conditions on estates are said to have been greatly improved lines have been reconstructed and piped water supplies installed, crèches for children established and anti malarial works undertaken. All mines and estates were visited by the Medical Officer or by Assistant Medical Officers and Sanitary Inspectors during the year. Premises licensed for the manufacture and sale of foods and drinks are regularly inspected by Health Inspectors.

Port Health Work—The passengers and crews of 241 junks were examined and special precautions taken in view of the continuance of cholera in Siam.

Hospitals Dispensaries etc—Additional accommodation was provided by the completion of new buildings during the year. These included new wards to the Kuala Trengganu Hospital the first ward of a new hospital at Kuala Dungun a ward at Chukai Kemaman Hospital where a new hospital is being built. With these additions there are now 213 hospital beds available for in patients. The work performed at all hospitals during the year is detailed hereafter—

Hospital	Beds	Admissions	Treated	Died
Kuala Trengganu General	158	2 622	—	49
Kuala Dungun	7	64	—	1
Chukai Kemaman	20	453	—	7
	23	275	—	9
Totals	213	3 414	3 538	66

For the treatment of out patients permanent *Dispensaries* are established at 7 centres (these also include Out-patient Departments at Hospitals) there are 6 *Travelling Dressers* who deal with cases in outlying villages *vaccinators* who distribute medicines during their visits and 11 *Police Stations* and 4 *Customs Stations* situated in places where there are no dispensaries supplied with stocks of simple drugs. Patients treated during the year were—

By <i>Dispensaries</i> and <i>Travelling Dressers</i>	New Cases.	Attendances
<i>Vaccinators</i>	125 740	157,853
<i>Police</i> and <i>Customs Stations</i>	15,822	16,571
<i>Hospitals</i> maintained by <i>Mining Companies</i> and <i>Estates</i> have been referred to in the <i>Section Public Health</i> above.	863	863

The most reliable information as regards the *incidence of disease* in Trengganu is supplied by the statistics of patients treated at Hospitals

and Dispensaries and the notes which follow briefly summarize references to some of the prevailing diseases discussed in the Report under review.

The incidence of *malaria* varies widely in different parts of the State these variations being indicated by the spleen rates recorded at the medical examinations of school-children (see *School Hygiene* above). During the year under review there were 579 admissions to Hospitals for the disease (representing 17 per cent. of the total admissions) and 587 patients were treated for malaria with 8 deaths. For the total cases treated types of infection were distributed as to 188 *subtertian*, 113 *benign tertian*, 24 *quartan*, 12 were mixed infections, 13 malarial *cachexia* and 237 were unclassified. Out-patients treated at Hospitals and Dispensaries totalled 20,860. No case of *blackwater fever* was recorded.

Mining Companies with an average monthly population of labourers and their dependants of 5,042, reported 1,247 cases of malaria and 8 deaths. *Estates* with an average monthly population of labourers and dependants of 2,180 supply no record of malaria cases but report 7 deaths due to this cause.

It is of interest to note that in the State as a whole only 84 deaths were medically certified as being due to malaria, while 2,677 deaths were ascribed to unspecified fevers. 19 of the latter were stated to be due to *demam hepatis* which means a long continuous fever and might be enteric or typhus but no cause can be assigned to the remainder (see also this *Bulletin* 1938 Supp. p. 203*).

At the Laboratory where 4,180 blood films were examined, 3,603 gave negative findings; the positives included 290 *P. falciparum*, 228 [*P. 221*] *P. vivax*, 33 *P. malariae* and 33 mixed infections.

No case of *plague*, *cholera*, *smallpox* or other dangerous infectious disease was reported. During the year 12,304 anti-smallpox vaccinations were performed and of these 11,742 were primary vaccinations.

Three non-fatal cases of *tropical typhus* were treated at Hospitals; all diagnoses were confirmed by serological tests and typed as to 2 Scrub type (*Proteus* X K strain) and one "Shop" type (*Proteus* Y W strain).

Only 9 (non-fatal) cases of *enteric fever* were reported. At the Laboratory where 26 Widal reactions were performed, in 5 cases the serum agglutinated positively with *Bact. typhosum* and 1 with *Bact. paratyphosum B*. Sixty-two in-patient and 196 out-patient cases of *dysentery* were dealt with. 19 of the in-patient cases and 24 of the out-patient cases were amoebic dysentery. Six Hospital deaths were ascribed to the disease. On *Mines* and *Estates* 38 cases of dysentery were recorded. Among 4,239 faecal specimens examined at the laboratory 13 were found to contain the protozoon *E. histolytica* alone or with other infections.

Fifty-one deaths in the State are said to have been due to *tuberculosis*. It is noted there were 78 in-patient cases of tuberculosis (all forms) and of these 74 patients were suffering from the *pulmonary* form of the disease and 17 died (i.e. 28 per cent. of total hospital deaths). The majority of the patients were Chinese. At the laboratory where 492 specimens of sputum were examined 70 were positive with *Mycobacterium tuberculosis*.

Beriberi was less prevalent during the year under review. Deaths due to this cause in the State as a whole numbered 23. Cases treated by the Medical Department totalled 1,190 and of these 117 were

in-patients of whom 2 died. On Munnig properties 291 non fatal cases were reported. Incidence is said to be greatest among the Chinese in women it is usually noted after a confinement it is rare in the interior where home-grown rice is the staple diet but common on the coast. The low mortality is partly attributed to the fact that all cases were treated with concentrated injections of Vitamin B₁.

Helminthic infections are very prevalent 72 per cent of the 4,239 faecal specimens examined at the laboratory had some kind of helminthic infestation which was usually multiple with *ancylostoma* present in 27.4 per cent, *ascaris* 52.3 per cent and *trichuris* 45.2 per cent. Hospital Returns show 111 in patient cases of *ankylostomiasis* and 143 of *ascariasis*.

Leprosy.—During the past five years a register has been kept of all lepers coming to the notice of the Medical Department. Of the 90 persons recorded over the period 29 have died 10 have left the State 6 are at the Leper Settlement Sungai Buloh (Selangor F.M.S.) 16 cannot be traced and 30 are known to be alive.

Veneral Diseases.—It is said that *sypilis* is rarely seen among local Malays and that the majority of the cases are Chinese. Admissions to hospitals with distinction as to race were as follows —

	Malays	Chinese	Indians	Others	Totals
Gonorrhoea	103	54	44	0	201
Syphilis	3	22	7	1	33
Soft Sore and Granuloma venereum	9	11	9	0	29

In addition to the above 1 018 persons received out patient treatment for gonorrhoea. The figures are said to be no measure of the incidence of the disease which is believed to be very common in the towns. Cases of yaws treated during the year were in-patients 231 and out-patients 3 694 (see also *School Hygiene* above).

Laboratory Returns show that out of 244 Kahn tests 50 were positive and that 204 out of 388 specimens were positive with *N. gonorrhoeae*.

Other diseases dealt with by the Medical Department included 4 797 cases of influenza a few cases of mumps chickenpox measles and whooping-cough 377 in patient cases of ulcers and upwards of 200 of wounds and fractures. Menaces to life other than those contributed by disease are evidenced by the mention of 8 persons killed by tigers 1 by an elephant and 1 by a snake.

Scientific.—The Kuala Trengganu Hospital is equipped with a laboratory and all permanent dispensaries are supplied with microscopes for the confirmation of clinical diagnoses. Specimens examined and findings recorded are summarized in an Appendix to the Report under review and have been referred to in the preceding notes.

Financial.—Total expenditure on Medical Department services during 1937 amounted to \$112,516 a sum which represents 4.2 per cent of the total revenue of the State (or 4.3 per cent. of the total State expenditure) during the same year.

P. Granville Edge.

REVIEWS AND NOTICES

RODENWALDT (Ernst) [Dr med., o. & Professor der Hygiene in Heidelberg] *Tropenhygiene*. [Tropical Hygiene]—pp ix+146. With 11 figs 1933 Stuttgart Ferdinand Enke Verlag [Unbound Rm. 8 Bound Rm. 9 60] [Review appears also in *Bulletin of Hygiene*]

The author has had a long tropical experience and his conclusions from it are embodied in this book. This is not one of those manuals to which people can turn for detailed instruction on practical measures of hygiene in the tropics, but the author expresses views which are of much general interest.

Climate, fitness for service settlements and housing, diet, water, refuse and excreta, clothing and bodily activities are dealt with in that order, the subject matter being in two subdivisions, the first applicable to Europeans and the second to the indigenous peoples.

Acclimatization of Europeans in tropical regions is a topic which should be considered from the individual as well as from the racial point of view. The tropical area is to be thought of not as a place lying between two rigid lines but rather as a series of regions, often disconnected, which possess certain meteorological characteristics as regards rainfall, atmospheric humidity, solar radiation and temperature. Many conclusions formerly reached about climate were really based on the effects of disease on the individual. That the blood, light-eyed northern European type with a tendency to corpulence is less well adapted for life in the tropics than the dark-haired, dark-eyed southern European is an idea that belongs to the early days of tropical hygiene.

The healthy European woman can live in the tropics, and the more normal in respect of health conditions life in the tropics is made the less need married life there suffer from that at home. Government and private concerns sending out a man even for his first tour should ensure that he can take a wife with him. The unmarried man of inferior education usually falls under the degrading influence of a half-coloured household, and the educated man often finds himself forced to lead a dual life—he may become so entangled in the end that he cannot marry a European. Under pressure of such conditions many able and carefully selected men fail to leave any issue, a deplorable loss of the best stock.

The author discusses the subject of health propaganda, especially in relation to the indigenous peoples. He takes an optimistic view largely as a result of his own experience in this matter. He thinks it essential that the methods adopted should be developed gradually from beginnings which will aim primarily at obtaining the co-operation of the people. Successful treatment of their most troublesome diseases is one of the easiest beginnings in gaining their confidence. A common cause of failure is trying to teach too many things at a time, and another is extending the effort over too large an area. He refers with approval to the methods employed by the workers of the Rockefeller Foundation. In particular he mentions the successful work of HYDRICK in Java as a useful model (see *Bulletin of Hygiene* 1937 Vol. 12, p. 674). He fully recognizes that where millions of widely distributed rural dwellers are concerned the progress of the prevention of disease along the present lines must be slow.

D B Blacklock.

Ghosh (Brendra Nath) [M.B.E. FRFP & S (Glasg)] *A Treatise on Hygiene and Public Health with Special Reference to the Tropics*. Ninth Edition—pp xvi+720. With 169 figs. 1938. Calcutta Scientific Publishing Co [15s] [Review appears also in *Bulletin of Hygiene*]

This edition, the ninth of Ghosh's *Hygiene and Public Health*, appears only three years after the previous one but nevertheless it contains much new material. Several chapters have been largely rewritten and others revised incorporating recent knowledge. For writing and revising the different sections the author acknowledges his indebtedness to various workers—MEGAN relapsing fever typhus epidemic dropsy and beriberi—WILSON maternity and mental disorders—BERKLEY HILL and MAITTI mental hygiene and mental disorders—LAL vital statistics—WILSON food and diet in India. He also expresses indebtedness to STEWART for generous assistance and co-operation.

Means for the prevention of the spread of tuberculosis are being seriously considered in India as elsewhere in tropical and sub-tropical regions. The mortality from tuberculosis has been steadily rising in India especially in the cities and towns owing to a combination of factors mostly social and economic. In Peshawar city out of 75 000 persons examined in 1927 3 000 were detected as suffering from active tuberculosis.

Leprosy is one of the important diseases in India the estimated number of cases being a million. Of these 80 per cent are non-infectious 10 per cent slightly infectious and 10 per cent highly infectious. The young being the most easily infected it is above all necessary to adopt preventive measures to immunize this risk.

No lice no relapsing fever is an axiom is perhaps somewhat of an over simplification especially as tick borne relapsing fever is described immediately after this. The frequent application of kerosene and oil recommended by the author is a more promising method of getting rid of lice and nits than the usual perfunctory dip in a bath of chemical solutions so dilute that they do not affect the eyes.

With regard to yellow fever which may be one of India's greatest problems of the immediate future the rôle of mosquitoes other than *Aedes aegypti* might have been given more prominence. The prevalence of rural yellow fever in South America may later have its counterpart in the East. In the same connexion it might be advisable to discuss the possible advantages of protective inoculation on a large scale as a measure of public security against yellow fever. The author is apparently unresponsive to the hints of the reviewer of the 8th edition on the yellow fever section or else it may be unrepentant.

The increasing realization of the importance of closer attention to maternity and child welfare is evidenced in the section contributed by Dr Jean ORKNEY. Village sanitation is becoming such an all pervading problem to the public health departments in India that no doubt it will be worthy of receiving increased space in future editions.

The present volume is one which can be recommended to students. In it they will find something of assistance in relation to the public health on almost any of the multifarious subjects of which they will be called upon to display some knowledge. Everyone engaged in public health practice in the tropics and sub-tropics will also find this new edition a useful guide.

D B Blacklock

honourable mention. The Chemical Section (IV) comprises the greater part of this book. Technical and detailed, of great importance to clinical medicine, it is nevertheless intelligible only to expert chemists.

Paradoxical as it may seem that in searching for some *raison d'être* for chemotherapeutic research it is necessary to state that many outstanding discoveries were made independently of each other and without any reasoned connexion. Among these we may place the discovery of *germanin* by ROEHL in 1916 *arsen-stibamine* by BRAH MACHARI in 1922, *fuadin* by H. SCHMIDT in 1928 *plasmogwina* by SCHULEMANN SCHONHOFER and WINGLER in 1928 and lastly that of *ac-trin* by VIETZSCH MAUS and KIEUTH in 1930. Thus we are presented with the paradox of achievement outstepping chemotherapeutic theory.

The chemotherapy of arsenicals as well as quinoline derivatives in malaria *emacina* and *quinoral* in amoebic dysentery is explored in great detail. Helminthologists will find satisfaction in a similar examination of the various anthelmintics usually employed and research workers will assuredly discover in the elaborate *Toxicity Table* which forms an appendage a sure shield in time of trouble.

This comprehensive work is well annotated and the many references to British workers are a compliment to their activities in this field. Its compilation has entailed an immensity of labour and it has succeeded, in the avowed object of its author in stimulating thought and as an inspiration for future endeavour. The text is singularly free from errors and the one slip discovered is on p. 131 in the spelling of "Mietzsch."

LEWIS'S MEDICAL AND SCIENTIFIC LIBRARY Catalogue of Lewis's Medical & Scientific Lending Library Part I.—Authors and Titles. New Edition. Revised to the end of 1937—pp 8+550 1838. London H K Lewis & Co Ltd. 138 Gower Street, W.C.1 16s (to Subscribers 8s) [Review appears also in *Bulletin of Hygiene*]

The founding of Lewis's Medical and Scientific Lending Library in 1848 goes back to within a very few years of the time when CARLYLE driven to distraction by the hours wasted in waiting for books at the British Museum successfully agitated for the founding of a lending library for the use of scholars. Possibly Carlyle's plea which led to the founding of the London Library suggested the usefulness of a lending library of medical books for hard-pressed practitioners and thus brought about the establishment of Lewis's library. Whether this be the case or not the appearance of a new edition of Lewis's Library Catalogue revised to the end of 1937 is a welcome reminder of the growth and continued usefulness of this library. The Catalogue is of books available in the library and is estimated to contain about 20,000 titles. Counting the large number of duplicates of all the most frequently required works the number of volumes in circulation and in the library to-day must be over 60,000 and expressed in terms of money a subscriber to Lewis's library has available for his study a collection of standard medical and scientific books worth something like £50,000.

TROPICAL DISEASES
BULLETIN.

[Vol 36]

1939

[No 3]

SUMMARY OF RECENT ABSTRACTS *

III MALARIA

General

JAMES (p 255) gives a general account of the progress of malariology during the past 20 years in connexion with malaria in man, monkeys and birds and EDGE (p 256) brings together the information contained in the British Colonial Medical Reports for 1935 on the prevalence of the disease

Epidemiology

DECOURT (p 511) considers that other things being equal the severity of endemic malaria varies inversely with the density of the population affected which explains why it is less severe in towns than rural areas and why increase in rural population with more intensive cultivation tends to decrease anopheline prevalence. He discusses the cost and procedure of bonification

STRATMAN THOMAS *et al* (p 257) in Cyprus found infection with *vivax falciparum* and *malariae* but principally *vivax*. Spleen and parasite indexes were highest at altitudes of 1000-1500 feet but above 2000 feet the parasite rate was considerably higher than the spleen rate. The malaria problem of Cyprus is essentially a rural problem

GROOTINGS (p 902) discusses the increase in malaria which followed the improvement in housing which was undertaken as an anti plague measure in the Dutch East Indies. Mosquitoes are more prevalent in the new houses than in the old which may be due to a better environment for them than formerly or the possibility that the biological equilibrium of the population has been disturbed by the creation of breeding places during the construction of the houses may be the predominant factor. The procedures advised to prevent malaria arising from this necessary anti-plague house improvement will be given in the section on prevention. ROSIER (p 417) describes how this house improvement and reconstruction for the prevention of plague in Java has led to increased malaria. The factors are engineer

* The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1939, Vol 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

ing works, an immigrant population, an endemic area, borrow pits and rubbish heaps.

LEGENDRE (p. 511) in Cambodia found *falciparum* and vovax infections occurring sporadically in the thickly populated areas on river banks. FARNAUD (p. 808) reports that malaria in the deltas and on the coast of Indo-China is much less severe than in the hyperendemic hilly interior but that severe outbreaks may occur. A sudden increase in morbidity has been accompanied by an equally sudden increase of salt water breeding anophelines, of which the most important is *A. sinensis*.

VICKERS and STRAHAN (p. 416) report that Alor Star in Kedah, in spite of rice cultivation, swamps and abundance of anophelines is relatively non-malarious with spleen and parasite rates of 1.9 and 2.3. Rice cultivation in hilly areas on the other hand, is sometimes associated with hyperendemic malaria. LEFÈVRE (p. 809) in Laos finds malaria to be hyperendemic. The vast majority of the population are infected in early life and repeated infection leads to the immune state. Clinical manifestations are therefore uncommon and not severe. Healthy carriers abound and constitute a great danger to non immune immigrants. MARTIAL (p. 727) in Tonking found malaria to be most prevalent near the limestone hills and most severe amongst the immigrant Annamese population. Incidence diminishes when temperature falls below 18°C. and increases when it rises above 20°C.

GENEVRA, TOUMANOFF and HOANG-TICH TRY (p. 806) observed in a severe epidemic in a village of Tonking that the highest spleen rate was only 24 per cent. whereas the parasite rate was 90 per cent. and the gamete rate over 80 per cent. *P. falciparum* was most in evidence.

ANDREWS and CHU (p. 509) near Shanghai found parasites in the blood of 8.0 per cent. of school-children in autumn and 1.7 per cent. in spring. In all 7,766 bloods were examined.

SPILLENGREY, DE BOCK and KRAAN (p. 659) regard as good carriers those who show one parasite or more per 100 leucocytes. They investigated 31 families in North Holland and found that the proportion of good carriers was about equal in children who had and those who had not had fever that year but that it was much higher among adults who had had fever than among those who had not. KLIGLER and MER (p. 99) point out that in the case of *P. falciparum* and *P. malariae* the most infective carrier was not necessarily the one with the greatest number of gametocytes. CLARK and LOMP (p. 806) found that a certain number of carriers were missed during surveys in an unimmunized area in Panama, and that these are enough to keep up transmission in communities where drug treatment was used and where anti-mosquito measures were impossible. Crescent carriers were more numerous in the atabrin-plasmoquine treated group than in the unsupervised controls who received only quinine but that may have been due to heavier infections. Only 8 of 59 infants under 1 year were infected. SAUTET (p. 259) finds that adult foreigners in Corsica often play as gamete carriers, an important part in spreading infection. Children are also such carriers. Vovax infections occur mainly in spring *falciparum* in autumn and *malariae* in winter but the latter are much less common than the two former.

SCHWETS and GERONNET (p. 804) examined a large number of blood films, especially of children in the Belgian Congo. In the intensely malarious regions infection begins a few weeks after birth.

is almost universal at 6 months and the parasite index decreases gradually after the fifth year. *Falciparum* infections are the most common, *vivax* the least and *malariae* intermediate. *Falciparum* infections can be found at all ages. In the coastal region incidence is less though the general trend resembles that described above. DUREN (p 22) in the Belgian Congo found that the mean annual morbidity rates for Europeans fell from 220 per thousand in 1918-20 to 141 in 1931-34 and the mean mortality from 6.39 to 1.82 in the same periods. In the native population malaria causes 16.5 per cent of deaths in the age group 0-3 years. At high altitudes where malaria is only mildly endemic serious epidemics with severe and fatal cases of haemoglobinuria occur for example in Ruanda Urundi.

LEGA RAFTAELE and CANALIS (p 509) in Italian East Africa found that malaria was very prevalent at altitudes of 1 000 to 1 200 metres, with spleen rates up to 90 per cent. *Falciparum* infections were the most common. In the plains incidence was lower but still great with predominance of *vivax* infections. MIRA (p 610) found in the inhabitants of part of Abyssinia spleen indexes from 4 to 33 per cent and parasite indexes from 10 to 12. *Vivax* infection was commoner than *falciparum*. PIETRO (p 510) in Eritrea found three-quarters of the malaria to be due to *falciparum*, the remainder to mixed *falciparum* and *vivax* infections. Abnormal Nile floods probably accounted for the increased prevalence in Egypt in 1935 (p 96).

ROOT and ANDREWS (p 805) in Grenada found that the spleen index alone was not a reliable index of malaria prevalence. Other causes of splenomegaly were found. The incidence of malaria is not high [See also WILSON this Bulletin 1935 Vol. 32 p 109].

FAUST (p 811) from mortality records in the Southern United States for 1936 found an increase in three States especially the coastal regions but a decrease in the Mississippi delta. The average mortality is higher than 10 years ago and the disease is spreading but the factors causing this are unknown. DAUER and FAUST (p 20) show that in the South East United States the mortality rates in 1935 showed a tendency to decline in the worst endemic areas and to increase elsewhere. FAUST (p 259) states that mortality data are very poor in the southern United States and pleads for greater accuracy in diagnosis, treatment and recording. Whereas it has been estimated that for each death caused by malaria there are at least 200 cases in one State only two cases were reported for each death. This is a serious discrepancy.

Actiology

BOYD and KITCHEN (p 263) found that the incubation period of *falciparum* infections transmitted by *A. quadrimaculatus* varied from 6 to 25 days and that the variations were due to the different strains used.

ALEXEIJEW and KOVACHOV (p 101) found evidence of binary fission in the female nucleus in *falciparum* crescents. CASINI (p 27) describes senescent forms of crescents in *falciparum* infections which have lost the power to infect anophelines. They most commonly occur in chronic cases.

RAFFAELE and LEGA (p 418) recognize morphological characteristics which are described justifying the appellation *P. falciparum* var. *aethiopicum* of a strain found in Italian East Africa. In this strain the

ring forms are less constantly circular the chromatin granules coarser and pigment appears later than in typical forms. Also the crescents are shorter and broader and, especially, the male gametocytes less falciform flagellation occurs earlier in 3-5 minutes as compared with 15-20 for typical strains.

NUCCIOTTI (p 895) notes that the designation *immaculatum* has been given to the strain of *falciparum* commonly seen in Italian East Africa. It is strictly comparable with the Italian strain from the point of view of relapse production following primary infection.

BOYD and KITCHEN (p 425) infected two patients simultaneously with *P vivax* and *P falciparum*. At first *falciparum* was most in evidence with characteristic clinical features. Later *vivax* was dominant and *falciparum* decreased in numbers suggesting antagonism but in one case *falciparum* reappeared and both remained at a low equal density. ANTSCHELEWITSCH (p 39) found that blood containing parasites and mixed with various solutions containing glucose citrate and other salts may remain infective if used for transfusion up to the eighth day. *Vivax* infected blood was largely used in this investigation, which is important both in the matter of transfusion and as a means of inducing therapeutic malaria.

IVANIĆ (p 101) describes stages in the nuclear division of *P vivax* which take place by a process of mitosis.

BOYD and KITCHEN (p 261) think that the frequency of renewed clinical activity after the cessation of the primary attack varies with different *vivax* strains. They worked with the McCoy strain.

FRIEDMAN (p 100) found certain changes in *P vivax* examined in dry blood films stained by various Romanowsky methods, which produced resemblances to *P ovale*, *P cameroni* and parasites of monkeys. HAGER (p 101) found that a strain of *P ovale* during the course of repeated passages showed a tendency to assume characters of both *P vivax* and *P malariae* but does not consider that it is merely a variety of *P vivax*. ESKIN (p 814) describes a case of infection with *P ovale* in Russia the first contracted in Europe to be reported. *Vivax* infection was also present but the two could easily be distinguished, and in five successive passages through G.P.I. patients *P ovale* could be seen. The diagnosis was confirmed by WERNOV and HOARE.

CIUCA *et al* (p 428) record that 79.8 per cent of 158 general paralytics were successfully infected with *P knowlesi*. The illness produced was usually mild but HALLIF *et al* (p 429) show that immunity against reinfection was absolute. Patients treated by *vivax* infection were completely resistant to *vivax* and partially so to *knowlesi*. The authors therefore postulate both common and specific antigenic factors.

BARBER and RICE (p 724) in Poona found the following percentages of splenomegaly in children harbouring the parasites named—*vivax* 57, *falciparum* 66, *malariae* 84 and mixed 100.

[A table showing the proportions of infection by the three principal plasmodia was constructed from the abstracts giving such information, but was considered to be too incomplete to be useful. Readers are referred to the original abstracts on this subject.]

Transmission

BEKLEMBICHEV and ZHELOCHOVITSEV (p 691) have found *A. maculipennis* as far north as lat. 66°N. Its southern extension in Asia and Africa is determined by the heat of the summer. POKROVSKI

and POLIKARPOVA (p 194) found that *A. maculipennis* is transported into cities on steamers on the Volga and consider that this fact undoubtedly has epidemiological significance.

In Normandy as a result of the study of the eggs of *A. maculipennis* ROUBAUD *et al* (p 571) consider that crossing has taken place between *typicus* and *atroparvus*. This has hitherto been supposed to be impossible.

MOSVA (p 189) records investigations into rate of development of two races of *A. maculipennis labranchiae* and *atroparvus* under controlled conditions of temperature. SAUTET (p 192) found that both *A. maculipennis labranchiae* and *A. elutus* in the hot weather in Corsica show a preference for outdoor existence and believes that malaria is contracted in the open air more commonly than is generally supposed. POLEZIAEV (p 190) shows that the average numbers of *A. maculipennis* seen varied indirectly with the intensity of light in the cowsheds and stables examined. CORRADETTI (p 426) investigated the food preferences of the races of *A. maculipennis* var *mescae* never exhibits Jugoslavia found that *A. maculipennis* var *mescae* never exhibits the leanings towards exclusive zoophilism which it does in other parts of Europe. RICE and BARBER (p 39) in Macedonia found that *A. maculipennis* and *A. superpictus* are attracted to domestic animals whereas *A. elutus* is indifferent as regards choice of human or domestic animal sources of blood. Sporozoite indexes were *elutus* 7.7 *maculipennis* 0.3 when the two species were collected on the same day in the same house or stable.

SWELLENGREBEL DE BUCK and KRAAN (p 425) in North Holland found that the natural rate of infection of *A. maculipennis atroparvus* is 118 times higher than that of *mescae*. In autumn the Anopheles spread malaria from man to man and the parasites are kept alive in man until the next transmitting season.

PAPADAKIS (p 195) investigated the biology of *A. superpictus* in Greece and (p 196) describes its breeding in warm shallow sunlight collections of water. STRATMAN THOMAS BARBER and CARTER (p 257) in Cyprus found infected *superpictus* in March probably surviving in overwintering females. The bulk of transmission takes place from June to September but some occurs in autumn. Winter transmission probably does not take place.

KLIGLER and MER (p 99) experimenting with *A. elutus* found that it was most susceptible to infection with *P. vivax* and least to *P. falciparum* though development was slowest in the case of *P. malariae*. Atebrin like quinine does not deprive crescents of their capacity to develop in mosquitoes.

DE BUCK (p 663) details observations on the secretions of the salivary glands and stomachs of *A. maculipennis Th. annulata* and *C. pipiens*.

DE MEILLOV (p 194) has been successful in maintaining *A. gambiae* in culture in the laboratory by using a large cage heated to 25°C and offering a small pig as food. He has (p 662) found evidence to suggest that providing *A. gambiae* can obtain blood every night it can survive continuous exposure to very low humidity (20 per cent at 26°C). The same author (p 662) in Northern Rhodesia found that *A. funestus* may fly up to 2.8 miles down wind. The breeding habits of *A. gambiae* and *A. funestus* are constant in different parts of Africa. GEBERT (p 193) in Mauritius found that to destroy the eggs of *A.*

gambiae in tanks, etc. in gardens, the common practice of emptying them for a few hours is insufficient. A period of 4 days is necessary.

Experiments were conducted in Bengal (p. 39) to discover why *A. culicifacies* the chief vector elsewhere in India, is relatively a failure as a vector in Bengal. It was found that breeding in the muddy water with aquatic vegetation usually found in Bengal was difficult. The investigation continues. SWEET (p. 85) found that *A. culicifacies* though the most prevalent anopheline in Mysore, is not strongly attracted to human beings as a source of blood.

SWEET and RAO (p. 426) recognize two forms of *A. stephensi*—the B or type form, first recognized in Bangalore, apparently anthropophilic and probably the urban vector and the M form, first obtained in Markanave apparently zoophilic and possibly the rural form and a poor vector. The authors propose for the latter the name *A. stephensi* var. *mysorensis*.

SEN (p. 188) gives the percentages of 11 species of anophelines caught in a total of 15 453 during one year in houses and cattle sheds in Bengal. For details the full table should be consulted.

LEFÈVRE (p. 801) shows that in Laos *A. minimus* breeds particularly in moderately hilly country but is rare in flat low-lying places. It is adaptable and can breed in stagnant as well as stream waters and this adaptability probably explains why in *minimus* areas malaria is constantly hyperendemic. Malaria transmitted by other species in Laos tends to be seasonal. TOUMANOFF (p. 568) found sporozoites and cysts of *falciparum* in *A. minimus* persisting after several feeds on buffalo.

GASCHEN and RAYNAL (p. 192) found that *A. nigus* in Indo-China is very definitely zoophilic. In the absence of human blood, *minimus* and *jeyporensis* feed on bovines. *A. acuminatus* is markedly zoophilic but in parts of Tonking shows anthropophilic tendencies. HU and YU (p. 197) found in Shanghai that *A. sinensis* showed a marked preference for domestic animals. CHANG (p. 197) in Kiao-chiao found that *A. sinensis* though multidentate frequently contains human blood. TOUMANOFF and HOANG-TICK TRY (p. 680) explain the anophelism without malaria found in the health resort of Chapa, Tonking by the zoophilic tendencies of the anophelines.

TOUMANOFF (p. 661) shows that rainfall is more important than other meteorological factors in determining the seasonal prevalence of anophelines in Indo-China.

GENEVRAI *et al.* (p. 809) in Tonking found that old borrow pits made during the construction of a bund were the most important anopheline breeding places. There had been a severe epidemic of malaria in Ha-tri, a village in the Tonking delta. Precipitin tests carried out on engorged mosquitoes showed that 41 per cent of *acuminatus* and 35 per cent of *hyrcanus* caught in human dwellings had fed on man and the small number of cattle had intensified the anthropophilism of the insects, which were breeding in large numbers.

BOYD KITCHEN and KUPFER (p. 424) found that *A. quadrimaculatus* can be simultaneously infected with *cruvi* and *falciparum* and can transmit both. ROZENBOOM (p. 807) found in Panama that *A. albatus* is refractory to local *P. falciparum* in contrast to the susceptibility of the Brazilian *albatus* to the Brazilian *falciparum*. The control of malaria still depends on the control of the only really dangerous vector *albatus*. BOYD CARR and ROZENBOOM (p. 659) as a result of experiments in the infection of Anopheles, consider that West Indian

strains of *vivax* and *falciparum* might spread if introduced into the south-eastern United States but that the United States strains would only spread to a limited extent if at all if introduced into Cuba or Panama.

BOYD and KITCHEN (p 195) experimenting with anophelines found that if the stomach wall is heavily occupied by *falciparum* cysts the mosquito will not mature as many infectious sporozoites as will a lightly infected mosquito. This is not the case with *vivax*.

WILLIAMSON and ZAIN (p 198) found that the developmental cycle of the two common malaria parasites and probably of quartan also can proceed to completion in *Culex blaesiorhynchus* but in the absence of proof of transmission no epidemiological conclusion is at present warranted.

[An attempt has been made to construct a list of all the *Anopheles* mentioned in abstracts during the year but since in many of the papers abstracted no mention was made of the capability of mosquitoes to transmit malaria and since without that information a list is of little value the idea has been abandoned. Readers are therefore referred to the original abstracts for this kind of information.]

Pathology

TALIAFERRO and MULLIGAN (p 25) discuss the origin of macrophages which they consider may arise from all cells retaining mesenchymal potencies of development and occur normally in various connective tissues. They do not agree with MALLORY regarding endothelial cells. Phagocytosis is non-specific during natural immunity but in acquired immunity it is in addition specific. When parasites are introduced into an immune animal there is a regional concentration of parasites and increased phagocytic action. Phagocytic activity, lymphoid hyperplasia and cytogenesis of macrophages are initiated in the spleen where they are most pronounced but also occur in the liver and bone marrow. RODHAIN and VALCKE (p 100) in severe *falciparum* infections found that the polymorphonuclear leucocytes especially the young forms were actively phagocytic towards the parasites. This activity is usually displayed by the monocytes.

СИТОВ (p 106) points out that in monkey malaria one morphological species may be made up of a number of different races or strains which do not protect to any extent against each other which vary in virulence and respond differently to therapeutic agents. Similar races have been met in human malaria. The host may have natural or acquired resistance. Thus *Silenus irus* appears to be naturally resistant to a *P. knowlesi* infection usually fatal to *S. rhesus*. Acquired resistance is seen in animals resistant to superinfection due to chronic infection with the same strain. In endemic areas highly susceptible children probably die leaving the more resistant to propagate their kind.

SCHILLING (p 429) discusses the possibility of the production of immunity in children by means of minimal treatment to allay symptoms without interfering with the production of immunity. He suggests lines on which observations should be conducted to determine whether such immunity is possible.

FAIRLEY (p 265) describes the structural and functional changes in the liver which can be attributed to malaria. These cannot be further abstracted. LINTWAREFF (p 24) as a result of the experimental

injection of haemoglobin from untreated malaria patients into guinea pigs came to the conclusion that in malaria there is a specific toxin which combines with haemoglobins and may cause nephritis.

FONG (p 576) found that in 1 012 patients treated with therapeutic malaria two died from rupture of the enlarged spleen though palpable spleens are very rare.

BARBER and RICE (p 724) describe Barber's index of microscopic anaemia based on the number of abnormal erythrocytes stainable in the manner characteristic of retained nuclear material. In thick films stained by Giemsa these appear as blue clouds of which the number indicates the grade of microscopic anaemia.

Clinical

There is some difference of opinion as to the value of examination of bone marrow in the diagnosis of malaria. Thus VOORHOEVE (p 102) established the diagnosis of malaria by sternal puncture in two cases where the blood was negative but MATSUMOTO (p 28) found that parasites are not more numerous in sternal puncture smears than in the peripheral blood and that the plasmodia showed no particular tendency to invade the younger forms of erythrocytes. The marrow picture was normal in cases of malaria. RAFFAELE (p. 514) found non pigmented forms of parasite in the bone marrow obtained by sternal puncture of a man infected 5 days previously with *vivax* sporozoites. Two schizonts were seen, one free and one included in a reticulo-endothelial cell and in one such cell two young trophozoites were found.

KEHR and HARBHAGWAN (p 83) found the average sedimentation rate in normal human subjects in India to be 6.4 mm. per cent. There is a considerable increase during acute phases of infection which cannot be correlated with temperature or splenic enlargement.

Henry's reaction—RAYNAL (p 264) considers this reaction to be of diagnostic value in malaria. It may be positive in non-malarial cases if the Bordet Wassermann reaction is strongly positive. It should be performed on donors for blood transfusion. The reaction is a good index of the success of treatment. VOLAVSEK (p 102) found that Henry's reaction always becomes positive in therapeutic malaria. The reaction is non-specific and is important in liver damage, tuberculosis, carcinoma and syphilis. D'ALESSANDRO (p 28) found that the reaction usually becomes negative after treatment by the Ascoli method. If negative at the beginning it becomes positive and then finally negative. AKASHI and NAKASHIMA (p 264) consider that melanin acts merely as an indicator and not as an antigen in Henry's reaction. The reaction is of great use in the diagnosis of malaria. VILLAIN and DUPOUX (p 27) regard the melanins as the best serological detectors of malaria. They have prepared an artificial melanin combined with iron which they designate M.A. which behaves almost exactly like Henry's melanin. PIKOU and OSKOVA (p 514) replaced the melanin of Henry's reagent by quinine chlorohydrate and other substances, which gave successful results. The reaction is not therefore an immunity reaction but is probably connected with a disequilibrium between the albumin and globulin fractions of the serum. Too much reliance should not be placed upon it in diagnosis. LIVIERATO *et al* (p 515) describe the preparation of an antigen substitute for Henry's melanin. BRUMPT and CHORINE (p 102) record that Henry's reaction in normal uninfected fowls is given in an intensity which in human malaria would be counted as positive. MAYNE (p 284) reports

a patient whose first paroxysm occurred a year after inoculation with a blood culture of *vivax* sporozoites BRACHTEL (p 656) has seen in Bohemia patients in whom malaria appears after long latent periods usually from 7 months to 1 year

BROWN *et al* (p 728) report the occurrence of the Arthus phenomenon from the bites of *Aedes aegypti* in a girl of 15 Other mosquitoes caused less severe reactions. Desensitization and passive immunization were only partially successful The child died of Hanot's cirrhosis.

FISCHER (p 813) describes a patient with a crop of petechiae which he considers to have been due to benign tertian malaria They disappeared under quinine treatment LORANDO *et al* (p 728) describe a patient in whom each attack of *vivax* malaria was followed by urticaria with purpuric patches. CONÇA and BRUCKNER (p 513) saw two patients with *vivax* infection who were admitted to hospital with fever acute abdominal pain severe headache and a generalized urticarial rash Recovery followed quinine treatment.

ACREE (p 24) details symptoms due to malaria which simulate primary disease of the alimentary tract and which are cured by anti-malarial treatment Gastric catarrh peptic ulcer enteritis ulcerative colitis dysentery cholecystitis appendicitis acute peritonitis or typhoid may be simulated and ulcers of the tongue vomiting cramps herpes, urticaria erythema petechiae purpura ulcers and furunculosis may be seen. CANOVA (p 812) reports 3 cases (in 8 000 treated for malaria) in which *falciparum* infection caused symptoms characteristic of appendicitis. All cleared up under treatment for malaria. [Might these not have been appendicular colic in association with malaria?] FARINAUD (p 262) shows that malaria can simulate biliary colic even after the removal of the gall bladder VAUTHEY and VAUTHEY (p 818) consider that in 15 of 100 patients at Vichy malaria was the cause of cholelithiasis and may have been a factor in 16 others. FLEISCHMAN (p 514) considers that malaria has only a predisposing action in the production of cirrhosis of the liver

AKASHI and YOSHIMURA (p 260) in Formosa report albuminuria in 36 per cent and acute nephritis in 10 per cent of 490 cases of malaria and polyneuritis in 7 of 411 cases

JUNIOR and BRANDÃO (p 657) quote 10 cases of malaria in which signs and symptoms appeared to indicate suprarenal involvement with asthenia arterial hypotension muscular pain and digestive disturbance and in one case bronze pigmentation. The prognosis under malarial treatment is much better than in suprarenal insufficiency due to other causes.

MANOHAR and KHOSRAWY (p 513) describe a patient in whom severe anal pain cyanosis, rapid pulse and low blood pressure marked the onset of an attack of malignant tertian malaria GIORDANO (p 656) found that of 415 patients repatriated from Italian East Africa on account of malaria 60 suffered from some form of cardiac disturbance especially acute dilatation

LEO (p 262) reports a case of gangrene of the foot in a patient who showed so heavy a *falciparum* infection that all the red cells were parasitized by two to four parasites.

JOURNE and AUBIN (p 263) describe a patient with psychosis probably due to *falciparum* infection who was cured by anti-malarial treatment. Alcohol may have played some part. LE ROY (p 186) reports the case of a man admitted to hospital in Tunis as suffering

from cerebrospinal meningitis. The C.S.F. however was normal and on the 8th day a heavy *falciparum* infection was discovered. Complete recovery followed quinine treatment. MORR (p 727) describes 2 cases of epilepsy following malaria and stresses the inflammatory disturbance in the brain due to circulating toxins which may include haemorrhages, destruction of ganglion cells and proliferation of neuroglia. Scar tissue may result. Symptoms may resemble those of meningitis and the destruction of brain substance may lead to many disturbances, including epileptiform attacks. WILLOUGHBY (p 513) describes a patient with *vivax* infection whose condition simulated severe chorea. The symptoms disappeared abruptly on treatment with quinine. ROGER and BOUDOURESQUES (p 187) report a case of malarial polyneuritis with paraplegia in a woman who had suffered from repeated attacks of malignant malaria. Cure followed antimalarial treatment. The onset occurred during a febrile attack and the parasite could always be demonstrated in the blood during any exacerbation of the symptoms. HOUSIAU (p 657) describes a case of neuritis of the right radial nerve with *falciparum* malaria, which cleared up under quinine treatment.

THOMAS and SYDENSTRICKER (p 812) in America found that all the deaths in 244 cases of malaria were due to *falciparum* infection with pernicious symptoms. The mortality of pernicious cerebral malaria was 11.86 per cent. of 78 cases. PRICE (p. 97) describes pernicious malaria in 24 children. Three had haemoglobinuria 18 were of the algid type, 7 died.

FONG (p 576) found that of 34 patients dying while undergoing therapeutic malaria, 11 died from acute malaria and that in 2 others the malaria had activated quiescent pulmonary tuberculosis.

GOLDEN (p 574) considers that the primary effect of malaria in general parents is to destroy the spirochaetes.

BOYD and KITCHEN (p 576) used *P. falciparum* for therapeutic malaria owing to the immunity to *vivax* shown by negroes in Florida. The results were satisfactory. Infections during the winter had long incubation periods, short attacks and greatest liability to renewed activity. Infections must be closely watched and quinine given if the temperature exceeds 104-105° or the parasite count is more than 100 000 per cmm. Thorough intensive quinine treatment after the primary attack makes recurrences unlikely. BOHLS and LAWRENCE (p 574) in therapeutic malaria found that with the Mc-Coy strain of *P. vivax* the malaria can, under careful supervision, be allowed to terminate spontaneously and that very few relapses occur.

LOTTE (p 733) maintains that in acute infections vitamin C is used up more quickly than normally and that in benign tertian malaria doses of 1,000 mgm. of the vitamin given intravenously prevent rigors and give a feeling of comparative well-being. The vitamin has anti-toxic and anti haemolytic powers. The author discusses therefore the question of vitamin C therapy as an adjunct in blackwater fever. All recent benign infections give rise to a positive Wassermann reaction.

[To be continued]

C IV

RABIES

A REVIEW OF RECENT ARTICLES XXX*

I. *Virus*

KLIGLER and BERNKOPF¹ have failed to convince themselves that the virus of rabies multiplies in the allantois of the chick embryo. In no case did they succeed in obtaining serial passage beyond the third generation. Whether the virus can be adapted to the chick and its virulence enhanced by passage is a subject for further investigation.

Attempts of the same type have also been made by VEERARAGHAVAN and PHILIPPS² without success. 101 eggs were inoculated but no lesions which were definite enough to be considered as specific were observed. It was not possible to demonstrate the presence of the virus after the first egg passage.

Under the same conditions BADENSKI and BRUCKNER³ have failed to cultivate the virus of AUJESZKY'S disease. In one series the virus disappeared at the 7th passage and in another at the 3rd. They found no evidence of multiplication.

In a second communication⁴ from further experiments with AUJESZKY'S virus they found that a certain degree of multiplication did occur. A maximum was reached in 36 hours and this was followed by a decline which they believe to be due to a process of defence on the part of the membrane.

GERLACH⁵ has applied the fluorescent microscope to the study of the elementary bodies which are believed by some (BABES KOCH etc.) to form a part of the life-cycle of the virus of rabies. A number of microphotographs of these are reproduced. He finds these bodies in the meninges in the central nervous system in the salivary glands and in the serous exudates of the body cavities of animals which have succumbed to street or fixed virus rabies. He has found the same bodies in chorio-allantoic cultures and also in cell-free artificial media cultivated anaerobically. He believes that these bodies are true virus bodies. He states that they are not present in normal animals nor in other virus infections nor even in infections with other neurotropic viruses such as poliomyelitis or AUJESZKY'S disease.

⁴ BADENSKI (G.) & BRUCKNER (L.) Sur l'évolution du virus de la pseudorage sur la membrane chorio-allantoïde de l'embryon de poulet.—*C. R. Soc. Biol.* 1933 Vol. 129 No. 27 pp. 408-409

⁵ GERLACH (F.) Virusstudien bei Tollwut.—*Zeitschr. f. Infektionskr. u. Haustiere.* 1933 Aug. 12. Vol. 53 No 4 pp. 279-280 With 7 figs. [10 refs.]

Four highly virulent strains of street virus isolated from patients who have died in spite of treatment have been studied by JOXKESCO⁶. Each has been subpassaged and fixed in the rabbit and with subpassage in each case Negri bodies at first numerous, disappeared, as indicated in the adjoining Table in which the figure entered is the incubation period in days, and + or — indicates the presence or absence of Negri bodies.

	Number of passage										
	1	2	3	4	5	6	7	8	9	10	11
Virus Z	{ 11 +	{ 4 —	{ 3 —	{ 3 —							
T	{ 10 +	{ 10 +	{ 10 +	{ 6 +	{ 4 —	{ 4 —	{ 3 —	{ 3 —	{ 3 —	{ 3 —	{ 3 —
B	{ 12 +	{ 10 +	{ 9 +	{ 6 +	{ 4 —	{ 3 —	{ 3 —	{ 3 —			
H	{ 12 +	{ 10 +	{ 9 +	{ 9 +	{ 9 +	{ 9 +	{ 5 +	{ 5 —	{ 4 —	{ 3 —	{ 3 —

All four strains were highly pathogenic when administered subcutaneously to mice (mortality 80 per cent). They were also highly pathogenic on intracerebral inoculation into rabbits infecting in dilutions of 1/700 000 1/500 000 1/300 000 and 1 in 400,000 respectively. Each strain caused symptoms of excitation in the rabbit. There was no evidence of correlation between the incubation period in man and that in the first passage rabbit. These appear to be examples of strains of street virus which already in nature are highly adapted to the central nervous system.

It is well known that the rapid drying of a thin layer of emulsion containing rabies virus gives rise to a powder which conserves its virulence for many months. REYLINGER and BAILLY⁷ have studied the effects of exposing the powder so obtained to various temperatures. It appears that the powder remains potent after 2 minutes at 105°C., 3 minutes at 104° 4 minutes at 103°. One remembers in comparison that ordinary undried emulsions lose virulence after exposure for 60 minutes at 50° and 30 minutes at 60°C. The authors are of opinion that this loss of virulence in suspensions is not due to desiccation but to autolysis. The fact that dried virus does not lose virulence shows that desiccation does not attenuate but rather conserves virulence. They finally remark that the fact that the virus can support temperatures of 105°C. is not in favour of the view that the virus is protozoal in nature but rather that it is chemical.

⁶ JOXKESCO (Démètre). Etude de quatre souches de virus des rues isolées de cas pour lesquels le traitement antirabique a échoué.—*Ann. Inst. Pasteur* 1936. Nov. Vol. 61. No. 6. pp. 827-835. With 1 fig. [14 refs.]

⁷ REYLINGER (P) & BAILLY (J). La desiccation est-elle un facteur d'atténuation du virus rabique?—*C. R. Soc. Biol.* 1938. Vol. 129. No. 25. pp. 133-134.

In a subsequent communication⁸ the same authors show that these properties are not peculiar to rabies virus. The virus of Aujeszky in fresh suspension loses virulence when kept at 60 C. for from 45 to 50 minutes but in the dry powdered state survives for 2 minutes at a temperature of 104.5°C. The virus of equine encephalomyelitis in fluid suspension can stand a temperature of 50°C for 70 minutes but not 51 C for 10 minutes whilst in powder it withstands 112° for 10 minutes.

The fact that man in contradistinction to other mammals only quite exceptionally contracts Aujeszky's disease (this *Bulletin* 1938 Vol 35 p 643) has led NICOLAU CRUVEILHIER TRUCHE KOPCOWSKA and VIALA⁹ to investigate the resistance of the chimpanzee. Successful inoculation of one of these animals had been achieved by three of these authors (this *Bulletin* 1938 Vol 35 p 169). On the third day tremors were observed and temperature oscillated on the eighth day blood was withdrawn and proved virulent when inoculated into the brain of a rabbit. On the 15th day the chimpanzee presented no abnormal symptoms and was killed. Inoculation of two rabbits with brain substance did not reproduce the disease. Histological examination of the brain showed nuclear changes in neurones and glia cells. Chromatin was rarefied and clumped inclusions interpreted by the authors as masses of degenerated inframicrobes were observed. The authors believe this to have been a mild case of the disease characterized by oscillating temperature tremors loss of appetite and ending in cure by auto-sterilization.

In a further communication KOPCOWSKA and NICOLAU¹⁰ illustrate and describe a toxoplasmic cyst found in the cerebrum of the same animal.

GORET and MARIETTE¹¹ add the ferret to the long list of animals which can be infected with Aujeszky's virus. Intraocular intra-cerebral and intramuscular injections were alike successful in giving rise to the disease in this species.

The reviewer would draw special attention to a very comprehensive summary of Aujeszky's disease by GALLOWAY¹² of the National Institute of Medical Research. The treatment of the subject is excellent in every way and is based upon a bibliography of 97 communications.

It was stated by BABES in his treatise that two persons who had neither been bitten nor scratched but had felt the hot breath of a rabid wolf on their faces subsequently succumbed to rabies.

of the whole dog population of Singapore island the number of which was estimated at about 13,000. Between August and November 41 dogs brains were sent to the laboratory for examination, and 12 proved to be positive. The last positive result was obtained in November. The number of human patients treated in 1937 was 169 as compared with 21 in the previous year. No deaths occurred but one case of post vaccinal paralysis with symptoms of peripheral neuritis of the beriberi type is recorded. The vaccine administered was a 2 per cent emulsion of fixed virus sheep's brain in 0.5 per cent. carbol saline.

The sterility of cords utilized for the preparation of dried cord vaccines and of brains utilized for the preparation of phenol vaccines (Semple) has been studied by DODRISO²² at the Pasteur Institute of Hanoi. Of the former the percentage of contaminations during the hot weather was 18.3 and during the cold season 13.8. Of the latter the percentages of contaminations were 3.8 and 3.7 during hot and cold seasons respectively. Brain and cords were taken from the same animals. It appears that the brain is more resistant to contaminating infection than is the cord.

EDWARDS²³ puts forward evidence in favour of the view that treatment is unnecessary in the case of a person bitten by a dog which remains alive and well for 10 days after it inflicted the bite.

1. Rabies in Animals.

The problem of the spread and control of rabies in the South American cattle ranches is one of greater economic importance than may be realized. In a much condensed but very illuminating paper MOLINA²⁴ discusses the situation as it exists in the Matto Grosso. The following summarized Table shows the extent of the damage caused by the disease in the area served by the Pasteur Institute at Caceres (Matto Grosso).

Years	Cases of bovine rabies amongst		Total
	Unvaccinated	Vaccinated	
1934	5,700	193	5,893
1935	5,280	180	5,460
1936	2,430	345	2,775
1937	1,100	157	1,257
	14,510	877	15,387

The total number of cattle in the area in question is estimated at 115,000 so that the total incidence was about 1.09 per cent. in 1937. In certain ranches the incidence is greater for example in "Cachoeira."

amongst 2 500 vaccinated cattle 70 died or 2.8 per cent. It will be remembered that in these localities the disease is spread by the vampire bat and that naturally the distribution of the disease corresponds with the distribution of that vector. An intensive campaign of vaccination has been carried out in connexion with the Pasteur Institute at Caceres during recent years and the results of that activity coupled no doubt with measures against the bat are indicated in the above Table which shows that the incidence of cases in 1937 is approximately one-fifth of what it was in 1934. It is not possible to achieve complete vaccination of a whole herd. This is particularly difficult in breeding establishments where it is estimated that about 20 per cent escape vaccination on account of wandering over the prairies. The vaccine employed consists of 1 part of brain substance in 9 parts of phenol glycerine. The dosage is from 20–40 cc and this is easily tolerated. Animals which have received three such doses one each year appear to have acquired a solid immunity. In highly infected ranches the effects of herd inoculation do not persist for more than six months. In lightly infected ranches on the other hand single inoculations lead to the disappearance of the epidemic. The dominant factor controlling the size of an epidemic is not so much the density of the bovine population as the prevalence of the vampire bat. During the summer months the vaccine should not be kept for more than 40 days after preparation. The general results are as follows. In ranches situated within an infected area but themselves still uninfected vaccination of the herd has been absolutely efficient. When used in infected ranches within the infected area the effect is still great but eradication of the disease cannot be achieved. As a solid immunity can only be attained after three successive inoculations—a procedure which may be impossible in prairie country—complete eradication of the epizootic by prophylactic vaccination alone cannot be expected.

In a long critical review of rabies treatment in general and of the methods of control of the canine epizootic PENNA²⁵ discusses the various points which relate particularly to Rio de Janeiro. He recommends that in the case of animal inoculation dead vaccines should be used (phenol vaccine Semple) but that in the case of human beings a living vaccine (dried cords) should be employed. He draws attention to the dangers which may arise from the use of living vaccines on animals. Cases of *rage de laboratoire* may occur with serious results.

Further statistics regarding the prophylactic vaccination of dogs at Tunis relating to the year 1937 are reported by BALOZET²⁶. Amongst 1,829 primary and 782 revaccinations of dogs no failure has been recorded. With regard to curative treatment of 44 horses one died and of 32 cattle three died of rabies.

vi. Post Vaccinal Paralysis

BEACH²⁷ reports a case of painful paralysis of the extremities after antirabic treatment and asks the editor of the *Journal of the American*

TRYPANOSOMIASIS

PRÉCIS OF ABSTRACTS IN THIS SECTION

LESTER (p 204) shows that in Northern Nigeria sleeping sickness is most prevalent in the central part of the country. It is usually of mild type but produces lowered resistance to other diseases. A rapidly fatal toxæmic form without any sign of involvement of the nervous system and the classical form also occur. Recently there has been a spread into areas previously little affected. Treatment is by germanin or antrypol and trypanamide.

HOARE (p 205) gives a detailed account of the size, shape and position of the kinetoplast in mammalian trypanosomes. This cannot be further abstracted. He concludes that JACONO's classification cannot be applied to mammalian trypanosomes and that the generic name *Castellanella* is inadmissible.

CORSON (p 208) reports that further cyclical transmission of a strain of *T. gambiense* which has now been studied in this way for four years, by *G. morsitans* in monkeys has not resulted in change of virulence or morphology. Direct transmission through monkeys, guinea-pigs and white rats, however has led to certain variations. As a result of maintaining a strain of *T. rhodesiense* in sheep by cyclical passage through *G. morsitans* for almost four years he (p 208) concludes that *T. rhodesiense* is a parasite not only of man, but also of wild and domestic animals in sleeping sickness areas and may retain its infectivity for man for several years at least. He recognizes differences between individuals in resistance to infection, and describes the local swellings caused in man by trypanosomes at the site of infection. Working with a strain of *T. rhodesiense* the same author (p 210) found that no change in virulence occurred as a result of prolonged passage through ruminants. Flies fed on a reedbuck infected with this strain frequently showed infected salivary glands, no such glands were found in flies fed on a similarly infected gazelle. He also (p 210) found that the cerebrospinal fluid of 22 of 27 monkeys infected with *T. rhodesiense* was infected. In one the duration of the disease was only 19 days, in the remainder it was from 1½ to 7 months. In man early diagnosis and treatment are of importance in view of the possibility of early cerebrospinal involvement.

VAN HOOFF *et al.* (p 211) found that drug resistance of *T. gambiense* to Bayer 205 is unstable, decreasing on mechanical passage and on cyclical passage through *G. palpalis*. LAUNOV and LAGODSKY (p 212) found that a trypanamide-resistant strain of *T. oxymurum* was less sensitive to antimony than the normal strain. LAUNOV (p 212) found that the natural chemo-resistance of *T. congolense* is not identical with the artificial chemo-resistance of *T. oxymurum* since the reaction of these in mice was not the same under treatment with certain drugs.

HALBERSTADTER (p 213) measured the dose of X rays necessary to cause loss of motility and infectivity in *T. gambiense*. JAIDOT (p 213) found that *T. equiperdum* and *S. recurrentis* remained alive after cooling to -260 °C.

CARPANO (p 214) recognizes that trypanosomes can be arranged in series from those essentially blood parasites (*T. evansi* and *T. vivax*) to the almost exclusively tissue parasites (the leishmanias).

GHIDINI (p 214) notes the distribution of *Glossina* in Italian East Africa.

TALIAFERRO (p 214) found that in *T duttoni* as in *T lewisi* infections a specific reproduction inhibiting antibody, ablastin and a specific trypanocidal antibody, both passively transferable are found in mouse serum. A group reaction between *T duttoni* and *T lewisi* and their ablastins occurs *in vitro*.

FRENCH (pp 215-216) discusses the changes in blood sodium potassium calcium chlorine and inorganic phosphorus in *T congolense* and *T brucei* infections.

FOURNIAIS (p 216) points out that signs of trypanosomiasis may only appear after the return of infected persons to Europe.

GUIBERT and BOSCH (p 216) emphasize the importance of bone marrow examination in diagnosis. It may be positive when blood and gland juice are negative. JOSPIN and GALLAIS (p 217) also describe a patient whose bone marrow was positive when other examinations were negative. THIROUX (p 217) emphasizes that the inoculation of monkeys with blood is a very delicate test.

BROWN and BROOM (p 217) studying the red cell adhesion test found that standard concentrations of red cells and trypanosomes are necessary to produce constant results and complement must be present. Certain human red cells will not adhere to sensitized trypanosomes. BROWN (p 218) found that in mice the electrical charge of polymorphic trypanosomes undergoes a reversal of sign if relapse occurs after spontaneous cure. The nature of the host apparently has a definite effect upon the sign of the change of trypanosomes. A simple test is described for determining the sign, positively charged trypanosomes becoming adherent to the red cells.

PARKIN (p 219) records instances of spontaneous recovery in animals infected with *T vivax* and *T congolense*.

MASSEGUET (p 220) has written a general account of treatment.

HAWKING (p 220) analyses the trypanocidal action of trivalent arsenicals and acriflavine. The reaction probably occurs in three stages: fixation of the drug, secondary chemical reaction and death of the trypanosome. KING, LOURIE and YORKE (p 221) obtained permanent cure in approximately 100 per cent of mice and rabbits infected with a laboratory strain of *T rhodesiense* by the use of *n*-undecane-1, 11-diamidine. This drug has also a definite action on human simple tertian malaria. Several aromatic amidine and guanidine compounds showed trypanocidal action *in vitro* and some produced cures in mice. LOURIE and YORKE (p 221) describe drug resistance in trypanosomes. Each of the four types of resistance is specific for its own group of chemical compounds. The four types are: (a) resistance to the aromatic compounds of arsenic and antimony and to acriflavine; (b) Superadded tartar emetic resistance; (c) Resistance to Bayer 205; (d) Resistance to the amidine and guanidine compounds.

VAN RENSBURG (p 222) found that surfen C caused serious local reactions in bovines on intramuscular injection and was ineffective against *T congolense* infection. BIOZZI (p 223) found that various oligodynamic solutions and colloidal preparations of metals possessed therapeutic properties.

BROWN (p 223) shows that in parts of Uganda an almost perfect equilibrium between *T gambiense* man and *G palpalis* has been reached. He discusses bush clearing and other means of control. Antypol in 1 gm. doses can protect clearing gangs for three months. NASH (p 224) considers that in Northern Nigeria (unlike East Africa) it would be inadvisable to practise densification of woodland by fire.

exclusion in *G. morrisians* belts. It could only be successful in the south where a cooler moister climate makes tsetse prefer open conditions.

TALICE and various others (p 225 *et seq*) describe early cases of Chagas disease in Uruguay. Oedema of the face, dacryoadenitis, cervical and other adenitis, thyroid enlargement, anaemia, leucocytosis with relative mononucleosis and slight splenic enlargement were among the features noted. "Sulfanil" was beneficial in one case. MAZZA *et al* (p 227) describes the pathological appearances found post mortem in a case of chronic Chagas disease. LONO *et al* (p 228) found the incidence of thyroid enlargement in certain parts of the Argentine to vary from 23.34 to 45 per cent. of those examined. This is interesting in view of the importance attributed to this condition in Chagas disease.

CARDOSO (p 228) showed that metacyclic forms of *T. cruzi* in faeces of *T. infestans* can pass through intact mucous membranes and scarified skin. Infection by bite occurred in one instance, possibly owing to regurgitation from the insect's intestine or contamination of the mouth parts. DIAS and TORREALBA (p 229) found crithidial and metacyclic forms of *T. cruzi* in the duodenum and rectum of *Eutritoma maculata*, a natural vector of infected *Triatoma* in Santiago province. (p 229) gives the percentages of infected *Triatoma* in one area. Forty-five per cent. were infected in one area.

TALICE (p 230) obtained a positive result with the xenodiagnostic test in a patient regarded as suffering from a reinfection. DIAS (p 230) reports that two patients who were in the chronic stage of Chagas disease in 1922 both gave positive xenodiagnostic tests with *Paratrypanosoma (Triatoma) marginatus*. MAZZA (p. 231) gives instructions for laboratory diagnosis, including the xenodiagnostic procedure.

TALICE (p 231) found cats to be naturally infected in Uruguay. COLBERTSON and KOLODY (p. 231) found complete immunity in rats which have recovered from *T. cruzi* infection. C II

LESTER (H. M. O.) The Progress of Sleeping Sickness Work in Northern Nigeria.—*West African Med J* 1938. Oct. Vol 10 No 1 pp 2-10 With 1 map

In a previous paper [this Bulletin 1933 Vol. 30 p 430] the author described the history of sleeping sickness in Northern Nigeria up to the end of 1931 and the train of events which led to the adoption of the French system of mass survey and treatment. At that time it was thought that the areas of epidemic sleeping sickness were quite circumscribed, but the first year's work of the survey system in 1931 showed that the position was much more serious than had been thought previously.

By the beginning of 1938 some 2,200,200 people had been examined and about 300,000 cases found and treated. Investigations into the incidence of the disease have now been made in every province in Northern Nigeria. The main epidemic belt is confined to the central part of the country viz Zaria Province, Niger Province, the Southern parts of Katsina and Kano Provinces, and parts of Benue and Plateau Provinces.

Taken as a whole the disease is of a mild type. Lester states that three types of the disease are met with —

(a) The commonest is a mild form which often constitutes more than 95 per cent. of the cases met with. After initial fever and headache the

patient reaches a stage where the disease and his resistance to it appear to have obtained a state of equilibrium. He suffers from periodic attacks of headache and fever and a certain amount of weakness. The cervical glands are enlarged, there are transient signs of toxæmia, such as puffiness of the face, swelling of the limbs, and occasional albuminuria. The patients are below par mentally and physically, and may remain in this state for years. They have a lowered resistance to other diseases so that the death rate among them is higher than it should be. It is this lowered resistance which is at the root of the very real depopulation which has occurred in some of the more heavily infected areas.

(b) In the second type which is much rarer toxæmia is the salient feature. Patients complain of headache, fever and weakness, oedema is common and a certain proportion become completely waterlogged. The progress of the disease is rapid, the patients dying without any sign of involvement of the central nervous system.

(c) In this type the disease behaves as it should do according to the text book description. Sooner or later the nervous system becomes involved extensively and the patient reaches the characteristic sleeping stage.

The proportion of cases in the three classes varies in different epidemics, but almost always the first type preponderates. In the more virulent epidemics the second and third types are relatively more numerous than in the milder ones.

Lester states that all the evidence available suggests that there has been a disconcerting spread of the disease into areas previously little affected. The disease has become epidemic recently in many places where it was previously endemic. There are three chief causes for this rise: (1) the change in the habits of the people consequent on pacification and settled rule, (2) the increase in transport facilities, (3) the employment of gangs of labour for railway constructions, mining and roadmaking.

Therapeutic measures—At first the disease was treated with trypanamide. The results were on the whole good, but ocular disturbance and arsenical dermatitis, although comparatively rare, gave a good deal of trouble.

References have already been made [this *Bulletin* 1934 Vol. 31 p. 570] to a very serious accident which occurred at one centre in 1932, many of the patients becoming violently ill after the first 2 gram dose, some of them dying of acute arsenical poisoning in from three to seven days and others becoming blind. It was later observed that toxic symptoms only occurred when boiled and filtered water was used instead of distilled water. The issue of portable stills to all sleeping sickness teams overcame this difficulty.

Towards the end of 1934 the present system of treatment with three 1 gram doses of germanin or antrypol followed by five 2 gram doses of trypanamide was introduced.

The rest of the report which must be studied in the original by those interested, consists of an account of the work of the sleeping sickness teams and a description of the present organization. *W. Yorke*

HOARE (Cecil A.) *Morphological and Taxonomic Studies on Mammalian Trypanosomes. V. The Diagnostic Value of the Kinetoplast.*—*Trans Roy Soc Trop Med & Hyg* 1938 Nov 26. Vol. 32. No. 3 pp. 333-342. With 12 figs. [11 refs.]

This paper is an attempt to bring together and to correlate the data concerning the features presented by the kinetoplast in various species

Differential Characters of the Kinetoplast in *Leishmania trypanosoma*

*Only two specimens of this species were available.

*Only two specimens of this species were available.

of mammalian trypanosomes. The term kinetoplast is employed in its original sense to denote the kinetonucleus alone without the blepharoplast. The material forming the basis of the study consisted of blood films stained by one of the Romanowsky methods of 14 species of mammalian trypanosomes. The characters of the kinetoplast examined were its shape size and position in the body. The author summarizes his observations in the above Table.

The differential diagnosis of the various trypanosome groups and species on the basis of the characters of the kinetoplast (as shown in this Table) can be stated as follows —

I *Lewis* Group

Kinetoplast large (1.0 to 1.4 μ) shape rounded position subterminal or subcentral never terminal

(1) *T. lewisi* kinetoplast typically elliptic in outline position subterminal, far from posterior end of the body

(2) *T. theileri* kinetoplast typically circular in outline position subterminal far from posterior end of the body in all and marginal in majority

(3) *T. cruzi* kinetoplast very large typically irregularly circular in outline position subterminal near the posterior end of the body. Owing to its size and position it is in contact with both sides of the body

(4) *T. evansi* (from vole) kinetoplast typically circular in outline position subterminal in a few marginal

(5) *T. melophagium* (ovine) (available material too scanty for comparison included in the table as an illustration of trypanosome with large kinetoplast in subcentral position)

II *Lucas* Group

(6) *T. vivax* and (7) *T. uniforme* distinguished from the remaining three groups of pathogenic trypanosomes by the large size of the kinetoplast (1.1 μ) its shape is always rounded more or less regularly circular or elliptic in outline position terminal or subterminal, in a fair number also marginal

III *Congolense* Group

(8) *T. congolense* and (9) *T. simiae* kinetoplast of medium size (0.7 to 0.8 μ) (considerably smaller than in the *Lucas* group but slightly larger than in the *Brucei* group) shape may be rounded or rod-like position in great majority subterminal and marginal. When the arrangement is marginal the rhizoplast of the flagellum frequently starts from the posterior part of the kinetoplast and the latter if elongated usually lies more or less parallel to the long axis of the body (cf *Brucei* group)

IV *Brucei* Group

(10) *T. brucei* (11) *T. rhodesiensis* and (12) *T. gambiense* kinetoplast small (0.6 μ) usually rod-shaped position in the majority subterminal, and in a fair number marginal. In the latter case the kinetoplast, if elongated usually lies transversely to the long axis of the body while the rhizoplast in most cases starts from the anterior part of the kinetoplast. The last two features may help to distinguish the stumpy trypanosomes of this group from *T. congolense* (v. supra)

V *Evansi* Group

(13) *T. evansi* and (14) *T. equiperdum* as regards the kinetoplastic characters, the above members of this group do not differ in any respect from those of the *Brucei* group but *T. equinum* (not shown in the table) differs from all other trypanosomes in the absence of the kinetoplast.

CORSON (J F) Observations on the Pathogenicity for White Rats of a Strain of *Trypanosoma rhodesiense*—*Trans Roy Soc Trop Med & Hyg* 1938 Nov. 26. Vol. 32. No 3 pp 343-345

A strain of *T. rhodesiense* was obtained in October 1934 by feeding laboratory-bred *Glossina morsitans* on an untreated patient infected in Kahama. The strain was transmitted through sheep by means of *G. morsitans* 24 passages having been made up to May 1938. At the 13th passage in October 1938 a branch line through antelopes was begun. Infective flies were isolated by feeding them singly on white rats and were used to infect man and various animals, including white rats. Inoculations of white rats were also made from time to time from infected animals and man. In all 177 white rats were infected by inoculation from 58 vertebrate hosts consisting of 17 men, 27 sheep, 9 monkeys and 5 antelopes and 197 rats were bitten and infected by 80 isolated infective *G. morsitans* which had become infected by feeding on 19 vertebrate hosts consisting of 1 man, 9 sheep and 9 antelopes. The blood of the rats was examined, but the virulence of the strain was estimated from the life of the rats and, to a less degree, by the incubation period.

The following are the conclusions—

White rats were used as test animals in an experiment to see whether a strain of *T. rhodesiense* would lose its infectivity to man or undergo other changes in its characters during maintenance in mammal animals. The rats were infected by the bites of isolated *G. morsitans* and also by inoculation from the infected animals and volunteers. No change in virulence was observed.

The infections in rats produced by inoculation and by the bites of flies which had fed on the same hosts were similar but those produced by the flies appeared to be rather more acute.

The infections of a reedbuck and a Thomson's gazelle were apparently similar as tested in white rats but when *G. morsitans* were fed on these animals those which fed on the reedbuck showed a large proportion with infected salivary glands, while no fly with infected salivary glands was found among those which fed on the gazelle. [V]

CORSON (J F) The Cerebrospinal Fluid of Monkeys (*Cercopithecus* sp.) Infected with a Strain of *Trypanosoma rhodesiense*—*Ann. Trop Med & Parasit* 1938 Aug. 2 Vol. 32 No 2 pp 197-199

Reference is made to the fact that PERUZZI (1928) [see also this Bulletin 1928 Vol. 25 p. 771] found trypanosomes in the cerebrospinal fluid of three monkeys (*Cercopithecus* sp.) between the 28th and 31st day of infection with *T. rhodesiense*.

During the year March 1937 to March 1938 monkeys of the same species as those used by Peruzzi were infected at Tinde with a strain of *T. rhodesiense* which was being maintained in various antelopes by means of cyclical transmission by *Glossina morsitans*. The monkeys were infected by flies fed on antelopes. As it was at first intended to note the duration of life of the monkeys observations to find the dates of infection of the cerebrospinal fluid were not made but the cerebrospinal fluid was examined in some of the monkeys and the trypanosomes and leucocytes were counted. The duration of the disease was reckoned from the day on which trypanosomes were found in the monkey's blood as the exact date of infection was unknown but the incubation period of the strain in question in these monkeys was usually 4 to 7 days.

The results of the examination of the cerebrospinal fluid of 27 such monkeys are given in a Table. In all but two of the animals the duration of the disease was between 2 and 7 months. In the remaining two it was 19 days and 1½ months respectively. In 19 of the 27 animals trypanosomes were found sometimes in large numbers by direct examination and in 3 of the 8 negative cases their presence was demonstrated by inoculation of the cerebrospinal fluid into rats. The leucocyte count was greatly increased in all but one of the 27 monkeys.

It is interesting to note that the animal in which the duration of the disease was only 19 days contained trypanosomes in the cerebrospinal fluid and that subinoculated rats became infected and the leucocyte count was 211 per cmm.

The author compares these results with some observations that have been made on man particularly those of KEEVILL [this *Bulletin* 1928 Vol 25 p 795] and of MACLEAN and FAIRBAIRN [this *Bulletin* 1933 Vol 30 p 108]. The general conclusion is that the cerebrospinal fluid may contain trypanosomes very soon after a person becomes infected and that consequently very early diagnosis and treatment are of importance.

II 1

VAN HOOFF (L.) HENRARD (C.) & PEEL (E.) The Stability of Bayer 205 Resistance in *Trypanosoma gambiense*—*Trans Roy Soc Trop Med & Hyg* 1938 Aug 23 Vol 32 No 2 pp 197-208.

The authors have investigated the stability of Bayer 205 resistance in *T. gambiense*. MURGATROYD and YORKE [this *Bulletin* 1937 Vol 34 p 532] working with *T. rhodesiense* and *T. brucei* have shown that Bayer resistance is very slow to develop and that the *rhodesiense* strain lost its Bayer-resistance after repeated mechanical transmission through mice but that the *brucei* strain kept its resistance unaltered after one cyclical passage through *G. morsitans*.

The work of van Hoof, Henrard and Peel with *T. gambiense* generally confirms that of Murgatroyd and the reviewer except that van Hoof and his colleagues observe a definite loss of Bayer resistance after a cyclical transmission through the tsetse fly.

The following summary is given—

It has been shown how *Trypanosoma gambiense* either a susceptible strain or an arsenic-resistant one may be rendered resistant to Bayer 205. The experience acquired while treating numerous patients has proved that from time to time trypanosomes are found which are naturally resistant to 0.01 gramme but hardly ever to 0.02 gramme per kg. No strain has yet been isolated that did not respond to 0.10 gramme per kg. It must be concluded, therefore, that the Gemena strain had undergone true modifications.

MURGATROYD and YORKE (1937) have been able to prove that successive mechanical passages reduce drug resistance till it completely disappears. Their investigations extended over a period of 4 years during which a considerable number of passages through mice were made. The observations conducted at the Laboratory of Leopoldville were discontinued as soon as it was noted that passage through guinea-pigs was bringing about a decrease in Bayer resistance and the conclusions of these authors had been confirmed. It was further established that transmission through a different host, such as the monkey considerably accelerates the loss of Bayer-resistance.

From the practical point of view of prophylaxis of sleeping-sickness caused by *Trypanosoma gambiense* this loss of resistance is of much less

with the trypanosomes and spirochaetes thus cooled became infected. It follows therefore that the parasites had survived a fall in temperature (from the body temperature) of over 300°C. [17]

CARPANO (Matteo) Sulla morfologia dei tripanosomidi in rapporto all'ambiente [Morphology of Trypanosomes in Relation to Environment].—*Riv di Parassit* Rome 1938. May Vol. 2 No. 2 pp 81-90 With 1 plate [11 refs] English summary (10 lines)

Having encountered various cultural forms of *Trypanosoma theileri* in haemorrhagic lesions of the brain of an ox and later in a similar lesion of a lymphatic gland of another ox, the author reflects that, as regards the tendency to invade the blood stream or tissues, trypanosomes can be arranged in series from those forms which are essentially blood parasites (*T. cruzi* and *T. evansi*) to the leishmanias which are almost exclusively tissue parasites. C M Wernon

GHIDINI (Gian Maria) Le glossine dell'Africa Orientale Italiana. [The Tsetse Flies of Italian East Africa].—*Riv di Biol Colon*. 1938 Feb Vol. 1 No. 1 pp. 53-71 With 6 figs [15 refs] English summary (5 lines)

The paper extends our limited knowledge of the distribution of *Glossina* in Abyssinia and Italian Somaliland.

Among the new records published perhaps that of *G. morsitans* on the R. Didezza (a tributary of the Blue Nile, about 9°N) is the most interesting. Recent work has added to our knowledge of *Glossina* in Italian Somaliland particularly in the valley of the R. Juba. There is no extension of the range of *G. palpalis* since it was collected by BRUNET in the valley of the R. Omo which flows into the north end of Lake Rudolph. Other species recorded are *G. longipennis brevipalpis austeni* and *pallidipes*.

Much of the country is arid, and it seems that the tsetse flies are extremely localized, at least in most areas. The highlands of Abyssinia are (presumably) free of *Glossina* but the upper limit of altitude is not yet known. The paper gives no information on one most curious riddle. *G. tachinoides* is a West African species its eastern limit being on the Shari River about 18°E. But it also occurs in Southern Arabia in the hills behind Aden the gap in its range being about 27° say 1600 miles. The present paper contains no record of *tachinoides* (which one might expect to be found in some part of the area under review). The old record of *morsitans* from Massawa is quite rightly discredited. One is probably correct in thinking that the Red Sea littoral (British and Italian) is too dry for any species of *Glossina*.

The paper includes some indefinite remarks, but no facts about human and animal trypanosomiasis. The author provides a key to local species and figures of certain diagnostic points. P A Buxton

TALIAFERRO (William H.) Ablastic and Trypanocidal Antibodies against *Trypanosoma duttoni*.—*Jl Immunology* 1938 Oct. Vol. 35 No. 4 pp 303-323. [27 refs]

The non-pathogenic trypanosomes of rodents present a number of immunological problems of peculiar interest. These infections are

characterized by an initial period of rapid reproduction of the parasites followed by a period during which reproduction is either completely inhibited or greatly reduced and they are generally terminated by self-cure with a subsequent immunity of variable length.

In previous work [this *Bulletin* 1933 Vol. 30 p. 122] the author has shown that this peculiar development in *T. lewisi* is associated with the formation of two antibodies. The inhibition of reproduction is associated with a passively transferable antibody termed ablastin which has the specific property of inhibiting reproduction of the organisms—it possesses many of the classical features of ordinary antibodies but it exhibits no marked *in vitro* affinity for the organisms. The termination of the infection is associated with a trypanocidal antibody which shows all the classical characteristics of antibodies in general. As the reproduction-inhibiting antibody has been demonstrated serologically only in infections with *T. lewisi*, Tahaferro considered it to be of interest to ascertain whether it is present in an infection with another trypanosome. The matter has been studied in the case of *T. duttoni* of the mouse and the *duttoni* and *lewisi* antibodies are compared by various homologous and heterologous tests. The technique and results of the experiments are described in detail. The following are the conclusions—

1. The inhibition of reproduction of *T. duttoni* after 10 to 12 days in the mouse is brought about by a specific ablastin found in immune mouse-serum which is similar to that described in *T. lewisi* infections in the rat, and is passively transferable.

2. The eventual self-cure (to the extent that no trypanosomes are found in the peripheral blood) is associated with a specific trypanocidal antibody which is passively transferable and behaves as a typical trypanolysin.

3. A group-reaction can be demonstrated between *T. duttoni* and *T. lewisi* and their ablastins *in vivo* and between *T. lewisi* and the anti-*duttoni* trypanocidal antibody *in vivo* and somewhat weakly *in vitro*. Whether the reaction of anti-*lewisi* trypanocidal antibody against *T. duttoni* *in vivo* and *in vitro* is a true group-reaction of an immune anti-*lewisi* antibody is not evident because normal rat-serum is also trypanocidal against *T. duttoni*.

IV Y

FRENCH (M. H.) Studies in Animal Trypanosomiasis. IV. The Effect of *Trypanosoma congolense* and *Trypanosoma brucei* on Some Inorganic Blood Constituents.—*Jl Comp Path & Therap* 1938. June Vol. 51 Pt. 2. pp. 119-127 [18 refs.]

In a previous paper [this *Bulletin* 1938 Vol. 35 p. 712] the author has shown that *T. congolense* and *T. brucei* infections of cattle and sheep cause a loss of body tissues and an increased rate of excretion of body bases, chlorides and phosphates.

The present paper summarizes the changes in the blood sodium, potassium, calcium, chlorine and inorganic phosphorus caused by *T. congolense* and *T. brucei* infections in cattle, sheep and donkeys.

The author summarizes his conclusions as follows—

1. The inorganic phosphorus content of the blood was unchanged by trypanosome infections in cattle, sheep and donkeys.

2. The blood calcium was unaltered in several cases of trypanosome infections but showed a tendency to decrease in other cases. Interpretation of the calcium changes is therefore difficult.

and human red blood corpuscles. If the serum is homologous, the red cells become firmly adherent to the trypanosomes.

The authors state that when they were using this test for the study of the serology of strains of *T. brucei* which had been transmitted cyclically through tsetse flies, they obtained irregular and unrepeatable results from time to time. The present investigation was consequently undertaken in order to obtain some light on the explanation of these irregular results. The following conclusions were reached —

1. We have shown that standard concentrations both of red cells and of trypanosomes are necessary in order to obtain constant results in the Red Cell Adhesion test.

2. The character of adhesion obtained can be varied at will by altering the relative proportions of the various reagents or the time of incubation.

3. Agglomeration and lysis of trypanosomes take place, in presence of homologous serum, when other conditions necessary for adhesion are not present, e.g. an unsuitable indicator (red cells or bacteria).

4. The necessity for the presence of complement in this test has been confirmed and it is shown that the absence of any single component of complement inhibits the reaction.

5. The end titre of an immune serum has shown only slight variations when repeatedly examined by the adhesion test.

6. Certain human red cells will not adhere to sensitized trypanosomes.

7. This condition is met with both in pathological conditions and in normal individuals. We have been unable to correlate it with any altered physical state of the red cell.

8. In the same way certain bacteria adhere to sensitized trypanosomes and others fail to do so. This is not correlated with rough and smooth states of the culture."

BROWN (H. C.) Some Observations on the Electric Charges of Micro-organisms.—Reprinted from *Scans JI Roy College of Science* 1933. Vol 8 pp 52-57 With 3 figs

The object of this address was to give a general idea of the subject and to discuss some of its simpler applications.

When particles are suspended in a fluid through which an electric current is passed, they will travel either to the positive or negative pole according to the sign of the charge which they carry. Moreover their rate of migration will be directly proportional to the magnitude of the charge. The phenomenon can be studied by making use of a microcataphoresis cell, which is described and figured.

Various observers have from time to time attempted to determine the size of the charge carried by trypanosomes when suspended in different fluids. The results have been extremely contradictory, some of the observers stating that the flagellates carry a negative charge whilst others assert that they are positively charged. According to Brown, the technique used by these observers is open to criticism. In his own experiments he has employed a medium of pH 7.2 consisting of one volume of physiological saline and nine volumes of 4 per cent. glucose in freshly boiled distilled water. In such a medium the following results were obtained —

Charge of the Insect Forms—The developmental stages of the sheep trypanosome *T. melophagium* in its insect vector *Melophagus ovinus* proved to be negatively charged.

Charge of the Cultural Forms—Cultural forms of *T. lewisi* and *T. cruzi* were always found to be negatively charged.

Charge of the Blood Forms—In the earlier experiments which were made on the charge of the various species of trypanosomes in mice rats and guinea pigs it was found that some strains were positive some negative and that others showed both positive and negative individuals in the same animal. It was not until the same animals were examined day after day that the explanation of these earlier findings was understood.

In the case of the polymorphic trypanosomes it was found that when a relapse occurs after a spontaneous cure in mice a reversal of the sign of the charge of the trypanosome invariably takes place.

The nature of the host has apparently a definite effect upon the sign of the charge of the trypanosome. If negatively charged trypanosomes from a mouse are injected into a more resistant animal such as a guinea pig or rat it is found that as soon as the infection in this animal is manifest the trypanosome will almost invariably have changed its charge whereas when the trypanosome is passed from mouse to mouse the charge remains constant.

With the object of overcoming certain technical difficulties due to the use of the cataphoresis cell, Brown has advised a simple test for finding the sign of the charge of the trypanosomes. The test consists in adding 0.02 cc. of infected blood to 0.3 cc. of a solution consisting of one volume of normal saline and nine volumes of 4 per cent glucose. After being allowed to stand at room temperature for a few minutes the suspension is examined under the microscope with a 1/4 inch objective. When the trypanosomes are positively charged they will be seen to be firmly adherent to the red cells either singly or in groups whereas negatively charged trypanosomes are perfectly free and non-adherent.

Certain experiments were conducted with *T. evansi* which showed very distinct differences in the susceptibility of the positively and negatively charged variants to the action of arsenical drugs. It was found that the positively charged variant is distinctly more susceptible to the action of the negatively charged ion of trypanamide. Brown adds that so far he has been unable to obtain similar results with other species of trypanosomes. W. Y.

PARKIN (B. S.) Auto-Sterilization in Trypanosomiasis.—*Onderstepoort J. Vet. Sci. & Animal Industry* 1938. Jan. Vol. 10 No. 1 pp. 21-27.

In the course of experiments on the chemotherapy of infections due to *T. congolense* and *T. vivax* it was observed that infected animals some considerable time after treatment or even without treatment made spontaneous recoveries. The purpose of the present article is to record various instances of spontaneous recovery observed by the author. Details are given in tables.

A number of cases of sterilization was noted in *T. vivax* infections of bovines and in *T. congolense* infections of bovines and ovines but no such cases were observed in *T. brucei* or *T. equiperdum* infections of equines. H. J.

MASSEGUIN. Quelques règles de traitement à propos de la maladie du sommeil [Rules for the Treatment of Sleeping Sickness].—*Marseille Méd* 1938. Sept. 5-15 Vol. 75 No 25-26 pp 253-260

A general account of the treatment of sleeping sickness, apparently written for the guidance of physicians in France. It contains nothing new and requires no notice here. W. J.

HAWKING (Frank) Analysis of the Trypanocidal Action of Trivalent Arsenicals and Acriflavine.—*Ann Trop Med & Parasit.* 1938. Oct 12 Vol. 32 No 3 pp. 313-331 With 6 figs. [14 refs.]

It has been shown by the reviewer and his colleagues and also by JANCsó and others, that normal trypanosomes readily absorb trivalent arsenicals when exposed to dilute solutions of these compounds. atoxyl-fast trypanosomes absorb them much less readily and it is now considered that this explains the phenomenon of drug-resistance.

In the present paper which is of a technical nature and must be consulted in the original by those interested, Hawking attempts to analyse the combination between drug and trypanosome in greater detail and to investigate its relation to the eventual death of the parasite.

The following summary is given —

"1 Time-action curves for the trypanocidal action of trivalent arsenicals and acriflavine show that there is a constant death-rate following an initial lag which is much longer than the time required for fixation of the compound.

"2 Time-concentration curves show that the trypanocidal action follows the equation $(C-C_0)e^{-kt}=k$, where n is 0.5-0.8 except in the case of phenylarsenoxide (1.04)

"3 From analogy with other pharmacological processes, it is probable that the reaction between drug and trypanosome occurs in three stages, viz., fixation of the drug, secondary chemical reactions, and eventual death of the organism. The fixation occurs rapidly being complete in a few minutes, and is reversible. The earlier part of the secondary chemical reactions is also reversible. The temperature coefficient (Q_{10}) of the whole trypanocidal process is 1.8

"4 When equilibrium has been reached between drug inside and outside the trypanosome, the partition-ratio (i.e., concentration inside trypanosome/concentration outside trypanosome) of reduced trypanamide is about 5,000 for normal trypanosomes and 5 for resistant ones. for phenylarsenoxide it is about 10,000 for arsenophenylglycine about 30, for sodium arsenite 30-100 and for tartar emetic about 200

5. The relation between the concentrations of acriflavine inside and outside normal trypanosomes respectively approximates to Langmuir's equation for adsorption, viz., $kx = \frac{Y}{B-y}$. With low concentrations this gives a constant ratio (partition-ratio) between the internal and external concentrations respectively viz. 8,000. When normal trypanosomes are saturated with acriflavine they contain drug equivalent to 3 per cent. of their own (moist) weight.

6. The absorption of acriflavine by resistant trypanosomes shows a similar relationship with the lower concentrations, but the partition-ratio is only 60. With higher concentrations the relationship is distorted by the fact that the death of resistant trypanosomes is accompanied by an increase in their powers of absorption.

"7 The amount of reduced trypanamide required to kill a normal trypanosome in three hours is about $8 \times 10^{-9} \gamma$ which is sufficient to form

a monomolecular film over only 5 per cent. of its surface. The corresponding amount of acriflavine is $9 \times 10^{-2}\gamma$ which is sufficient to cover the whole surface

KING (H.) LOURIE (E. M.) & YORKE (Warrington) Studies in Chemotherapy XIX. Further Report on New Trypanocidal Substances. — *Ann Trop Med & Parasit* 1938 Aug 2. Vol 32. No 2. pp 177-192

This communication amplifies the earlier results obtained by the authors in their examination of a considerable number of guanidines isothioureas amidines and amines with alkyl and alkylene chains

The following summary is given —

1 The investigation described in this paper was instigated by the discovery that synthalin has a powerful direct trypanocidal action

2 A considerable number of guanidines, isothioureas amidines and amines with alkyl and alkylene chains were prepared and examined for trypanocidal activity

3 It was found that certain of the diamidines exhibit a powerful trypanocidal action *in vitro* and that with the most active member of the series, viz. n. undecane-1 11-diamidine it is possible to produce permanent cures in approximately 100 per cent. of mice and rabbits infected with our laboratory strain of *T. rhodesiense*

4 Undecane diamidine had little curative action on mice infected with *T. congolense* but when given in large doses on the day of inoculation and on the following nine days it exhibited a pronounced prophylactic action.

5 This compound had no action on *T. cruzi* infections in mice or on mice infected with *Spirochaeta recurrentis* or *Spirillum minus*

6 It has a definite action on human simple tertian malaria, causing the parasites to disappear from the peripheral blood and the febrile paroxysms to cease.

7 The structural feature common to all the compounds referred to above is the possession of a central inert carbon chain with terminal polar groups of strongly basic nature

8 As it seemed possible that this carbon chain merely served as a carrier of the active groupings and might be replaced by an inert aromatic structure of approximately the same molecular weight, a number of aromatic amidine and guanidine compounds were prepared

9 Several of these aromatic compounds were found to exhibit pronounced trypanocidal action *in vitro* and with three of them, viz. pp-diguanidino-diphenyl methane pp-diamidino-diphenyl methane and 2 7 naphthalene diamidine it was found possible to cure mice infected with *T. rhodesiense*

10 This work opens up a new field in the search for substances of therapeutic value against trypanosomal and malarial infections.

LOURIE (E. M.) & YORKE (Warrington) Studies in Chemotherapy XX. The Preparation of Strains of Trypanosomes resistant to Synthalin and Undecane Diamidine and an Analysis of their Characters. — *Ann Trop Med & Parasit* 1938 Aug 2. Vol. 32. No 2. pp 201-213

In this paper the authors describe the preparation of strains of trypanosomes resistant to synthalin and undecane diamidine. The

characters of these strains are compared with those of strains of the same trypanosome previously made resistant to the aromatic arsenical and antimonial compounds to tartar emetic acriflavine and to Bayer 205 respectively

The following summary is given —

" 1 The preparation of strains of *T. rhodesiense* resistant to synthalin and to n undecane-1 11-diamidine respectively is described in detail.

2 The development of synthalin- and undecane diamidine resistance is a slow process as compared with the development of resistance to the aromatic compounds of arsenic or antimony or to acriflavine

3 The characters of these two strains were examined and compared with those of strains of the same trypanosome which had been made resistant to trypanamide and to Bayer 205 respectively

4 It was found that the synthalin and undecane diamidine-resistant strains are indistinguishable from one another in that they are both resistant to each of these drugs and to pp'-diguanidino-diphenylmethane and naphthalene-2 "-diamidine Both these strains are however as sensitive to Bayer 205 and to halarsol as is the normal parent strain and, conversely the Bayer 205- and trypanamide-resistant strains are just as sensitive to undecane diamidine as is the normal parent strain

" 5 The characters of the four different types of resistance to therapeutic substances which we have developed in *T. rhodesiense* are discussed These types of resistance are

" (a) Resistance to the aromatic compounds of arsenic and antimony and to acriflavine

(b) Superadded tartar emetic resistance

(c) Resistance to Bayer 205

(d) Resistance to the amidine and guanidine compounds

Each of these types of resistance is specific for its own group of chemical compounds.

VAN RENSBURG (S. W. J.) Surfen C. Therapy in *Trypanosoma congolense* Infection in Bovines and Ovines.—*Onderstepoort Jl. 1 et Sci & Animal Industry*, 1938 Jan Vol. 10, No. 1 pp. 13-20

Prior to the advent of antimosan the only drug of any value for the treatment of *T. congolense* infections of cattle and sheep was tartar emetic. Owing to its ease of administration antimosan is immeasurably superior to tartar emetic, and PARKIN in 1930 concluded that bovines infected with *T. congolense* could be sterilized by the subcutaneous injections of 3 gm. of antimosan given at four weekly intervals

When Surfen C appeared a claim was made that a single dose of about 10 mgm. per kilo of body weight, given either intramuscularly or subcutaneously proved a certain sterilizing dose in animals infected with *T. congolense*. The author writes that Surfen C has now been subjected to tests in various parts of Africa but the reports regarding its efficacy and local tolerability are conflicting

A summary is given of the more important results hitherto obtained. This is followed by a description of the author's experiments on cattle and sheep artificially infected with various strains of *T. congolense*

The general conclusions reached are that the intramuscular injections of Surfen C into bovines caused serious local reaction, and that the treatment of bovines and ovines infected with *T. congolense* by Surfen C was ineffective.

BROWN (Arthur A Forbes) Trypanosomiasis Gambiensi. Some Observations in Uganda and their Bearing on Prophylaxis.—*Jl Trop Med & Hyg* 1938 June 15 July 1 & 15 Aug 1 & 15 Sept. 1 & 15 Vol. 41 Nos. 12 13 14 15 16 17 & 18 pp 200-207 220-222 234-237 247-251 265-270 281-286 296-301 With 12 figs (1 map) [47 refs.]

As the author writes in the introductory remarks which precede this long series of articles they cannot be held to contain anything new and whatever is advocated in them has already been stressed by others. One of the author's reasons for bringing up certain methods of prophylaxis is that close co-operation between the medical man and the local administration is an absolute essential.

In the West Nile the focus of sleeping sickness at Aringa has been a problem for years and the cause of much dispute between the Medical Officer and the Administrator. Out of the turmoil a combined scheme for dealing with the situation was eventually decided upon.

The author summarizes his conclusions in the following terms —
(1) In the West Nile, an equilibrium has now reached a stage nearing perfection between *T. gambiense* man, and *G. palpalis*. This allows the trypanosome a placid existence in its human host, and in *G. palpalis* polymorphic trypanosomes develop cyclically to give a salivary-gland infection of not less than 0.6 per cent. The balance is not yet perfect because (a) the disease though mild, is still fatal (b) salivary-gland infections are attenuated.

(2) Owing to the suitability of man nowadays to an adapted trypanosome symptomless human reservoirs are numerous and owing to the complexity of rivers, widespread infection is inevitable i.e., the degree of balance attained is actually more troublesome than if it did not exist.

(3) The fly population of all rivers is small abrupt variations in water volume by destroying pupae will never allow it to increase. *G. palpalis* is forced to live precariously conditions are so unfavourable that it seldom can leave the river beds, and it is not sufficiently hardy to survive other than by a small margin. Narrow strip debushing thus can alter conditions so as to prevent its further existence.

(4) Administrative measures must aim at (a) Quarterly inspection of the population (b) Continuation of examination by suitably placed microscope posts. (c) Modified resettlement of population. This must not exceed its scope which at best, is limited by the complexity of rivers and scarcity of good soil.

(5) Debushing is absolutely essential, and reduces fly to 10 per cent boy-day and probably less. This can be attained by width of 10 yards each side on small streams and not more than 25 yards each side in the case of main Nile tributaries.

(6) It is the length of clearing which impedes *G. palpalis* which does not readily undertake more than 1 000 yards of strip-clearing. The ideal road and crossing clearing is 2,000 yards by 10 yards each side. The minimum is 1 000 yards by 10 yards each side. Settlement clearings must project beyond the last homestead for not less than 500 yards, and, better 1 000 yards.

(7) Hand-catching can reduce fly probably to 10 per boy-day. The ill-effects of clearing on agricultural activities can be mitigated by a scheme of alternate strip clearings 1 mile in length, isolating bushy strips of equal length, in which catching and trapping can be done. Erosion is best prevented, and clearings maintained, by controlled grazing, which promotes rotation of grasses and establishes creeping varieties.

(8) Debushing must always commence with the headwaters, and progress downwards. By doing so in the wrong direction there is great danger of fly being driven into a mass of tributaries, to spread infection.

(9) Livestock act as a biological barrier. Instead of removing livestock from rivers for fear of attracting tsetse they should be introduced deliberately.

(10) Antrypol, as a 1-grm dose, can protect clearing gangs for three months. It is also of value in preventing extension of epidemics."

W J

NASH (T. A. M.) The Probable Effect of Densification of Woodland upon the Distribution of Tsetse in Northern Nigeria.—*West African Med J* 1938. Oct. Vol. 10 No 1 pp. 10-13

It has been found that in East Africa the exclusion of fire in certain vegetation communities results after a few years in a striking thickening of the vegetation, and that this densification is accompanied by a steady decrease in the *G. swynnertoni* population.

Judging from the East African reports it might naturally be assumed that a policy of densification of woodland would be an excellent anti-tsetse measure to employ in Nigeria, but most unfortunately this is not the case as owing to the much severer climatic conditions experienced in Northern Nigeria densification of woodland is precisely what tsetse need in order that they may extend their range.

Nash compares the habitats of *G. morsitans* in East and West Africa, and the reasons for the differences which occur in these two countries. He also discusses the habitats of *G. tachinoides* and *G. palpalis* in Northern Nigeria. As the result of his reflections he reaches the following conclusions—

"1. A large scale policy of densification of woodland by fire exclusion would be beneficial to tsetse in the Northern parts of Nigeria, enabling all the three common species to extend their range owing to the greater protection against adverse climate conditions afforded by thicker vegetation.

"2. It would be most inadvisable to practise fire exclusion in *G. morsitans* belts.

"3. Wherever possible forestry reserves in which fire exclusion is practised should be sited in uninhabited areas where *G. morsitans* does not occur.

"4. In the vicinity of towns it is advisable that all streams within forestry reserves should be cleared and that no attempts be made to exclude fire. In this manner areas of woodland can be safely protected from exploitation, without unnatural densification and the consequent risk of becoming tsetse sanctuaries.

"5. In the vicinity of towns all fuel plantations should be sited in areas lying *in between* streams. If possible the edge of the plantation should not approach within quarter of a mile of a stream.

8 Densification of vegetation could only succeed as an anti tsetse measure in the southern parts of Nigeria where a cooler moister climate makes tsetse prefer more open conditions, whilst the high rainfall tends to produce excessively dense vegetation.

Attention has been drawn by forestry officers and others to the very real danger to Nigeria of the deforestation which is taking place in many parts. The conservation of moisture by the soil is enormously reduced by the destruction of forest and serious erosion is likely to take place when the natural covering of woodland is destroyed. It is the aim of the Nigerian Forestry Department that approximately 25 per cent of each district should be under woodland.

Nash hopes that the present paper will help to clarify the issue between foresters and those engaged in sleeping sickness control by explaining the relationship which exists between tsetse climate and vegetation and further that it will be realized that there are no real obstacles between the policy of conservation of woodland and tsetse control providing that due care is taken in the siting of forestry reserves and fuel plantations.

TALICE (R. V.) & TERRA NÚÑEZ (G.) Tercer caso uruguayo de enfermedad de Chagas. (Forma aguda.) [Third Case of Acute Chagas' Disease in Uruguay].—*Arch. Uruguayos de Med. Cirug. y Especialidades* 1938, Mar Vol. 12 No 3 pp 241-248 [15 refs.]

Talice and his co-workers continue to record cases of Chagas disease in Uruguay [see this *Bulletin* 1938 Vol. 35 pp 351-352]. The patient in this instance was a man of 20 years. He woke up one morning feeling a hot itching sensation of the right eyebrow and three red spots were seen. The following day each of the three small lesions was covered by a scab and two days later there was oedema at first of the brow but later spreading to involve the eyelids cheek and adjacent part of the neck. By this time the sixth day from the onset he consulted a doctor. Palpable glands were felt in the neck temperature was 38°C and there was marked prostration with intense headache. *T. cruzi* was found in the blood. Improvement was very rapid and the patient was discharged from hospital four days after admission. He came from a rural part of the Department of Tacuarembó and this is said to be the first case recorded from this part of the country.

H. H. S.

TALICE (R. V.) RIAL (Benito) & DE MEDINA (Federico) Forma aguda de enfermedad de Chagas (6° caso uruguayo) acompañada de hipertrofia de la glándula tiroidea. [A Case of Chagas Disease accompanied by Enlargement of the Thyroid Gland.].—*Arch. Uruguayos de Med. Cirug. y Especialidades* 1938, May Vol. 12, No 5 pp 497-510 With 7 figs. on 2 plates & 1 chart. [18 refs.]

This is the sixth case to be recorded by the authors in Uruguay this time it was a boy of two years and the case also was one running an acute but on the whole a mild course. The chief reason for calling attention to it is that during the illness the thyroid enlarged. The child's mother was very definite in her statement that there had been no such enlargement prior to the present illness nor did either of the parents or any relatives suffer with a goitre. The enlargement

began to show itself at the end of the first week of illness and progressed for about a month then became smaller but was still observable three months afterwards. The authors are convinced that there was an "acute congestive thyroiditis of trypanosomal origin." There were none of the usual signs of disturbance associated with ordinary goitre

TALICE (R. V.) REGULES (Uruguay) & ALAMBARRI (Alfredo) Los dos primeros casos de enfermedad de Chagas comprobados en la ciudad de Mercedes. [Two Cases of Chagas Disease, the First to be recorded in Mercedes.]-*Arch. Uruguayos de Med. Ciruj. y Especialidades* 1938 Apr. Vol 12. No 4 pp 438-447 With 3 figs & 1 map [17 refs.]

The cases here described sisters aged seven and four years were typical of the mild acute form of the disease with dacryoadenitis palpebral oedema and regional adenitis no constitutional symptoms of any note but the usual blood changes of anaemia, leucocytosis with relative mononucleosis. The only reason for recording these is that Mercedes is a place where cases have not been seen, or at all events recorded hitherto. These are the seventh and eighth Uruguayan cases.

H H S

TALICE (R. V.) DE MEDINA (Federico) & RIAL (Benito) Nueva observación de forma aguda de enfermedad de Chagas (9° caso uruguayo) con síntomas particulares. [A Case of Chagas Disease with Peculiar Symptoms.]-Reprinted from *An. Facid de Med. Montevideo* 1938. Vol. 23 Nos 4 & 5 8 pp With 2 figs on 1 plate & 1 chart [19 refs.]

This case of a patient in the Department of Paysandú is the ninth Uruguayan case recorded by the authors. The peculiarity in the symptoms referred to in the title consisted in the fact that although conjunctivitis and dacryocystitis were marked and acute there was no regional adenitis, preauricular or carotid but later [? two days but day of disease not stated] there was more general adenitis especially inguinal, and slight enlargement of the spleen leucocytes 11,500 per cmm with relative lymphocytosis, 59.4 per cent. The authors incline to the belief that the condition was due to a "septicaemic phase of the trypanosomiasis. Symptoms on the whole were mild but were still present two months after the onset. There was no thyroid involvement

H H S

TALICE (R. V.) Dos nuevas observaciones de formas agudas de enfermedad de Chagas en el departamento de Paysandú (10° y 12° casos uruguayos) [Fresh Observations of the Acute Form of Chagas Disease in Paysandú.]-Reprinted from *Arch. Uruguayos de Med. Ciruj. y Especialidades* 1938. June. Vol 12. No. 6 pp. 645-651 With 3 figs. [20 refs.]

Two more cases of the "mild acute" form of this disease one an adult of 28 years and the other a child of three years occurring in the Paysandú Department of Uruguay. They were typical and call for no comment.

H H S

TALICE (R V) ALAMBARRI (A) & REGULES (U) Forma aguda de enfermedad de Chagas en un niño del Rincón de Cololó (Dpto de Soriano) (11° caso uruguayo) [Case of Chagas Disease in a Child at Rincón Cololó].—Reprinted from *An Facul de Med* Montevideo 1938 Vol 23 Nos. 9 & 10 7 pp With 1 plate. [24 refs.]

The patient was a boy of six years with typical symptoms. This is the eleventh case to be reported in Uruguay. The only reason for drawing attention to it here is that treatment consisted of Sulfanil Emar by mouth two tablets daily of 0.3 gm for fifteen days. In a few days the oedema dacryoadenitis and the glandular enlargement subsided and no trypanosomes were found on examination of a thick drop of blood. When he was seen eleven weeks later the symptoms were still in abeyance except that the pre auricular and carotid glands on one side were palpable there was no enlargement of spleen or thyroid. The author is of the opinion that the sulfanil was highly beneficial and he intends to test it in future cases in man and also experimentally (in animals) H H S

MARZA (Salvador) JÓRC (Miguel E) & FEIJÓO (E J Canal) Investigaciones sobre la Enfermedad de Chagas. Primer caso crónico mortal de forma cardíaca de enfermedad de Chagas demostrado en Santiago del Estero [Study of a Chronic Case of Chagas Disease ending Fatally].—*Universidad Buenos Aires Misión de Estudios de Patología Regional Argentina Jujuy* 1938. Publicación No 38. 75 pp With 61 figs. [15 refs.]

This long and detailed account cannot be satisfactorily abstracted. It concerns a girl who was six years old when first observed by one of the authors (E. J. C. F.) in September 1926 when she gave a history of fever and headache for the preceding 15 days and had a slow arrhythmic cardiac action. She was seen at intervals till her death 10 years 5 months later. The last fifty pages are devoted to a very minute description of the histopathological changes in the heart and liver with abundant illustrations photomicrographs very well reproduced. The former showed chronic infiltrative myocarditis with polymorphonuclear and eosinophil infiltration and disorganization of striation in places. These are changes which have been found in other fatal cases of American trypanosomiasis and in animals subjected to experiment. There was also focal endocarditis with some oedema the liver showed nothing very characteristic. [Unfortunately trypanosomes do not seem to have been looked for in the earlier

and in thick drops was examined of 30 persons and the same number of animals and inoculations made into guinea-pigs and white mice with entirely negative results. There is little doubt however in the author's mind that Chagas' disease does exist in the district because the infestation index among *Triatoma* is fairly high in some parts and probably xenodiagnostic methods might reveal its presence.

Altogether 1 097 specimens of *Triatoma* were examined 382 from Carem 178 from Cajón del Maipo 25 from Lepe and 2 from Melipilla. Of those from Carem 405 (45 per cent.) were infested 292 of 564 adults (51 per cent.) and 113 of 324 larval and nymphal forms (26 per cent.). In Cajón del Maipo 63 were positive among 178 (35 per cent.) 50 out of 108 adults (46.3) and 13 of 70 in larval and nymph stages (18.5). Nine of the 25 from Lepe were positive. Of the two one imago and one larva from Melipilla neither was infested. H H S

TALICE (R. V.) Xenodiagnóstico positivo en una niña que un año antes presentó una forma aguda de enfermedad de Chagas. (18° caso uruguayo) [Xenodiagnosis in Chagas Disease].—Reprinted from *An. Facul. de Med. Montevideo* 1938 Vol. 23 Nos 9 & 10 10 pp [24 refs]

A girl, seven years of age, was attacked in April 1937 with Chagas disease in an acute form. When she was seen again a year afterwards there was slight oedema of the right eyelids (the side affected the year before had been the left). A xenodiagnostic test was made with positive results. [Nothing is said regarding blood examination for trypanosomes.] The author interprets this as a re-infection, since according to the parents, the child had been in good health in the interval. H H S

DIAS (Emmanuel) Persistence de l'infection par le *Schizotrypanum cruzi* chez l'homme. Xenodiagnostic positif dans deux cas, 18 ans après l'isolement. [Persistence of *T. cruzi* Infection in Man. Xenodiagnosis in 2 Cases, 18 Years after Isolation.]—*C. R. Soc. Biol.* 1933. Vol. 129 No 27 pp 430-432

In September 1922, two patients in the chronic stage of Chagas disease were admitted to the Oswaldo Cruz Hospital at Rio de Janeiro. These patients were women, aged 32 and 28 years respectively and came from the north of the State of Minas Geraes. Since 1922 they have frequently given positive Machado reactions.

In one of the patients (T) the presence of *T. cruzi* was demonstrated 12 years after her removal from the endemic area. In the other patient (A) inoculation of blood into a guinea-pig gave a positive result. Since 1934 periodic attempts have been made to find the parasite in the blood. Inoculation of the blood of T into a guinea-pig was positive on 25th May 1934 after VILLELA had obtained two negative results. Patient A, whose blood was injected into a guinea-pig on the 24th March 1923 gave negative results on the 1st November 1933 and 25th May 1934.

The xenodiagnostic test performed on both patients with *Pan. strongylus* (*Triatoma*) *marginatus* bred in the laboratory gave positive results on 14th February 1933. W Y

VLAZA (Salvador) Instrucciones para el diagnóstico de laboratorio de enfermedad de Chagas [Instructions for Laboratory Diagnosis of Chagas' Disease.]—*Instrucción No 1 Misión de Estudios de Patología Regional Argentina* 11 pp With 7 figs

This is a short paper presumably for the information of the general practitioner instructing him how to take a thick drop of blood for examination for trypanosomes how to carry out the venodiagnosis test how to collect blood in a Bayer's venule for inoculation into animals and in another for the Machado-Guerreiro reaction and how to obtain a fragment of lymphatic gland and forward them to the laboratory Illustrations depict details for the two first of these

TALICE (R V) Primeras observaciones en el Uruguay de gatos espontáneamente infectados por el *Trypanosoma cruzi* [First Observation in Uruguay of Cats suffering from *T cruzi* Infection.]—*Arch Uruguayos de Med Cirug Especialidades* 1938 July Vol. 13 No 1 pp 61-65 [21 refs]

That cats may be naturally infected with *T cruzi* was proved many years ago by Chagas himself in Minas Geraes. The author has found the same to occur in Uruguay
H H S

CULBERTSON (James T) & KOLODNY (Maxwell H) Acquired Immunity in Rats against *Trypanosoma cruzi*—*Jl Parasitology* 1938 Feb Vol. 24 No 1 pp 83-90

The experiments described in this paper have shown that rats which have recovered from a *Trypanosoma cruzi* infection are completely immune to re-infection. Administration of serum of a recovered animal prophylactically will not prevent but will reduce the severity of an infection. When an infection has been established serum will reduce the number of trypanosomes in the blood but these will increase again when the immune serum has been eliminated.

C M Henyon

LEPROSY

PAPERS OF ABSTRACTS IN THIS SECTION

GERMOND (p. 234) emphasizes the benign character of the leprosy found in eastern Basutoland. The incidence is probably a little over 2 per 1,000 but is lower in the surveyed lowlands than in the surveyed highlands. Nutrition is good at present. Treatment is by intradermal chaulmoogra esters. LOWE (p. 235) regards the problem in Burma as serious with incidence of from 1-6 to 5-6 per cent of the population and with a high proportion of serious cases. SARDJITO MOCHTA and TJITRONOEROJO (p. 235) found 330 cases in a survey of Blora (Java). They describe the measures taken for the discovery of the cases, the classification and treatment adopted. KOESLAN (p. 236) shows that the incidence of leprosy varies directly with the degree of contact in various environments. SAKOYAMA, YAGAI and MAEDA (p. 236) consider that leprosy tends to be more severe in colder than in warmer climates. LOWE (p. 236) considers that leprosy is more severe in Burmans than in Indians in Burma although the Burmans are better fed. He therefore postulates a racial factor in resistance.

DE MOURA (p. 237) gives the results of a study of 971 cases in Paraná. The mixed form was found in two-thirds of the patients. PINKERTON (p. 237) shows that in leprotic ulceration of the nose the bony structures escape. Nodular lesions of the tongue, soft palate and larynx occur. Chaulmoogra is not of much assistance and in laryngeal lesions rest of the voice as in tuberculosis affords most relief. RODRIGUES and GUTYTO (p. 238) describe the clinical features found in a re-survey of Cordova in the Philippines. COCHRANE and RAJAGOPALAN (p. 238) class very early cases as "precutaneous" when they have not developed definitely into either cutaneous or neural. The patients are usually under 14 and usually give a history of contact with a well-developed cutaneous case. SLOAN (p. 238) describes leprosy affecting the prepuce. BALISA and BASOMBINO (p. 238) suggest a classification of leprosy and RABILLO and RABILLO (p. 239) discuss their own.

RABILLO (Jr) (p. 239) discusses tuberculoid leprosy which is a result of a blood distribution of bacilli to skin, nerves and glands. He also discusses the allerge-specific reactions in this condition. PARMARSON (p. 239) considers that tuberculoid changes in nerve leprosy may be related to the presence of a certain degree of immunity. Twelve of 56 nerve cases in Estonia showed these changes in varying degrees. TRISSEUIL (p. 240) from tests with skin grafts, believes that spread in tuberculoid patches is due to bacilli in the extending edge, and not to trophic or toxic effects.

MARCHOUX and PRUD'HOMME (p. 240) describe a method of determining *in vitro* without culture whether leprosy bacilli are alive or dead. By this means they have arrived at conclusions as to the longevity of the bacilli under conditions of heat and desiccation. The bacillus of human leprosy is killed at 60°C. in 30 minutes. PRUD'HOMME

(p 240) by the same method found that the bacillus of rat leprosy is killed at 100°C in 5 minutes, and by other agents in various periods.

BURNET (p 240) succeeded in infecting a hamster with human leprosy bacilli thus confirming the work of ADLER. MARCHOUX and CHORINE (p 241) found it possible to infect a rat with five rat leprosy bacilli only. The development of the disease was slow.

GOMES (p 241) reports that both filterable and non filterable forms of rat leprosy bacilli occur in the nasal mucosa of rats 24 hours after infection. COWDRY and RAYOLD (p 241) describe rosette shaped masses of bacilli in rat leprosy unlike the faggot like masses of the human bacilli. DE SOUZA ARAUJO (p 241) found bacillaemia in experimental rat leprosy with bacilli in the nasal mucus and the faeces. Possibly they appear in the nose through infection from the faeces. SELLARDS and PINKERTON (p 242) report that the intra cerebral injection of rat leprosy emulsions into monkeys rabbits white rats and mice produces progressive and often generalized lesions. White mice may be infected by injection into the spleen liver or peritoneal cavity. In monkeys only low grade infections were produced by human leprosy material. The invasion of reticulo-endothelial cells is discussed.

ROTBURG (p 242) considers that the tuberculin reaction is not a group reaction and found that the percentage of lepers reacting to it was only slightly higher than that of non lepers. PEREIRA (p 242) working with the reaction of Lleras Acosta obtained results which differed considerably from those obtained by that author. SPEIGHT (p 243) gives results of the serum formalin reaction in leprosy. DI LIDDO (p 243) tested the Witebsky Klingstein and Kuhn reaction in lepers, contacts and controls but found the results to be of little diagnostic value.

BOENJAMIN (p 244) describes a syndrome in which the diagnosis between leprosy and syringomyelia was made by the microscopical examination of a thickened nerve which showed acid fast bacilli and the histological appearances of leprosy. He advocates this method.

COELHO (p 244) describes six lepers with infantilism and concludes that leprosy acquired up to the age of puberty may bring about this condition.

PARAS (p 245) found that of the chemical fractions of leprotic nodules only the wax appeared to possess significant biological properties in producing skin reactions.

DE SOUZA ARAUJO (p 245) obtains better results by combinations of many different treatments (which he details) than by the chaulmoogra treatment alone. BOENJAMIN (p 245) reports satisfactory results of treatment with 4828-a. The leprosy reaction if set up may be treated with ommadin. The Central Leprosarium of Goa and the treatments used there are described (p 246). ROSS (p 246) describes the biochemical changes (all temporary) which occur in the blood during treatment by pyretotherapy. Renal function is impaired but not permanently. BASU (p 246) reports on the value of animal protein in diet. RYRIE (p 247) records success in the treatment of leprotic ulcers with dettol locally and intravenously and BETZ (p 247) used cod liver oil locally while MEHTA (p 247) injects a solution containing rivanol, glucose and other constituents at a distance from the ulcers and a very similar solution intravenously. - i. GERMOND (R. C.) A Leprosy Survey of the Eastern Border Districts of Basutoland showing the Results of Strict Segregation combined with Inspectorate Control, and the History of a Leper Family — *Internat. J. Leprosy* Manila. 1938. July-Sept Vol. 6. No. 3 pp 303-314 With 3 figs. (2 maps)
- ii. BASUTOLAND ANNUAL MEDICAL AND SANITARY REPORT 1937 [DYKE (H W) P.M.O.] Appendix IV pp 42-48.—Annual Report on the Leper Settlement at Botabelo, Basutoland for the Year ended 31st December 1937 [GERMOND (R. C.) M.O.]
- iii. BASUTOLAND ANNUAL MEDICAL AND SANITARY REPORT 1937 [DYKE (H W) P.M.O.] Appendix V pp 47-50 —Report of a Leprosy Survey of Part of the Lowlands of Mafeteng District January 19th to February 2nd, 1938 [GERMOND (R. C.) M.O.]

1 The author summarizes the results of this survey as follows —

1 A leprosy survey of the eastern border districts of Basutoland is described

2 The results are summarized 13 157 individuals examined, 42 new cases found.

3 The extraordinary benignity of these cases is stressed 90.5 per cent are N1 while only 7.1 per cent were C1 and 2.4 per cent C1 N1

4 More than 50 per cent. of the neural cases are clinically almost negligible, the rest are early and slight.

5. Most of the recurrences are extremely mild, and none of them severe or obviously infectious

6 The position revealed by the survey is described as highly encouraging, if not unique.

"7 There seemed to be no definite relationship between malnutrition, scabies, and syphilis on the one hand and leprosy on the other

8. The most heavily infected families were well nourished, but very dirty

"9 The probable incidence of leprosy in Basutoland is estimated at a little over two per thousand of the population.

"10 The present satisfactory position is attributed to the success of the Native Leprosy Inspectorate established in 1929

11 The methods employed by these inspectors are described. The writer is of the opinion that the employment of natives is essential."

ii The report on the Basutoland Leper Settlement at Botabelo shows a decrease of 15 at the end of the year 1937 to 689 in spite of a number of admissions due to the surveys dealt with above. Among 83 admissions in 43 or 48.9 per cent the disease was of not more than 12 months duration in 17 per cent. it was 13-24 months in 13.6 per cent. over two years and in the remainder unknown but mostly of long duration. This shows a high proportion of early cases. Between 1929 and 1938 the proportion of admissions within 12 months of the onset of the disease has risen from 36.8 to 52.2 per cent. The average age of development of symptoms was at the unusually high figure of 36.7 years and has remained almost constant for seven years. The admissions of children up to 16 years remain from 15 to 16 per cent. Intradermal chaulmoogra esters constitute the routine treatment, and 71 patients were discharged during the year their disease having been arrested. Contentment of the inmates has been successfully fostered by social amenities. [See this *Bulletin* 1938 Vol. 35 p 285 for previous Basutoland reports.]

iii. The results of this further survey are summarized thus by the author —

- 1 The general nutrition of the population is an extremely unstable factor. It is at present excellent in the lowland area recently examined whereas in the depression (1933 and 1934) and for a year or more afterwards it was one of the worst in Basutoland.
- 2 The incidence of scabies is much lower in the lowlands than it was in the mountain area examined in 1936. The comparison is especially interesting with the well nourished population of the Melikane Valley.
- 3 The incidence of active external syphilis was found to be the same in the lowlands as in the mountain area.
- 4 The incidence of leprosy is very much lower in the surveyed part of the lowlands than in the surveyed part of the Eastern highlands. This is strikingly illustrated by the following comparison —

Melikane Valley (1936) incidence	8 per mille
Qacha's Nek South	4
Quthing District	2
Mateteng Lowlands (1938)	1

L. Rogers

LOWE (John) The Leprosy Problem in Burma.—*Leprosy in India*
1938 Oct Vol. 10 No 4 pp 120-131

This paper contains much information gleaned during a short tour in Burma. The census figures of advanced cases are quoted to show that the highest leprosy rates occur in a central belt from the Arrakan Hill tracts in the west to the Shan States in the East. Surveys indicate an incidence of about 1.6 per cent of the population rising in places to from 3 to 5 per cent. Examination of 586 village children gave the high rate of 5.6 per cent. The more serious lepromatous type formed 60 per cent and neural cases 40 per cent. This shows a larger proportion of serious cases than in India proper. In institutions the lepromatous type formed 70 per cent, and in out-patient clinics no less than 56.5 per cent. The problem in Burma is thus a very serious one. It was also observed that the villagers often isolate lepers generally at a little distance from the village and the encouragement of this system and the founding of leper colonies at small cost are recommended as prophylactic measures.

SARDJITO (M) MOCHITAR (A.) & TJITROHOEPOJO (M. Soeparmo Honggopatij) De voortgang van lepra fieldwork in het Regentschap Blora. [Continuation of Leprosy Fieldwork in the Regency of Blora.]—*Geneesk Tijdschr v Nederl Indië* 1938 July 26 Vol. 78 No 30 pp 1822-1830

A survey of the Regency of Blora revealed 330 cases of clinical leprosy, distributed in 129 of the total 296 villages. They were classified into 192 V (nerve) 63 C (cutaneous) and 75 CN (mixed) cases of which 53 (16 per cent) were children under 15 years. As there were 29 sample polyclinics distributed through the regency no leprosy individual was more than 3 km. distant from one of these. Bedridden patients were visited at their own homes and therefore it could be said that systematic medical treatment was at the disposal of all. Treatment consisted of administration in low dosage of iodized ethyl chanimoogra ethylate intramuscularly (this *Bulletin* 1936 Vol. 33

p 611) A grading of the degree of leprosy infection was indicated by subdividing nerve cases into categories N_1 , N_2 , N_3 and the cutaneous cases similarly into C_1 , C_2 , C_3 . In tracing leprosy cases inspection was directed especially to sufferers from any sort of skin disease and lepers were thus discovered who would not otherwise have been found. Although co-operation was obtained from all the authorities it was found that the village police brought up for inspection almost entirely advanced cases of leprosy. It was the institution of treatment itself which resulted in the voluntary presentation of the early cases and this fact gives cause for hope that such patients may at least be prevented from joining the ranks of the advanced lepers. It is still too early to pronounce on the attainment of definite cure and improvement. The mortality due to leprosy may be already said to be under check and control.

W F Harvey

KOESLAN Een bijdrage tot de epidemiologie der lepra ten platte lande in het Regentschap Lamongan Java [Leprosy in the Regency of Lamongan, Java.]—*Geneesk Tijdschr v Nederl Ind* 1938 July 26 Vol. 78 No. 30 pp. 1792-1806. With 5 figs. on 3 plates.

Leprosy is essentially a contact disease and it is to be expected therefore that intimacy and duration of contact will be powerful factors in the development of infection. The author goes rather elaborately into detail on the subject of the degree of contact between individuals which is to be ascribed to the family the circle (fellow workers, playmates etc.) the village and to an indeterminate class. These he works out to be family/circle 48/1 circle/village 5/1. The case incidence of leprosy for each category is proportionately — family circle village intermediate 10-4 1.78 0.63 0.3

SHIONUMA (Emosuke) NAGAI (Kenji) & MAKIDA (Tei) The Climate Theory in Leprosy.—*Internat. J. Leprosy* Manila. 1938 July-Sept. Vol. 6. No. 3. pp 315-324 With 1 fig

As the result of their inquiries in Japan the authors support the view that the warmer the climate the less severe the symptoms of leprosy for they found the disease to be relatively mild in the warmer southern islands, with fewer cases of the lepromatous and more of the nerve type. The differences observed could not be explained as due to longer duration of the disease. They also found that alopecia leprosa eye lesions and nerve symptoms are more severe in the colder areas.

L. R.

LOWE (John) A Note on Racial Variations in Leprosy with Particular Reference to Indian and Burmese Races.—*Indian Med. Gaz.* 1938. Oct. Vol. 73 No. 10 pp 591-606 With 8 figs. on 2 plates. Also in *Leprosy in India* 1938. Oct. Vol. 10 No. 4 pp. 132-139

This paper is also the outcome of a three and a half weeks survey tour in Burma dealt with above. In a Bengal survey neural cases formed 82 per cent. of the total cases, and the Philippine Islands showed a proportion of 50 per cent. In Burma the Rangoon Leper

Asylum leprosy clinics and village data respectively showed in Burmans 75.56 and 53 per cent. of lepromatous cases and in Indians 39 and 31 per cent. in the two first series. The disease is thus more severe in the Burmans than in Indians in Burma although many of the latter had contracted the disease in Burma. The evidence indicates that both races become infected in childhood but age data indicates that leprosy develops earlier in the Burmans. Further tuberculoid cases and nerve abscesses are rarer in Burma than in India. Yet the Burman is better fed than the Indian although the former indulges in a stale fish product. The author therefore suggests that the Burmans have a hereditary and racial lack of resistance to leprosy infection. L. R

DE MOURA (Aureliano M.) Estudo bio-estatístico de 971 casos de lepra no Hospital Colônia S. Roque. [A Study of 971 Cases of Leprosy in the S. Roque Colonial Hospital, Paraná.]—20 pp English summary 1938. Curitiba—Paraná Empresa Gráfica Paranaense.

This study is in the main statistical at all events it deals with figures variously manipulated. Of the total 95.1 per cent were white 91.3 per cent. Brazilians the incidence in males was more than double that in females, 69.6 and 30.4 per cent respectively. 73.3 per cent. were over 20 years of age. Four fifths of the patients came from Paraná State and 10.5 per cent. from São Paulo. The mixed form was found in two-thirds of the patients the maculo-anaesthetic in 18.9 and the nodular in 14.4 per cent. The initial lesions occurred on the face in 27.8 per cent. then in order forehead 11.2 hands 10.8 feet 8.8 and legs 8.3 per cent. These figures are given also in tables and further subdivided into age and sex groups and frequency of the different symptoms and their sites.

Of non Brazilian patients 64 in number the ages ranged between 28 and 78 years most occurring in the fifth decade. In them also the mixed form predominates 63.1 per cent. The shortest time of residence in the country before the appearance of symptoms was 4 years one had been 68 years resident. H H S

PINKERTON (Forrest J.) Leprosy of the Upper Respiratory Tract. Discussion of Early and Moderately Advanced Cases.—*Jl Amer Med Assoc.* 1938 Oct 15 Vol. 111 No 16 pp 1437-1442. With 14 figs.

This paper is based on seventeen years experience at the Honolulu receiving hospital and the Molokai Settlement and gives a well illustrated account of the leprosy lesions of the mouth nose and larynx. The author stresses the atrophy and destruction of the cartilages of the nose and septum and the escape of the bony structures in which leprosy differs from syphilis. This leads to falling in of the nasal tip. The sinuses appear to escape damage. Perforation of the septum is common but he has not seen that of the hard palate occur in leprosy. Nodular lesions of the tongue soft palate epiglottis and other portions of the larynx are described and illustrated. He has not seen much good from chaulmoogra preparations in these advanced distressing cases including spraying the larynx with them but the use of bland oils in that way seems to be agreeable to the patient. Rest of the voice as in tuberculosis affords most relief. L. R

RODRIGUEZ (Jose N.) & GUINTO (Ricardo S.) A Field Study of Leprosy II. Re-examination of Cases of Leprosy at Cordova, Cebu Province, Philippine Islands.—*Internat J Leprosy* Manila 1938. July-Sept. Vol. 6 No 3 pp 285-302.

This paper deals only with the clinical features of a re-survey of the town of Cordova in the Philippines two years after the first inquiry in 1933. Several new cases were found although not all of the population of some 8,000 were examined. In 1933 20 of 45 closed cases were classed as active but only 13 were so two years later and the improvement tended to be greatest among females. Of 15 positive cases on parole two had died and four relapsed. Of nine formerly suspicious cases three were still so regarded and three were not leprosy. Six new open cases had developed in the two years only one of whom was a house contact.

L. R

COCHRANE (R. G.) & RAJAGOPALAN (G.) An Investigation Center for the Study of Childhood Leprosy.—*Internat J Leprosy* Manila 1938. July-Sept. Vol. 6 No 3 pp 325-330 With 6 figs. on 2 plates.

The author once more stresses the importance of leprosy in childhood and describes the formation of a clinic at Sandpet near Madras, for the study of the problem following a preliminary survey revealing a high incidence. Among 1,871 pupils of schools in the area 65 were classed as probably leprotic 40 as showing early and 3 late leprotic signs. He classes very early cases that have not yet developed definitely into either cutaneous or neural as "precutaneous" and they usually gave a history of contact with a well developed cutaneous case. Colour photographs are necessary to show clearly these lesions and the patients are nearly always below 14 years old. They resemble Muir's "juvenile leprosy".

L. R

SLOAN (Norman R.) Circumcision in Leprosy.—*Internat J Leprosy* Manila 1938. July-Sept. Vol. 6 No 3 pp 358-360

This is a brief note on a case of cutaneous leprotic lesions of the prepuce of such severity as to cause retention of urine and necessitate circumcision.

L. R

RYAN (Gordon A.) An Infantile Macular Eruption.—*Internat J Leprosy* Manila 1938 July-Sept. Vol. 6 No 3 pp 357-358

HARRISON (G. F.) A Case of Leprosy in a British Soldier.—*Jl. Roy Army Med Corps* 1938 Sept. Vol. 71 No 3 pp 184-189 With 2 figs.

BALISA (Pedro L.) & BASCOURIO (G.) Classification des formes cliniques de lèpre [Clinical Classification of Leprosy].—*Rev Brasileira de Leprologia* São Paulo 1938. Sept. Vol. 16 No. 3 pp. 225-228.

The authors discuss the Manila classification and suggest the following —

- I. Cutaneous or Lepromatous (C or L)
- II. Maculo-anaesthetic (Ma)

III Tuberculoid (Tde)

IV Nervous (N) Purely nervous without maculo-anaesthetic lesions.

V Combinations of the foregoing

Definitions of the terms used are given

L R

RABELLO (Ed.) & RABELLO Jr Une classification clinico-épidémiologique des formes de la lèpre. (Clinical-Epidemiological Classification of Leprosy)—*Rev Brasileira de Leprologia* São Paulo 1938 Sept Vol. 6 No 3. pp 229-243

This paper discusses in a general way the principles on which the authors founded the classification they set out in a recent paper [this *Bulletin* 1938 Vol. 35 p 290]

L R

RABELLO Jr Etiologie générale et pathogénie de la lèpre tuberculoïde. [Aetiology and Pathogenesis of Tuberculoid Leprosy]—*Rev Brasileira de Leprologia* São Paulo 1938. Sept Vol 6. No 3 pp 291-314

This paper is a lengthy discussion on the incidence and nature of the tuberculoid type of leprosy. Under aetiology the author mentions the presence of lepra bacilli in small numbers, reactions to the antigens of the bacilli shown by positive Mitsuda tests indicating good resistance and the morphological reactions of the affected tissues. He shows that this type has now been recognized over nearly world wide areas in varying proportions including 10 per cent. of Brazil cases. It differs from lupus in not having a predilection for children and is relatively common in females, but he found it of nearly equal incidence in white and dark races. Familial and conjugal infections are frequent with this form, although it is itself scarcely at all contagious. The author discusses fully the types of tissue and antigenic reactions. The lesions result from the bacilli being distributed through the blood stream to the skin nerves and lymph-gland tissues which afford suitable conditions for their growth. He recognizes three forms of allerge-specific reactions the first to antigens like vaccine lymph or tuberculin the second with high haemo-sedimentation and negative Mitsuda test and the third with low haemo-sedimentation and positive Mitsuda reaction

L R

PARMAKSON (P) Ueber die tuberkulösen Veränderungen bei Nervenlepra in Estland. [Tuberculoid Changes in Nerve Leprosy in Esthonia.]—*Arch f Schiffs u Trop Hyg* 1938. Sept Vol. 42. No 9 pp 401-412. With 6 figs. [23 refs.]

The author reports an examination of 144 compulsorily isolated lepers in Esthonia including 88 cutaneous and 56 nerve cases. Among the latter 14 showed active skin lesions and histological examination showed fully developed tuberculoid changes in two moderate changes in four and slight ones in six cases but no such appearances in two. The tuberculoid changes appeared to be peculiar to nerve cases, and the character of the lesions may possibly be related to the presence of a certain degree of immunity

TISSEUIL (J.) Différenciation par greffes dermo-épidermiques des différentes zones des taches de lèpre tuberculoïde. [Differentiation of the Zones of Tuberculoïd Patches by Skin Grafts.]—*Bull Soc Path Exot* 1938. Oct. 12. Vol. 31 No. 8. pp. 696-698.

The author records the results of grafting portions of healthy skin adjacent to either the active edge of a tuberculoïd patch or to a central quiescent portion of a patch. In the former case the healthy skin graft is invaded from the edge of the tuberculoïd patch, but no extension takes place from the centre of such a lesion. The author concludes that the spread is due to the presence of the leprosy virus in the extending edge and consequently the increase of the lesion is not due to trophic or toxic effects.

MARCHOUX (E.) & PRUD'HOMME (R.) Le bacille de Hansen meurt en moins de trente minutes à la température de 60° et par dessiccation. [Hansen's Bacillus killed in Less than Thirty Minutes at 60°C. Heat and by Desiccation.]—*Bull Acad M/d* 1938. Oct. 4 102nd Year 3rd Ser Vol. 120 No. 28. pp. 174-176.

PRUD'HOMME (R. O.) Moyen de reconnaître *in vitro* si le bacille de Stéfansky est mort ou vivant. [In Vitro Recognition of Living Stéfansky's Bacillus.]—*Ann Inst Pasteur* 1938 Nov Vol. 61 No. 5 pp. 512-518.

In these papers a method is described for the recognition *in vitro* without cultures, whether the human and the rat leprosy bacillus is living or dead. It is based on a reducing colour reaction produced by living, but not by dead organisms. O-cresol-endo-2-6-dichlorophenol is the reagent chiefly used in the experiments, by means of which the lethal action of heat and chemicals has been tested on the leprosy bacillus with the following results. A temperature of 60°C. kills Hansen's bacillus in 30 but not in 15 minutes. If the organism is desiccated over sulphuric acid, and then suspended in normal saline the reducing action occurs but not after the organisms have been washed three times.

The second paper records work on similar lines on Stéfansky's rat leprosy bacillus, which is killed by heating to 100°C. for five minutes, by the action of 1 in 100 formal in fifteen minutes and by ultra-violet rays in ten minutes. The emulsions employed contained very large numbers of bacilli. This method enables the vitality of the bacilli to be determined quickly without the use of prolonged animal experiments.

MARCHOUX (E) & CHORINE (V) Cinq bacilles de Stefansky suffisent pour infecter le rat blanc. [Infection of White Rat with Five Stefansky Bacilli].—*Ann Inst Pasteur* 1938 Sept Vol. 61 No 3 pp 296-299

It is known that very few tubercle bacilli may suffice to infect animals. The authors have carried out similar trials with the bacillus of rat leprosy and have demonstrated that five may suffice to infect white rats with certainty but with slower development of the disease than after larger numbers

L R

GOMES (J M) Pesquisas sobre a lepra murina eliminação de virus. [Elimination of the Virus of Rat Leprosy].—*Rev Brasileira de Leprologia* São Paulo. 1938. Sept. Vol. 6. No 3 pp 273-290 English summary

The author concludes from experimental inoculations of rats with a filtrate of Stefansky's bacillus that within 24 hours the organisms commence to be eliminated through the nose both as acid fast bacilli and in a filterable form. He noted a similar occurrence in a sporadic form in advanced cases of rat leprosy. The presence of filterable germs in the nasal mucous membrane was shown by the fact that emulsions of it filtered through a Seitz filter were infective by inoculation into rats with the appearance of acid fast bacilli in the lymph glands.

COWDRY (E. V) & RAVOLD (Amand) Rosettes in Rat Leprosy.—*Puerto Rico Jl Public Health & Trop Med* 1938 Sept. Vol. 14 No 1 pp 3-15 With 10 figs on 2 plates. [12 refs] [Spanish version pp 16-17]

The authors describe and illustrate by microphotographs the intracellular formation of rosette shaped masses of lepra bacilli in rat leprosy which differ from the faggot-like masses of Hansen's bacillus in globi in that the Stefansky bacilli are arranged radially. There may be a clear space around them and separate rod-shaped bacilli may be seen in other parts of the same large multinucleated cell containing a rosette which were stained by the Ziehl-Neelsen method.

DE SOUZA ARAUJO (H C.) A lepra dos ratos. [Rat Leprosy].—*Memo. Inst Oswaldo Cruz* 1938 Vol. 33 No 2. pp. 297-318. With 3 plates. [28 refs.]

The first half of this article reviews facts already known—the history, distribution, transmission, experiments with Stefansky's bacillus and the disease set up in rats. In the second part is an account of experiments carried out with three strains of the organism obtained one from Professor FICKER in Germany, one from Professor MARCHOUX in Paris and a third from Professor LAIDLAW in London.

Inoculation produced inflammatory granuloma. With the French strain infection was contracted by healthy rats in contact with diseased, but it was less virulent than the English strain. A bacillaemia is produced and the organisms are to be found in the nasal mucus and are eliminated in large numbers in the faeces. It may be that some of those with bacilli in the nasal mucus have been infected from the latter. Attempts to cultivate the organism from the three strains acquired were not successful.

- d PINKERTON (Henry) & SELLARDS (Andrew Watson) Histological and Cytological Studies of Murine Leprosy.—*Ibid* pp 435-442. With 8 coloured figs. on 1 double plate

i. This is a comprehensive account of experimental animal inoculations of rat and human leprosy bacillus emulsions which is largely confirmatory of earlier work. In addition it is shown that intracerebral injections of murine leprosy produced progressive lesions, often accompanied by generalization through the internal organs, in monkeys rabbits, white rats and mice but not in guinea-pigs. White mice of mixed breeds were readily infected by injection into the spleen, liver or peritoneal cavity but usually only abortive lesions resulted from subcutaneous injection except in some inbred strains. White mice have been infected by passage for four years.

In the case of human leprosy material in rhesus monkeys only low grade infections were produced, as by other workers. Rats have been infected intracerebrally from the pia mater of a monkey and acid-fast bacilli found up to 3½ years without progressive disease or active lesions developing.

ii This paper is illustrated by good coloured plates to demonstrate the invasion of the mesenchymal cells of the reticulo-endothelial system by rat leprosy bacilli in the case of the liver spleen brain sheath of a spinal nerve testis, stomach, striated muscle, bone lungs and to a slight extent the kidney. In animals surviving for long non-vacuolated cells filled with lepra bacilli develop in most organs. Non-pathogenic acid fast bacilli on the other hand, disappear within a few weeks after intracerebral injection into animals and never produce metastatic lesions. L. R.

- ROTHBERG (Abrahão) Estudos sobre as reações tuberculínicas na lepra [Tuberculin Tests in Leprosy].—*Rev Brasileira de Leprologia* São Paulo 1938 Sept Vol. 6, No. 3 pp 245-272. [38 refs.] English summary.

The author has studied in 242 lepers the Mantoux reaction with a 1-10,000 dilution of Dorset's synthetic tuberculin, but found positive reactions to be only a little more frequent than in non-lepers. He therefore considers that the tuberculin test is only specific for tuberculosis and is not a group reaction. L. R.

- PEREIRA (Paulo C. R.) A reação de Lleras Acosta na leprose (Reação de fixação do complemento com antígeno metílico de bacilos ácido-alcool-resistentes). [Reaction of Lleras Acosta (Complement Fixation with Methylene Antigen of Acid Fast Bacilli)].—*Rev Brasileira de Leprologia* São Paulo 1938, Sept. Vol. 6, No. 3 pp 315-339 [15 refs. English summary]

The author reports on 391 reactions carried out with the antigen of LLERAS ACOSTA. He obtained positive reactions in 97.5 per cent. of 120 cutaneous cases of leprosy, in 81.48 per cent. of 32 bacteriologically negative lepers, in 4 per cent. of 100 children of lepers, in 18.42 per cent. of 76 patients with syphilis or other skin affections and in 14 per cent. of 50 healthy persons. These data show large discrepancies

from those of Prof Lleras Acosta. He is continuing his inquiry draws no conclusions at present [See also this *Bulletin* 1938 Vol p 551 and p 887] L R

SPEIGHT (Arthur) Observations on the Serum-Formalin Reaction in Leprosy—*Leprosy in India* 1938 Oct Vol. 10 No pp 117-119

The serum formalin reaction in general use for the diagnosis of kala azar has been tried by the author in 100 cases of leprosy. Positive results were obtained in 55 per cent against only 4 per cent in 50 non lepers. Cutaneous cases gave 63.5 per cent and nerve cases 40.5 per cent of plus reactions. An attempt to correlate the reactions with the sedimentation test was inconclusive L R

LIDDO (Francesco) La reazione di Witebsky, Klingstein e Kuhn nella lebbra. [The Witebsky, Klingstein and Kuhn Reaction in Leprosy]—*Riforma Med* 1938, June 25 Vol. 54 No 25 pp 970-972.

This complement fixation reaction with tuberculous antigen has been tested in lepers for some years [see this *Bulletin* 1934 Vol. 31 p 266 1936 Vol. 33 pp 305-342] with discrepant results.

The author has carried out the test on 40 lepers on 52 relatives and others cohabiting with lepers and 71 controls. The subjects were divided into five groups as follows—

Group I comprising 34 cases of nodular leprosy of whom 29 gave a positive and 15 a negative reaction. 5 with nervous leprosy of whom 3 were positive 2 negative one suffered with the mixed form and he reacted positively.

Group II Fifty two relatives of or living with lepers but presenting no clinical signs of the disease. Eleven of these were positive the rest negative.

Group III Six lupus cases 4 with lupus vulgaris of whom 3 gave a positive 1 a negative 2 with lupus erythematosus both negative. They showed no evidence of tuberculosis.

Group IV Forty suffering from venereal diseases. 1 One with ulcus molle—negative 2 Four with gonorrhoea—3 negative 1 positive 3 Twenty five syphilitics (W.R. positive)—7 positive 16 negative 2 doubtful. 4 Ten syphilitics (W.R. negative)—3 positive 7 negative 2 doubtful. Of the total 40 11 were positive 27 negative and

Group V Twenty-five either free of disease or suffering from some cutaneous affection such as scabies eczema epithelioma. Of these 20 were negative 5 positive and of the latter 3 were healthy persons. Seeing that so large a proportion of non-lepers give a positive and a considerable number of lepers a negative the diagnostic value of the test is not great.

H H S

SOEPARNO (AL) Een groep uit het lepra-werk in het Regentschap Blora en het nut van de daarbij verrichte Takata-Ara-reactie [Leprosy Investigation in the Hageny of Blora. The Takata-Ara Reaction.]—*Geneesk Tijdschr v Nederl Indië* 1938 July 28 Vol. 78 No 30 pp. 1817-1821

considered to be satisfactory. During treatment a leprosy reaction may be set up which is of the nature of an exacerbation of the manifestations of leprosy and may be allergic. The treatment of this reaction was by 5 to 10 injections of ornodin in 2 cc. doses—daily in strong patients and twice weekly in the feeble. By this treatment fever came down by lysis, appetite returned, pain in the joints subsided and lepromata became quiescent again. *W F Harley*

ARQUIVOS DA ESCOLA MÉDICO-CIRÚRGICA DE NOVA GOA. Ser B 1937 No 7 pp 1602-1674 Leprosaria Central de Goa. [The Central Leprosarium of Goa.]

This is a report on the activities of the institute during 1935 and is mainly of local interest. The leprosarium is situated in the village of Macasana in the Sakete municipality; it occupies an area of about 18 hectares and is divided into two parts: in one are housed the patients; in the other the personnel engaged to attend them. During October and November there was an outbreak of influenza, but this did not appear to affect the course of the leprosy. Very brief notes are given of 103 patients treated in the institution during the year; there were 9 deaths. Treatment was by chaulmoogra oil given intravenously in doses of 1 cc twice a week with an interval of a fortnight between series of four injections, or by B.C.C.O. intramuscularly twice a week, by moogrol iodide intradermically, by chaulmoogra by mouth, and by injection of chaulmoogra and coconut oil. Much of the report is taken up by laudatory remarks by visitors to the leprosarium and by a list of subscribers. *H H S*

ROSS (Hilary). Pyretotherapy in Leprosy. Biochemical Changes resulting from Exposure to an Air-Conditioned Hypertherm.—*Internal J Leprosy* Manila 1938 July-Sept. Vol. 8 No. 3 pp 331-350. With 8 figs. (19 refs.)

Five patients in different stages of leprosy were given three courses of weekly treatments, during each of which the patients' rectal temperature was raised to between 105°-106°F for from one to three hours, and in one patient for five hours. Elaborate biochemical tests were carried out on blood obtained from a vein at intervals, which furnished the following information. The acid-base equilibrium was greatly affected to the extent of producing moderate alkalotic tetany in one patient. The total proteins were much reduced from an originally high level. Nonprotein nitrogen, urea, blood chlorides and cholesterol were retained, accompanied by impairment of renal functions, albuminuria and casts, but renal function tests showed no evidence of lasting damage to the kidneys. Haemoglobin and red blood cells decreased, but none of the changes were permanent. Contra-indications to the treatment are noted, but no information as to any results from it is recorded. The tests were made at the Carville Loper Settlement U.S.A. *L. R*

BASU (N. K.). Further Studies on Leprosy and Vitamin B₁₂ (C) Deficiency.—*Ztschr f Vitaminsf* Berne. 1938 Vol. 7 No 3/4 pp 297-298

The author concludes from experiments on white mice that animal protein containing vitamin B₁₂ is superior as a diet to vegetable proteins.

RYRIE (Gordon A) On the Treatment of Leprotic Ulcers.—*West African Med JI* 1938 Oct. Vol. 10 No 1 p 41

The author reports on the use of the proprietary antiseptic dettol both by injection of two or three ounces of a 30 per cent aqueous solution into the affected tissues and as a 10 per cent solution for irrigation and dressing in leprotic ulceration and pustular inflammation. Injections cause a rise of temperature but rapid improvement resulted in three bad cases. In eleven cases with pocketing or extensive ulceration very gratifying results were also obtained although he does not advise its long use as a dressing as the parts tend to become sodden. Intravenous injections have also been used as a general treatment in 21 patients with definite improvement in three but it is not clear that they are of value as a routine treatment I R

BETZ (Hans) Zur Behandlung leproser Ulcera. [Treatment of Leprous Ulcers].—*Arch f Schiffs u Trop Hyg* 1938 Oct. Vol. 42 No 10 pp 468-470

In this note the author advises the use of applications of cod liver oil containing vitamins which may be combined with chaulmoogra oil or alepol. Similar applications may be made to the nasal lesions L R

MEHTA (H) A Treatment of Perforating Ulcers in Leprosy.—*J Malaya Branch Brit Med Assoc* 1938 Sept Vol 2, No. 2 pp 88-90

The author recommends the injection of the following freshly prepared solution for the treatment of obstinate perforating ulcers of nerve leprosy. Rivanol gr 1 glucose gr 2 calcium lactate gr 1 sodium thiosulphate gr 2 and aqua cc 10. The rivanol should be dissolved separately in warm distilled water and added to the others. For use 3 cc is injected in the sole of foot in ulcers of the big toe and in the calf of the leg in those of the sole of the foot. In addition 1 to 2 cc. is injected in three places around the ulcers into the subcutaneous tissues. Intense pain rigors and fever follow the injections which may be repeated after a week's rest. Small ulcers may heal in three or four days and larger ones after two or three treatments. A very similar solution is also advised intravenously with the addition of trypaflavine and euflavine aa gr 1. Of 287 ulcers 268 are reported to have healed under the treatment L R

HELMINTHIASIS.

PRÉCIS OF ABSTRACTS IN THIS SECTION

TOTTERMAN (p. 248) found that alcoholic extract of tapeworm if administered *per os* to patients suffering from anaemia due to *Diphyllobothrium* infection, caused a sharp fall in the number of red cells, probably through a mechanism of hypersensitivity. SIEVERS (p. 249) using the complement fixation reaction found that antibodies were provoked in the serum of patients who had previously suffered from tapeworm anaemia, on the administration *per os* of either alcoholic extract of *D. latum* or of dried powdered worm. Controls were negative.

MUELLER (p. 250) describes the progress of *Sparganum mansonoides* infection from the intestinal tract in various hosts. In rhesus monkeys gelatinous swellings in the lower part of the trunk occur due to the burrowing and disintegration of the spargana in the subcutaneous tissues. Previous injections of tapeworm substance prevent this, and the parasites are promptly encapsuled. CORNET (p. 250) advocates surgical treatment for palpebral conjunctival and cutaneous sparganosis rather than intravenous novarsenobenzol.

WANG (p. 251) reports infection by *H. nana* in 0.33 per cent. of a large number of patients examined in Peiping. BACIGALUPO and AGUIRRE PEQUEÑO (p. 251) record a human patient infected with *H. diminuta* in Mexico.

BAXTETT (p. 251) gives figures of the incidence of hydatid infection in Australia and New Zealand. MARANGOS (p. 251) reports six cases of hydatid disease in one family. COUËLEN (p. 252) reports further work on the germinal layer of hydatid cysts. FRIEDRICH (p. 252) calls attention to the diagnosis of *Echinococcus strobilatus*. X-ray examination is useful. LESLIE (p. 252) describes a patient with a hydatid cyst in each lung and STEVENSON and HEGGIE (p. 252) two cases of hydatid disease of the lungs.

HARE (p. 252) records two patients with cysts in the brain. Both had epileptiform fits. DE SÈZE, LAPLANE and FIMMEL (p. 253) discuss the symptoms and diagnosis of cysticercosis of the optic chiasma. The colloidal benzoin reaction is described. ROGERS and TUDHOPE (p. 253) record the operative cure of a patient with a hydatid cyst of the spinal canal. CASTELLANI and ACANTORA (p. 254) describe a patient dying with massive cysticercosis of the brain heart and skin and refer to iatrogenic pseudocysticercosis.

VILJOEN (p. 254) discusses the frequency of cysticercosis in cattle and pigs in South Africa and the commonest site of infection in the muscles. He considers that freezing at -10°C . for 14 days is enough to ensure the safety of lightly infected carcasses, however fat. He recommends treatment in man and close inspection of abattoirs for the eradication of the disease.

ROY (p. 255) records the twelfth human infection with *Bertiella studeri*. C II

TOTTERMAN (Gundö) Ueber die Pathogenese der Wurmanämie [The Pathogenesis of Worm [Diphyllobothrium] Anaemia].—*Acta Med. Scandinavica* 1933. Vol. 98. No 2-4 pp 268-286. With 15 figs. [21 refs.]

The author's explanation of his findings is that the alcohol-soluble components of the worm may produce hypersensitiveness, a belief

favoured by the smallness of the doses used and by the failure of a second infection to cause anaemia and that the mechanism of production of the antipernicious factor is weakened so that this affection may supervene.

To nine patients with a history of anaemia from *Diphyllobothrium* infection there was given daily by mouth for 2 to 4 weeks 0.3 gram of dried worm or the corresponding dose of an alcoholic extract. In five of them the number of red cells fell sharply to as little as a million but the haemoglobin did not fall or did so but slightly (accordingly there was a rise in the colour index) but immediately on ceasing the administration of tapeworm substance the blood condition began to improve returning to normal in a few weeks when one of those reacting positively became infected with the tapeworm there followed a deterioration similar to that in this investigation there was no great alteration in white cells. The residue of the powder after extraction with alcohol had no effect on the blood. Of the other four patients two reacted to worm extract slightly two not at all. There was no reaction to the worm preparation in three persons with a normal blood picture and in three with cryptogenetic pernicious anaemia. A serological test showed that those with a history of worm anaemia and those with the pernicious anaemia seemed to react more often than the others by the formation of an antibody.

Claydon Lane

SIEVERS (Olof) Serologische Prüfungen der Sera von *Bothriocephalus* latius Trägern. [Investigations on the Sera of Carriers of *D. latum*].—*Acta Med Scandinavica* 1938 Vol. 96 No 2-4 pp 289-303 With 4 diagrams. [17 refs.] [English summary *Acta Med Scandinavica* 1938 Supp 89 pp 151-152]

Previous investigations have revealed that the precipitation as well as the complement fixation reaction may give positive outcomes with sera from carriers of the broad tape worm. Examined control sera have also given partly positive results and we have at least so far been unable to obtain any reaction of diagnostic importance. The character of the positive outcomes has been generally considered as non-specific. Animal tests however show that exceedingly specific worm immune sera may be acquired by injection of worm substance (into rabbits).

Dr G TÖTTERMAN has kindly placed at my disposal the cases related by him at this Congress and it seemed to me of interest from a general serological point of view to observe to what extent the blood of these patients, immunized with worm per os, contained worm antibodies. All the sera were tested with the complement fixation reaction worm powder as well as alcohol extract of worm powder being used as antigen. Sera were obtained several times from each patient during the course of treatment.

The results demonstrate that worm antibodies ensued in some cases, after administration per os of worm substance or alcohol extract of worm powder in persons who had suffered previously from bothriocephalus anemia. Positive outcomes were with but one exception, always obtained with the alcohol extract and sometimes also simultaneously with worm powder as antigen. The Wasserman test was carried out in each examination and always with negative result. The antibodies proved by me in these serological investigations sometimes appeared after administration of worm powder and sometimes after alcohol extract had been given but, in the examinations so far made never after administration of the residue left after alcohol extraction. The period of positivity was always very brief and there was no connection between the occurrence of antibodies and the symptoms indicating commencing anemia, at any rate not in this

material. Antibodies were not provable in sera from two control cases (non-bothrocephalus carriers) but they were present in some sera from persons with pernicious anemia.

"With a view to the present stage of these investigations one must be content with stating that worm antibodies may obviously ensue in the human organism on immunization per os and that patients who had suffered previously from bothrocephalus anemia and partly those also who had had pernicious anemia reacted more readily C L.

VON BOESDORFF (Bertel) Wird der antianämische Faktor in Leberpräparaten von *Bothrocephalus latus* zerstört? [Is the Anti-Anemia Factor in Liver Preparations destroyed by D. latum?—*Acta Med Scandinavica* 1938 Supp 89 pp 153-156]

MUELLER (Justus F) Studies on *Sparganum mansonioides* and *Sparganum proliferum*—*Annul II Trop Med* 1938. May Vol 18 No 3 pp 303-328 [With 18 figs. on 4 plates. [10 refs]

A continuation of observations already reported (this Bulletin 1938 Vol 35 p 687)

When *S. mansonioides* is swallowed by various hosts in which it does not become adult it penetrates the wall of the intestine reaches muscle and continues to grow. Because it travels for some distance laterally under the peritoneum before piercing it the intestinal contents do not escape into the peritoneal cavity. The adult taken from the cat and transplanted into tissues of the mouse lives and grows for about 3 weeks. The rhesus monkey will harbour plerocercoids to the number of 600 and will develop a condition of gelatinous swelling in the lower part of the trunk due to burrowing and disintegration of spargana in subcutaneous tissue. If however the monkeys have had injections of tapeworm substance this swelling does not occur for the parasites are promptly encapsuled. In various hosts the infection by sparganum leads to a persistent eosinophilia of 15 to 35 per cent while cats carrying the strobile show it apparently temporarily to about 8 per cent. A restudy of *S. proliferum* from Stiles's material shows no true scolex a confused arrangement of muscle fibres, excretory canals and nerve cords, so it is concluded that the form is an aberrant type of the sparganum of some other species perhaps of *S. mansonioides* since one or the other exists where *S. proliferum* has been reported. C L.

CORNET (Emmanuel) Note sur une nouvelle méthode de traitement de la sparganose oculaire. [A New Method of Treatment of Ocular Sparganosis.]—*Rev Méd Française d'Extrême-Orient* 1938. Feb Vol 18 No. 2 pp. 151-153 [17 refs]

Cornet is not enthusiastic about the treatment of ocular sparganosis by intravenous injections of novarsenobenzol as described by KELLER [this Bulletin 1938, Vol 35 p 223]

As contrasted with surgical intervention intravenous treatment is tedious, as Keller reports, needing 5 to 9 months in certain cases. Surgical treatment if the sparganum is palpebral, sub-conjunctival or cutaneous is rapid and sure whereas in retrobulbar infection local injection of alcohol or attraction of the parasite to superficial sites by

applied heat may be used. Acute inflammation means bacterial infection and for certain diagnosis a cut with a knife discloses a tunnelled fibrous mass

HARE (Clarence C) Cysticercus cellulosus of the Brain. Report of Two Autopsies.—*Jl Amer Med Assoc.* 1938. Aug 6. Vol. 111 No. 6. pp 510-515. With 6 figs.

In one of these cases there had been operations on two cysts in the brain. Autopsy revealed a number more widely disseminated and degenerating. The illness started with epileptiform fits and ended in

mental changes. In the second epileptiform fits had occurred for 20 years. In both there was hydrocephalus and reticulo-endothelial activity in the walls of cyst cavities. C L

DE SÈZE (S) LAPLANE (L.) & FIMBEL (M) Cysticercose opto-chiasmatique [Cysticercosis of the Optic Chiasma].—*Bull et Mém Soc Méd Hôpît de Paris* 1938 July 11 54th Year 3rd Ser No 24 pp 1202-1206

Excess of lymphocytes precipitation of colloidal benzoin in the first 10 or 12 tubes and local eosinophilia in the cerebrospinal fluid occurring in the absence of a Wassermann reaction give a certain diagnosis of cerebrospinal cysticercosis

The history is given of a woman with temporal hemianopsia of the right eye with headache loss of the power to distinguish scents with a constant bad smell in her nose pain in the sacrolumbar region with the right patellar reflex nearly absent and the left one active Cysticercus cysts in the lower part of the spinal canal and about the optic chiasma were diagnosed. Those about the optic chiasma were exposed and removed with some improvement in vision before she was lost sight of C L

[The authors lay stress on the colloidal benzoin reaction and its use in the diagnosis of cerebrospinal cysticercosis. The reagents are made up as follows (1) One gram of freshly powdered Sumatra gum benzoin is dissolved in 10 cc absolute alcohol This is well shaken and left to stand for 48 hours. It is then decanted and 0.3 cc. of the clear fluid slowly added to 20 cc of twice distilled water at 35°C A homogeneous suspension is thus obtained which must be freshly prepared for use (2) A 0.01 per cent. solution of chemically pure sodium chloride in water twice distilled through a glass condenser

For each cerebrospinal fluid to be examined a series of tubes is put up Into the first is placed 0.25 cc. and into each of the remainder 1 cc of the salt solution Into the first is measured 0.75 cc. of the cerebrospinal fluid into the second 1 cc After mixing 1 cc. is removed from the second and placed in the third tube and so on except that the last tube does not receive any C.S.F. acting as a saline control. To each tube is now added 1 cc of the gum benzoin suspension and mixed. Readings should be made after 12 hours at laboratory temperature Three degrees of precipitation are recognized 0 where no change takes place 2 where complete precipitation with clear supernatant fluid occurs and 1 intermediate (BRAXTON HICKS & PEARCE *Brit Med J* 1924 Feb 16 p 263)

GUILLAIN PÉRON & THÉVENARD (*C R Soc Biol* 1926 Vol 95 p 455) give readings in cerebrospinal cysticercosis of 1222122222100000 and 1222222222210000 In conjunction with excess of albumin, positive Pandy reaction lymphocytes numbering from about 76 to 312 per cmm. and negative Wassermann reaction a colloidal benzoin reaction positive in the first 10 to 12 tubes indicates the diagnosis of cerebrospinal cysticercosis—Ed]

ROGERS (J S Y) & TUDHOPE (G R.) Hydatid Cyst of the Spinal Canal successfully treated by Operation.—*Arch Dis in Childhood* 1938, Sept. Vol. 13 No 75 pp 269-274 With 3 figs. [16 refs.]

the case serves as a reminder that the site of election of hydatid cysts in the spinal canal, extradurally and on the posterior surface of the

[March, 1939]

cord, facilitates operative removal, and that the results of operation are frequently most favourable.

The child of 9 had paresis and paraesthesia of the lower limbs and lipiodol showed spinal blockage at the level of the first lumbar vertebra. A cyst easily shelled out measured $2 \times \frac{1}{2}$ inch and when opened displayed hydatid hooklets. She completely recovered movements and lipiodol passed to the lower end of the spinal canal.

CASTELLANI (Aldo) & ACANFORA (G) Brief Notes on Cysticercosis and Læstic Pseudocysticercosis.—*J Trop Med & Hyg* 1938. July 1 Vol. 41 No 13 PP 213-217 With 8 figs.

A general consideration of these two conditions with illustrative cases.

The ten year-old daughter of a Calabrian pig breeder ate pork, often underdone daily. Fever, headache, and exophthalmos were in her history, there was eosinophilia of 30 per cent, trichuris eggs in her stool, and a negative Wassermann reaction and many small nodules over the skin mostly as large as a pea, but varying from the size of a rice grain to that of a cherry. She became epileptic, cyanotic and developed tachycardia dying in her third epileptic attack. The cysts were cysticerci and photographs of the heart and brain show massive infections.

The læstic condition is illustrated by the man already reported (this Bulletin 1938 Vol 35 p 225) with the additional information that some nodules reappeared in March 1938 and disappeared under neosarphenamine bismuth treatment. The Wassermann reaction at the time of retreatment is not noted.

VILJOEN (Noel Francois) Cysticercosis in Swine and Bovines, with Special Reference to South African Conditions.—*Onderstepoort J Vet Sci & Animal Industry* 1937 Oct. Vol 9 No 2. pp. 337-370 With 4 charts, 2 maps & 17 figs. [14 pages of refs.]

C L

This exhaustive treatise (its digestion would have been quickened by a table of contents) takes the history of pork measles back to BC 424 when ARISTOPHANES mentioned the custom of examining pigs' tongues for glandular tumours through LEUCKART'S infection of a calf by feeding it on *Taenia saginata* to a survey of cysticercosis in swine and cattle in most countries of the world. The information regarding the last is got not only from the literature but also from replies to questions which were addressed by the author to many authorities in many places and which constitute a valuable record. As to Union abattoirs the discovered percentage of *C. cellulosae* varied from 0.5 at Hellbron North to 25.07 at Senekal and that of *C. bovis* from 0.08 at Altwal to 7.29 at Port Elizabeth. The commonest seat of infection in 30 pig carcasses minutely dissected was the muscles above the elbow (triceps etc.) and the only instances in which measles were not found there were two animals in which less than 10 measles in all were found. The means of spread in the Union will be understood from the following two examples. There is the instance of a farmer and his household who used the rear of a quince hedge close to the homestead because compared with a stinking, fly infested privy it was far cleaner thanks to the pigs which can be trained to come at a whistle. Then there was

that of three farmers amongst the foremost in the Union with pigs scrupulously styed. When measles were found in their pigs their faith in the life-history of the worm as told them was shaken till on Viljoen's advice they watched their native staff—two of them then reported enthusiastically that each had seen one of these men easing himself in the sty and in one case the culprit had a tapeworm. Enquiries as to the farmers' attitude to the culprits were not pressed. These illustrations justify the advice that insurance schemes for farmers which include indemnification for measles found at abattoirs in carcasses of their stock should be abolished since they encourage carelessness.

C. botis in 25 carcasses of oxen was found in largest numbers and in all animals in the hind limbs and about the shoulder and elbow—it was least common in the diaphragm—in lightly infected beasts the cysts were most frequently found in the masticatory muscles.

As judged by the evagination of the scolex of *Cysticercus* swallowed in a bag or celluloid case which was then recovered from the faeces *C. cellulosae* which had been first frozen for 5 days was not viable. For safety it is felt that a not too fat pig carcass frozen at -10°C for 7 days is safe and that from the public health point of view a lightly infected carcass however fat kept at this temperature for 14 days was so. For *C. botis* 6 days continuous freezing of the carcass is held to be enough. Here as elsewhere in the paper the literature is summarized (the extent of the references shows how fully) in addition to the author's own experience in animals and that of his correspondents in animals and man. His recommendations for sorely needed eradication are necessarily divided between the elimination of the strobile in man including free treatment and rewards for heads (but would not some of the class of person here described make themselves rich as self-breeders of tapeworms at 2/6 a scolex?) and close inspection of abattoirs.

PRÉCIS OF ABSTRACTS IN THIS SECTION

RUSSELL (p. 256) discusses the quinine supplies in India.

RICHARD (p. 257) found in dogs that quinine may produce disturbance of co-ordination through a reflex labyrinthine mechanism.

GORBITZ (p. 257) lays stress on the toxicity of quinine and prefers atabrin as a schizonticide. Plasmoquine has little toxicity in the small doses now recognized as sufficient.

GENTEKOW and CALLENDER (p. 257) detail the treatments given to the Panama Canal Department of the United States Army. These cannot be further summarized. Quinine in the large and long continued doses given is rather more effective than atabrin in preventing relapses in *vivax* infections and markedly so in *falciparum*. Plasmoquine has a pronounced effect in reducing the relapse rate. SIEGENRECK (p. 258) shows that atabrin is more effective than quinine in tertian malaria but points out that toxic effects occur after atabrin injections. KKKHCHER (p. 258) has found acridine to be efficient and well tolerated. DZORKTSEVA (p. 259) as a result of experiments on rabbits found that the combination of plasmoquine and acridine in the proportion of 1 to 3 is less toxic than either drug given alone. MACLAHOV (p. 259) finds that a treatment of quinine and plasmoquine compound followed by atabrin and plasmoquine compound (given simultaneously) gives better results than any other form of treatment in Trinidad, where the infections are chiefly subtertian.

FAGET PALMER and SHERWOOD (p. 260) report unfavourably on the sulphamamide treatment of two patients with *vivax* one with *falciparum* and one with malarial infection. YOOKHOEVE (p. 260) found good results in the treatment of malarial splenomegaly by intramuscular injection of iodinequinine, a mixture of quinine, adrenalin iodine and glycerol. RONCEO (p. 261) treated three patients successfully by the Ascoli method.

HILL and GOODWIN (p. 261) found that atabrin grains 1½ three times weekly gave good results in the prophylaxis of malaria in Georgia where mosquito control was impossible. MELIA ADAMIAN (p. 262) considers that prophylactic treatment with acridine should be reserved for those who have suffered from malaria the previous year. He records his results. FARTOVICH and LENTTI (p. 262) report that after a course of treatment with manganese iodomercurate 17 of 21 non-immune patients were refractory to *vivax* infection when a period of 45 days or more was allowed to elapse between the treatment and the bites by infected mosquitoes. KALMUS and KOSTIC (p. 263) in Jugoslavia found that 26 per cent. of 106 patients treated with quinine sulphate alone and 8.8 per cent. of 162 treated with plasmoquine showed a first relapse. Subsequent relapses occurred in 6.6 per cent. in the quinine and 0.62 per cent. in the plasmoquine series. C IV

RUSSELL (A. J. H.) La distribution de la quinine dans l'Inde. [Distribution of Quinine in India.]—*Bull. Office International d'Hyg. Publique* 1938 July Vol. 30 No. 7 PP 1566-1568.

The question of quinine supplies in India was treated more fully by the same author in the December 1937 issue of the Records of the Malaria Survey of India (see this *Bulletin* 1938 Vol. 33 p. 418).

The amount of quinine distributed by public health and medical agencies in 1935 in British India amounted to 0.06 gm. per head of population and of cinchona febrifuge to 0.43 gm per head. [The latter figure is erroneously printed as 0.06 gm] *Norman White*

RICHARD (Abel) Etude du mécanisme d'action de la quinine sur le système nerveux. [Mechanism of the Action of Quinine on the Nervous System.]—*C R Soc Biol* 1938 Vol. 127 No 13 pp 1232-1234

Experiments on dogs which are described lead to the conclusion that quinine is not toxic to the nerve centres has no direct action on the psychomotor centres and that the disturbance of co-ordination that quinine may produce is attributable to a reflex labyrinthine mechanism. *A II*

GORBITZ (Guillermo) Tolerancia de los medicamentos antipalúdicos [Toleration of Anti-Malaria Drugs.]—*Crónica Méd Luma* 1938 Jan Vol. 55 No 895 pp 22-31

This paper which starts with a list of anti malaria remedies is chiefly concerned with the pharmacology of quinine atabrin and plasmoquine with special attention to the toxic symptoms attributable to each. The toxicity of quinine for protoplasm is made much of. A very complete study of the literature concerning unfortunate sequelae to the administration of quinine has been made and the impression conveyed by a perusal of the four pages devoted to this topic is that quinine is a dangerous drug. The author reaches the conclusion that on all counts atabrin as a schizonticide is much to be preferred to quinine. It is much better tolerated by the organism than is quinine and produces fewer and less important subjective symptoms. Plasmoquine the only elective gametocide has but little toxicity given alone in the small doses now recognized as sufficient. *A II*

GENTZKOW (Cleon J) & CALLENDER (George R.) Malaria in the Panama Canal Department, United States Army II. Results of Treatment with Quinine, Atabrine and Plasmochin.—*Amer J Hyg* 1938 Sept Vol 28. No 2. pp 174-189

For the past few years the Panama Canal Department of the United States Army has had an average troop strength of about 13 000 with a malaria rate of approximately 40 per thousand per annum. The results of treatment of cases occurring in a population under continued careful observation and control cannot lack interest. Cases were treated in the different station hospitals or at the Gorgas or Colon Hospital. The treatment given in these different institutions was not uniform in fact many types of treatment have been used. In general it may be said that the doses given are largely in excess of those usually given at the present time. Before the use of atabrin the more or less standardized quinine treatment consisted of 1 gram of quinine in solution three times a day while in hospital followed after discharge by 1 gm. a day for 90 days. Atabrin when first used was given in doses of 0.1 gm. three times a day for five days the period was afterwards prolonged to seven and then to nine days or even

[March 1939]

longer if parasites persisted. Early in 1935 the atebirin treatment was standardized to a certain extent 0.2 gm. three times a day for the first day 0.1 gm. three times a day for the subsequent six days. In some hospitals this treatment was reinforced with plasmoquine 0.01 gm. three times a day on the third, fourth or fifth days, in the treatment of all types of malaria. At some hospitals the plasmoquine in these doses was given after the atebirin treatment. At the Colon Hospital atebirin 0.6 gm. was given in a single dose, daily for four days followed by plasmoquine 0.01 gm. three times a day for three days. This dosage was quite satisfactory but the dose of atebirin has recently been reduced to 0.4 gm. As a follow-up treatment 0.2 gm. atebirin is given daily for seven days a month after the previous attack.

The number of cases on which this report is based is 1696. Of 967 *vexer* cases 22.9 per cent relapsed of 683 *falciparum* infections 5 per cent relapsed of 48 *malariae* cases 2.2 per cent relapsed. Most relapses 83 per cent of the *vexer* and 97 per cent of the *falciparum* cases, occurred within six months of the preceding attack.

The following conclusions are drawn. Atebirin alone has failed to prevent relapses to a greater extent than any other of the treatments tried. Quinine in the large and long continued doses mentioned above is somewhat more effective in preventing relapse in *vexer* infections than is atebirin and markedly so in *falciparum* infections. Plasmoquine given concurrently with or following atebirin has a pronounced effect upon the relapse rate in all types of malaria this effect was specially noteworthy in the *vexer* cases.

SIEGENBEEK VAN HEUKELOM (A.) & OVERBEEK (J. G.) Behandeling van de acute malaria-anaal met atebirin pro injectie. Tweede mededeeling. [Treatment of Acute Malaria with Atebirin Injections.]—*Groenak Tijdschr v Nederl Indis* 1938 July 12. Vol. 78, No. 28, pp 1633-1633 With 3 figs. [47 refs.] English summary.

Of 875 cases of malaria treated in hospital in Batavia 518 were *falciparum* infections and 111 *falciparum* combined with *vexer*. The case mortality rate was high 7.5 per cent. in subtertian, 2.5 in tertian and 2.7 per cent in combined subtertian and tertian. Intramuscular atebirin injections were given to 634 of these patients. Two injections of 300 mgm. were insufficient to prevent subtertian relapses. Atebirin by mouth 300 mgm. a day for three consecutive days, starting five days after the last injection, was accordingly given to 410 patients, with the result that the relapse rate was only 4.4 per cent as compared with 16.2 per cent among those patients treated by atebirin injections alone. These are minimum figures as it was not possible to follow up all patients discharged from hospital. In uncomplicated subtertian fever treated by atebirin injections the temperature fell to normal within two days in 89 per cent as compared with 75 per cent. in a comparable series of cases submitted to a short course of quinine by mouth. Well-nourished Europeans and Japanese could generally tolerate three or four injections of atebirin if these were given at intervals of not less than 24 hours. In patients with jaundice or with damaged livers atebirin should be given with caution. A badly-nourished native infected with *P. malariae* developed jaundice the day following an atebirin injection and died five days later with acute

atrophy of the liver. No case of cerebral excitation following atebryn treatment was observed. Intoxication occurs with greater frequency after the intramuscular injection of atebryn than after the oral administration of the drug in tertian fevers the oral administration is to be preferred. Atebrin is more effective than quinine in the treatment of tertian malaria in so far as the prevention of relapse is concerned. In severe subtertian cases that are kept under observation the advantages of atebryn injections outweigh the attendant danger of drug intoxication. Atebrin injections are not suitable for mass treatment.

AEKICHER (O M) Epreuve de l'acriquine comme moyen anti paludique sur le terrain [Value of Acriquine as an Antimalarial Remedy in the Field].—*Med Parasit & Parasitic Dis* Moscow 1938 Vol. 7 No 2 [In Russian pp 155-177 French summary p 177]

The author has found acriquine to be well adapted to use in the field in the treatment of tertian fever with acriquine schizonts and gametocytes alike disappear from the blood in from three to four days. The percentage of early relapses after the treatment was 25.9. Health is rapidly re-established under the treatment and the drug is well tolerated. Symptoms of intolerance are few and insignificant. Yellow discolouration of the skin is more frequent among women and children than among men. Three courses of treatment prolong the intervals between relapses by not less than two months.

N II

DOZORTSEVA (P M) Sur la toxicologie et la pharmacologie du composé de la plasmocide et de l'acriquine [Toxicology and Pharmacology of Plasmocide and Acriquine Compound].—*Med Parasit & Parasitic Dis* 1938 Vol 7 No 2. [In Russian pp 197-206 With 21 figs. French summary p 207]

The author considers the results hitherto obtained in this inquiry as provisional only but the following conclusions are justified. The combination of plasmocide and acriquine in the proportion of 1:3 diminishes one of the most serious symptoms ascribable to the administration of plasmocide alone namely its spasmodic action on the vascular system of the isolated ear and of the kidney of the rabbit. It also lessens the toxic action that both plasmocide and acriquine exercise singly on the cardiac activity of both cold and warm blooded animals. Respiration does not appear to be depressed occasionally it is stimulated. Blood pressure is temporarily lowered but there is no weakening of the heart's action. Peristalsis of the isolated rabbit's intestine is weakened but the rhythm of isolated contractions is not slowed. Comparative experiments show that rabbits tolerate better the intravenous injection of the two drugs combined than the injection of acriquine alone. These intravenous experiments indicate the possibility that the proportion of acriquine in the combination might be increased.

N II

MACMAHON (Ryan) Treatment of Malaria. [Correspondence].—*Brit Med J* 1938 Sept. 24 p 681

In an article on the treatment of Malaria the British Medical Journal reproduced a statement of the Malaria Commission of the League of

MELIK-ADAMIAN (S. S.) Essai de l'emploi de l'acriquine en masse pour le traitement des enfants paludéens. [Acridine in the Mass Treatment of Malarious Children.]—*Med. Parasit. & Parasitic Dis. Moscow* 1938. Vol. 7 No. 2 [In Russian pp. 178-191 [55 refs.] French summary p. 191]

School-children to the number of 2 031 who had suffered from malaria the previous year were treated with acridine in April 1935. During the subsequent 13 months the percentage of relapses was only 11.5. Ordinarily there is a spring wave of relapses in the malaria curve. Of the relapses that did occur 60 per cent. were experienced in May and June 1935 they became less and less frequent as the year advanced and in the following spring 1936 their number was negligible 0.6 per cent. in April and 1.3 per cent. in May. No prophylactic administration of acridine was given to them in 1936. The treatment of acute cases of malaria among children of pre-school age with acridine was followed by a relapse rate of only 26 to 30 per cent. during a prolonged period of observation.

The author considers that prophylactic treatment with acridine ought to be reserved for those who have suffered from malaria the previous year. Periodic examination of the blood, especially during the epidemic season, with a view to identifying parasite carriers among those who suffered the previous year and the systematic treatment of such carriers, are important anti-malaria measures; they were of great assistance in improving the health of the community that was under observation.

N 17

FATTOVICH (Giovanni) & LENTI (Pietro.) Ricerche sperimentali sull'azione profilattica dello iodomercurato di manganese verso l'infezione malarica umana inoculata da zanzara. [Experimental Investigation of the Prophylactic Value of Manganese Iodo-mercurate in Malaria.]—*Arch. Ital. Sci. Med. Colon. & Parasit.* 1938. Mar. Vol. 19 No. 3 pp. 129-160. With 7 graphs. [51 refs.]

The observations recorded were made in three widely separated psychiatry institutions in Italy and had as their object the determination of the value of mercury in combination with manganese in the form of an iodate in association with spleen extract in the prevention of malaria. The patients were selected with due regard to past history only those who were unlikely to have any acquired immunity to malaria being used. These were submitted to a month's treatment, in one institution in January in the second in April and in the third in August. The drug was given in pill form, each pill containing manganese iodomercurate 0.011 gm. and spleen extract 0.05 gm. The commencing dose was one pill every second day; this was gradually increased to eight pills a day at the end of treatment. The drug was given in the morning on an empty stomach. There were no signs of drug intolerance and the general health of most patients was improved by the treatment. Increased haemoglobin, increased red cells and an increase in the leucocyte count were commonly noted.

At varying intervals after the completion of this medication the patients were bitten by anophelines infected with *P. vivax*. Controls

demonstrated the adequate infectivity of the batches of anophelines used. If an interval of not less than 50 days had elapsed since the end of treatment a very well marked resistance to infection was noted. Still better results are obtained if the interval be increased to two months or more. This refractoriness was shown by 5 of 7 patients at Imola inoculated 45 days after treatment and by all of three inoculated four months after treatment. In Venice 9 of 11 inoculated two months after treatment resisted infection.

The authors conclude that this mercury manganese preparation in association with spleen extract unlike quinine and synthetic malaria remedies has a real prophylactic action in malaria possibly brought about by an exaltation of the powers of resistance that the reticulo-endothelial system normally possesses. [See also this *Bulletin* 1938 Vol 35 p 31.] A II

KALMUS (H) & KOSTIĆ (D Y) Ueber die Herabsetzung der Zahl der Tropicarexidive durch Plasmochin [Reduction of the Number of Relapses in Malignant Tertian Malaria by Plasmoquine]—*Arch f Schiffs u Trop Hyg* 1938 Nov Vol 42, No 11 pp 501-502

The authors made a study of the records of the malaria dispensary of the hygienic institute in Skopje Yugoslavia. Case records for the year 1937 numbering 8700 were carefully investigated. Children under 1 year of age and cases of pregnancy being excluded. Plasmoquine was almost exclusively administered to patients in whose blood *Plasmodium falciparum* was found. Analogous cases of the same infection treated with quinine sulphate alone were used for comparison. Quinine sulphate was given in doses of 0.5 gm. twice daily till 5 to 6 gm. had been administered in all. The plasmoquine was administered in two methods: (1) As quinoplasmoquine namely 15 tablets one tablet thrice daily for 5 days each tablet containing 0.01 gm plasmoquine and 0.3 quinine. (2) As plasmoquine co. after a four-day period of quinine administration (0.5 gm. twice daily) one tablet containing 0.01 gm plasmoquine and 0.125 gm quinine sulphate was given thrice daily for a further period of five days. Since in Macedonia the risk of infection with malignant tertian malaria does not exist from the middle of October to the beginning of May the cases occurring during this period were regarded as relapses which after the completion of the above treatment gave a positive blood result.

The action of plasmoquine in reducing the number of relapses is seen in the following table —

Mode of treatment	Quinine sulph	Quin + plasmo- quine co	Quino- plasmoquine
Total cases	199	57	105
1st relapse	51	4	7
2nd relapse	8	0	1
3rd relapse	4	0	0
4th relapse	0	0	0
5th relapse	1	0	0

These cases were extracted from the 8,700 case records. Expressed in percentages, 28.0 per cent. had a first relapse after quinine treatment only and 6.8 per cent. after plasmoquine treatment. Subsequent relapses occurred in 6.6 per cent. in the quinine and 0.62 per cent. in the plasmoquine series. The authors consider that the results are fairly free from fallacies.

REVIEWS AND NOTICES

WORTHINGTON (E. B.) [M.A. Ph.D. (Cantab) Director of the Freshwater Biological Association of the British Empire formerly Demonstrator in Zoology at Cambridge University] Science in Africa. A Review of Scientific Research relating to Tropical and Southern Africa. Issued by the Committee of the African Research Survey under the Auspices of the Royal Institute of International Affairs—pp xiii+746 With 5 maps (1 coloured folding) & 8 plates 1938 London New York Toronto Humphrey Milford Oxford University Press 10s 6d]

This is a great achievement. The author has collected an enormous mass of detailed information put it together skilfully and presented it in a readable and entertaining form. The constituent chapters might have been written each by a specialist in the subject dealt with under one editor in chief but thereby the book would lose much of its charm and interest and become a collection of special reports or monographs whereas we have here the broad view of one who has studied so far as it is possible for one individual the many sides of the comprehensive subject of Science in Africa and the author visualizes the inter relation of the various problems which present themselves in a way which separate specialist accounts could never do.

Merely enumeration of some of the chapters will show the extent and depth of observation required. For one man to write on the geology the meteorology forestry (including under this forest reserves destruction of forest and its results) zoology game and game-preservation entomology (with accounts of disease vectors—tsetse mosquitoes ticks and fleas—insect pests and termites) agriculture health problems and the chief diseases of man and stock and anthropology and to do all this intelligently without padding betokens powers of observation and width of outlook possessed by few.

The chapters which most concern readers of this *Bulletin* are the three devoted to *Health and Medicine* on general lines to *Human Diseases* in more detail and to *Health and Population* these together make up more than one-fifth of the entire book. In the first of these the author mentions the present organizations international and special as regards individual Governments Colonies and Protectorates the arrangements made for dealing with disease and the prevention of it child welfare work and social assistance generally and of the utmost importance the medical education of Africans to undertake routine work under supervision for it is impracticable if not impossible to provide adequate medical attendance for millions of natives by practitioners with European qualifications. The training of nurses and midwives is another matter of the very highest importance and is hampered by the difficulty of finding native women of sufficient education to profit by the teaching.

In the chapter on *Human Diseases* the author groups these under four main categories—

1 Those due primarily to conditions of life and likely to disappear when the latter improve this group includes malaria and blackwater fever sleeping sickness and jungle yellow fever 2 Those due to unsanitary conditions such as bad housing water supply conservancy and so on such diseases as plague relapsing fever typhus tuberculosis leprosy helminthic infestations enteric infections and dysentery pneumonia and yaws It would appear to the reviewer that this is a

very arbitrary grouping several of the latter—tuberculosis plague typhus enteric, for example—being as much due to bad social conditions as malaria or even more so. 3 Diseases whose spread is largely due to ignorance such as the venereal infections. 4 Those due to or aetiologicaly associated with malnutrition. Readers will see that such a grouping would leave out some diseases and on the other hand several diseases might with equal right be placed under one or more of the groups.

This chapter gives also a survey of research work on malaria, yellow fever, trypanosomiasis and plague and of the work carried out to control leprosy.

The chapter on *Health and Population* points out the importance and value of vital statistics and demography and the regrettable but unavoidable lack of accurate data. In this chapter the question of food and nutrition is discussed and the closely connected question of the physiology and development of the African. The chapter ends with remarks on the health of Europeans and the vexed question of deterioration of it under tropical conditions and the means for preventing it.

The work is embellished by a few well chosen and well reproduced maps and illustrations and a full bibliography of 85 pages arranged according to the chapters to which the works named particularly apply so that anyone interested in any particular aspect of the subject knows where to seek for further information. Finally the author has given full acknowledgment to all who have helped him in providing information for this work which has the exception merit of being interesting to dip into and to have by one for reference. It is a mine of information.

H H S

MACCHIARELLO (Attilio) [D.M., Dr P H (Harvard) etc.] *Investigaciones sobre la bacteriología e inmunología del tifo exantemático*. [Studies on the Bacteriology and Immunology of Typhus.]—pp xx+222. With over 100 illustrations. [Bibliography] 1938. Santiago Soc Imp y Lito Universo Ahumada \$2.

The studies described and collected in this volume were carried out during a period of three years. The descriptions are so detailed, the methods and results so minutely given that the work becomes one of reference rather than a book to be read sequentially. The whole consists of four parts. The first dealing with bacteriology the second with immunology the third with serum treatment, preventive and curative and the fourth summarizing the conclusions and giving a bibliography of more than two hundred references. Appended are 36 photomicrographs, as clear as reproduced rickettsial photographs ever are.

In part I the author deals with cultivation of Rickettsia and discusses various factors entering into and influencing the culture—medium temperature, use of fresh or dead tissues—and the biological aspects of *R. prowazekii* in tissue culture—morphology staining colony formation filtrability virulence etc. A new method of staining is described. The following is the technique—

- Solution 1 Saturated solution of basic fuchsin in absolute alcohol
- Solution 2 Two per cent. thiocta in distilled water
- Solution 3 Buffer solution of monopotassium (1 per cent.) and disodium phosphate (25 per cent.) with pH 7.4-7.8
- Solution 4 0.8 per cent. citric acid.

From these are prepared —

- I 0.1 cc of solution 1 added to 25 cc of solution 3 and filtered
This is unstable
- II 25 cc of solution 4 are added to 75 cc. distilled water and 0.5 cc. of solution 2, and filtered. This keeps permanently

Procedure — Smears of culture or organs or exudate containing *Rickettsia* even and thin are stained for 3-5 minutes with the 0.25-1 per cent basic fuchsin in the buffer solution or distilled water the stain is filtered directly on to the slide. Decolorization is obtained by 2-3 seconds exposure to the citric acid solution (if longer the *Rickettsia* lose stain). Counter staining is done with carbol methylene blue diluted to 1 in 4 and allowed to act for 1-2 seconds.

The results as judged by coloured plates reproduced are very clear.

In part II vaccination against murine and the European types of typhus is discussed. The technique of Zinsser and Castañeda's vaccine is described the results of animal experimentation carried out with it and the possibility of preparing this vaccine in Chile is discussed. Analogously the manufacture and use of a culture vaccine for European typhus is considered. Employing Zinsser's technique and large flasks he is able to obtain a sufficient quantity of *Rickettsia*. It has proved effective in animal experiments with the guinea-pig and the author states that there is no danger of injecting the living virus and the product should be tested in man. There follow several protocols on the results of sero-vaccination of guinea-pigs against infection by the European type.

Part III as stated deals with preventive and curative therapy. In one table is a record of 70 contacts receiving the Harvard anti-murine serum prepared by ZINSSER and CASTAÑEDA and none of them contracted the disease. In the curative section a few cases only of the European type are recorded. The treatment appeared to shorten the fever lower the temperature and favourably influence the toxic and nervous symptoms but seemed not to affect the evolution of the physical signs present. The book is a valuable record of work meticulously performed.

H H S

MAJUMDAR (Abhil Ranjan) [MB Bengal Medical Service etc.] *Bed-Side Medicine. A Hand-Book of Medical Diagnosis Including Symptomatology, Physical Signs, Pathology, Treatment and Laboratory Methods, from Tropical Standpoint.* Fourth Edition.—pp. xii+939. With 259 text figs & 49 figs. on 26 plates. 1938. Calcutta. The Book Company Ltd. 4/4A College Square [8 Rupees 8 Annas.]

The aim of this book appears to be to describe in a single volume those facts of medicine clinical pathology and treatment which enable the student or practitioner to examine patients intelligently to arrive at an accurate diagnosis and to prescribe adequate and rational treatment. The author states that he has tried his utmost to keep the material within the confines of a handy volume which can be carried about in routine work and he is fully aware that this may have led to omissions. Some of these omissions are not without importance especially to the workers in the tropics. For example yellow fever is described as endemic in tropical America but no mention is made of its presence in Africa undulant fever is said to be centred in Malta and in India is sometimes seen in the Punjab among troops recently

arrived from the Mediterranean Coast, while there is no mention of species of *Brucella* other than *mediterranea* the virus of climatic bubo appears unaccepted Frel's test is ignored and scant attention is paid to the less obvious manifestations of the infection there is no recognition of the effect of sulphonamide drugs in *Bact coli* urinary infections or in gonorrhoea which disease does not even appear in the terminal index. The book has increased in volume but whether such an increase is inevitable is doubtful. Pages might have been saved by the suppression of statements which rest upon little foundation of experimental or practical experience. For example where is the evidence that in blackwater fever the actual process is one of lowered resistance of the red blood cells to the osmotic (sic) tension causing their rupture and haemolysis " and who would agree that organic arsenical drugs are specific curative agents for filarial disease?

Nevertheless, the fundamental excellence of the book has been favourably commented upon in previous reviews (see this *Bulletin* 1935 Vol. 32 p 464 and 1931 Vol. 28, p 336) and the early appearance of the fourth edition is sufficient indication of the value placed upon the work by its readers. The present edition, which is well illustrated by diagrams, photographs and illustrations, will probably prove equally popular particularly in India for which country it is especially designed.

TROPICAL DISEASES BULLETIN

Vol 36]

1939

[No 4

SUMMARY OF RECENT ABSTRACTS

III MALARIA *

[continued from p 192.]

Treatment

Quinine atabrin and plasmoquine

RUSSELL (p 418) discusses the requirements and production of quinine in India. COHEN KING and AINLEY (p 515) tested and report on the chemistry and activity of certain derivatives and analogues of cinchona alkaloids.

GUNTHER (p 102) in New Guinea regards quinine as much superior to any other drug in the treatment and prophylaxis of malaria. EJERCITO and SANTOS (p 31) found that quinine sulphate and Philippine totaquina gave similar results. MRYAHARA *et al* (p 419) found that the therapeutic value of euquinine in mass treatment was low. It has no effect upon the gametocytes of *P. falciparum* and is most widely used by children who are the source of infection. It is also expensive. This author considers that takequina a totaquina is eminently suitable for mass treatment and is cheap. The dose is 0.8 gm. daily for 14 days. Fifteen cases were treated with euquinine and 20 with takequina.

GUPTA (p 517) reports the treatment of a pregnant woman with *falciparum* malaria by the intramuscular injection of 10 grains of quinine three times daily for three days. Recovery was rapid and two months later she gave birth to a healthy child. Reference is made in the *Journal of the American Medical Association* (p 517) to experiments in which quinine was found in human milk soon after administration but not after 24 hours.

THOMAS and SYDENSTRICKER (p 812) treat cerebral malaria by giving 2 to 4 litres of Ringer's solution subcutaneously during the first 24 hours to combat dehydration. Dextrose solution 10 per cent. is given intravenously 500 cc. every four to six hours. Quinine dihydrochloride 0.5 gm. is added to the first dextrose injection and repeated every six hours until cerebral symptoms have disappeared.

The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938, Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

or the patient can take drugs by the mouth. BORMIOLI (p. 29) treats pernicious *falciparum* infections by a first intravenous injection of 2 gm. quinine followed during the first 24 hours by three intramuscular injections each of 1 gm. quinine. On the second and third days 4 gm. daily are given by injection and further treatment on the same heroic scale is given if necessary. He states that this kills all forms of the parasite and prevents relapse.

MUHLERS (p. 103) reports cases of quinine idiosyncrasy with circulatory disturbances, urticaria, oedematous swellings of or hæmorrhages into or from skin and mucous membranes. These hæmorrhages may be serious, even fatal. The synthetic drugs have not produced hæmorrhages.

PIETRO (p. 510) gives a heavy course of treatment for malaria in Italian East Africa which includes quinine intravenously and by the mouth, the synthetic drugs, and neosalvarsan.

Comparisons between quinine and atabrin have been made by several authors. KRANZFELD *et al* (p. 420) treated 388 cases with acridine the Russian equivalent of atabrin (0.15 gm. b.i.d. for five days) and 94 with quinine (1.5 gm. daily). The proportions of parasitic relapses were almost equal *vixx* relapses being four times as frequent as *falciparum* with both treatments. TILLEMA (p. 421) treated 140 patients with quinine (0.4 gm. thrice daily for a week) and 120 with atabrin (0.1 gm. thrice daily for a week). Differences in results were negligible and relapses frequent. Quinine should be continued for a week and atabrin for five days after disappearance of parasites. OVERBEEK and GILBERT (p. 516) treated 100 cases of benign tertian malaria 53 with 0.3 gm. atabrin daily for five days 47 with 1.3 gm. quinine daily for seven days. The rates of action were equal, but three weeks after treatment 34 per cent. of the quinine group harboured parasites compared with 5.6 per cent. of the atabrin group. MIYAHARA (p. 516) after treating 30 cases with 0.3 gm. atabrin daily for five days concludes that it is no more effective than quinine in preventing relapses. *Vixx falciparum* and *malariae* infections were included.

These results should be compared with those of CALAN and others below.

Action.—The action of drugs on the various stages of parasites has been studied by a number of authors. CUDCA *et al* (p. 32) consider that the therapeutic action of quinine and atabrin are upon the asexual forms of the parasite and not upon the sporozoites or any intermediate stages. SURTON (p. 884) states that atabrin is known to produce morphological changes in both sexual and asexual forms of *P. vixx* and *P. malariae* and in the asexual forms of *P. falciparum*. Observations at Horton however have shown that atabrin is not without effect on the crescents of the Rumanian strain of *P. falciparum* in use there if administered before crescents are detected in the peripheral blood. When crescents appeared after this treatment, certain changes were noted and are described. DE SANT'ANA QUEIROZ (p. 565) in experiments on monkeys infected with *P. knowlesi* found that atabrin was progressively more active as the development of the parasites progressed—most so when given at the stage of chromatin division—much less so when sporulation was taking place.

GUNTZKOW (p. 569) describes a method of estimating atabrin in the blood, and CHOPRA and ROY (p. 570) one for estimating atabrin in tissues. WEISS (p. 103) discusses the estimation of atabrin in urine.

stools and blood. FARINAUD *et al* (p. 518) found that after a five-day course of quinacrine (the French equivalent of atebryn) the drug only appears in the urine after a lapse of time (4 days in the first case). It is then excreted for four or five days in considerable amounts becoming less and less for a month. A period of 70 days is usually required for total elimination but the total amount found in the urine is only a small proportion of the amount administered.

The Malaria Advisory Board of the Federated Malay States (p. 20) report that atebryn musonate is one of the most powerful schizonticides known but as toxic effects are occasionally alarming it is not a drug which can be recommended for indiscriminate use. [See also this *Bulletin* 1936 Vol. 33 p. 235-834.]

HILL (p. 657) considers that atebryn is the first drug known that could possibly be used effectively in mass treatment and prophylaxis. A curative dose can be given without interference with working efficiency.

MATILLA FÁBRIGA and VICH (p. 419) prescribe for persons over 10 years atebryn 0.3 gm. daily for seven days a pause of three days than plasmoquine 0.03 gm. daily for 5 days. They claim from 100 cases rapid cure and protection from relapses in benign and malignant tertian malaria. This treatment is not contraindicated in pregnancy and atebryn is the drug of choice in blackwater fever followed by plasmoquine if gametocytes are present. DOMÍNGUEZ CALÁN (p. 895) compares relapse rates of from 1.2 per cent. to nil in three groups of patients with *vivax* infection treated by three combinations of atebryn and plasmoquine (total 150 cases) with a relapse rate of 59.58 per cent in 2,712 cases treated with quinine for 20 days. VELMAN (p. 513) cured a child of four with atebryn and plasmoquine when quinine had failed and advocates atebryn for malaria in childhood. CHOPRA, HAYTER and SEN (p. 30) compared 45 cases of malaria (14 *vivax*, 20 *falciparum*, 3 *malariae* and 8 mixed infections) treated with atebryn plasmoquine dragées (atebryn 0.1 gm. plasmoquine 0.005 gm. one dragée thrice daily for five days) with 37 treated with atebryn alone. The combination is no more effective than atebryn alone in *vivax* and *malariae* cases but is more effective in *falciparum* infections especially if crescents are present. REV (p. 897) in Spain used Atepe tablets containing atebryn 0.1 gm. and plasmoquine 0.005 gm. in the treatment of 686 cases of benign tertian malaria. The dose for adults was 3 tablets daily for five or in severe cases seven consecutive days. The tablets were given in one daily dose. The relapse rate was 12 per cent.

NANDI and DIKSHIT (p. 664) describe a colour test for plasmoquine in blood and tissues. It is not suitable for urine.

Other drugs

MISSIROLI and MOSNA (p. 564) give 2 cgm. Cilonal (discovered by SCHULEMANN) daily for six days. They consider that used with quinine or atebryn cilonal provides a complete anti-malarial remedy. Its action on the gametes of *P. falciparum* is equal to that of plasmoquine and it is not toxic in efficient therapeutic doses. KIKUTHI (p. 563) found that Certuna (which is probably the same as cilonal) though inferior to plasmoquine possesses marked gametocidal power in malignant tertian malaria. His method of testing this power is described. MÜHLENS (p. 562) believes that Certuna (Bayer) is superior to plasmoquine as a gametocide in malignant tertian malaria. He

gives it after aiebrin in doses of 0.03 gm. or more daily for at least three days. STOLI (p. 563) increased the dose of Certuna to 0.07 gm. thrice daily for seven days. Cure is not obtained.

HILL and GOODWIN (p. 561) report very favourably on prontosil in 83 cases of *falciparum* and 7 of *vivax* infections. It was given intramuscularly 10 cc. every 12 hours. More than four injections were seldom necessary and it acted particularly rapidly if symptoms were severe. DÍAZ DE LEÓN (p. 581) treated 15 cases of benign tertian infection with rubiarol (prontosil) with completely satisfactory results. It was usually given by the mouth. READ and PINO (p. 582) on the other hand, consider that sulphonamide in benign tertian malaria has a poor specific antimalarial action. MOTZFELDT (p. 596) treated two patients undergoing a course of therapeutic malaria with prosectasine with good results. He states that all three principal forms of malaria are equally amenable to treatment by sulphanilamide but reserves opinion on the general use of this as a specific remedy.

GLYNN HUGHES, LOURIE and YORKE (p. 655) found that *n*-undecano 1-11 diamidine had a beneficial effect in human malaria, especially on the asexual forms of parasites. They do not however recommend the drug for treatment.

SAUTER (p. 30) reports that dihydroquinamine, though useful by intramuscular injection, produced nausea and gastralgia. By the mouth it was ineffective.

CABRAL (p. 31) treated 13 patients with M3 a double iodide of mercury and manganese combined with spleen extract. It is not a reliable gametocide but may improve general nutrition and anaemia and reduce the spleen. Symptoms of intolerance were observed in half the cases.

RADYAN *et al* (p. 34) discuss the action of acaprine with which they obtained favourable results in malarial splenomegaly. Its effects resemble those of adrenalin.

Ascoli's method

Page	Author	No. treated	Results and remarks
35	Marcialis <i>et al.</i>	15	Splenomegaly in children Satisfactory
563	Monaco <i>et al.</i>	6	Very satisfactory in all.
566	Acanfora	5	Chronic. Very satisfactory in all
658	Pizzillo	6	Acute. Adrenalin with quinine. Very satisfactory in quinine-resistant infections.
893	Milletari	70	Great value in splenomegaly and on patients general condition.
893	Moona	9	Chronic splenomegaly Good results in all.
893	Dell	6	Good results in all.
895	Noemoth	10	Primary attack treated with quinine. Then adrenalin. Three febrile relapses. Several parasite relapses.
895	Noemoth	6	Adrenalin no effect on crescents.

From this table it is seen that the results of adrenalin treatment are usually good. Marcialis administers it by intramuscular injection

in small children. The infections of Monaco's cases included *vivax falciparum* and *malariae*; those of Nucciotti's series were all *falciparum*. Otherwise the infections are not stated in the abstracts.

TIMPANO (p 104) describes the method of using the treatment in malaria and kala azar. Good results were obtained in both. The adrenalin is given 1 to 2 hours after quinine (or the antimony compound) if this is given by the intramuscular route. If by the intravenous method the adrenalin is given at the same time.

GOSTO (p 188) describes the measurement of the spleen by radioscopic methods. The adrenalin treatment is specific for the *stato malarico*. PIZZILLO (p 566) describes the form and rhythm observed in the changes of size of the spleen during the process of reduction under the Ascoli treatment.

Other methods

LORANDO and SOTERIADES (p 35) in Greece treated 20 more children suffering from malaria [their earlier paper dealt with 23 cases] with subcutaneous injections of maternal whole blood which presumably contains immune bodies. In some cases small doses of quinine were given also but in 9 haemotherapy alone was used. In all cases the treatment was successful with a rapid fall in temperature and reduction in the size of the spleen. Many remained free from fever for a long period although living where reinfection is inevitable. [See also this *Bulletin* 1937 Vol 34 p 63]. ARACTINGI (p 31) treated 100 patients (principally with *vivax* infections) with subcutaneous injections of their own blood in 10 cc. doses at 3 to 5 days interval to a total of 40 cc. The blood was taken and injected during fever free periods and the treatment was conceived on the supposition that at such times the blood contains a toxin which injected leads to the formation of antitoxin. In 80 of 100 patients fever ceased after the third injection and no relapses occurred during seven months. In 15 fever ceased after the fourth injection and reappeared slightly after three weeks. In 5 no benefit was seen.

Prophylaxis

(a) Drugs

Opinion as to the value of drug prophylaxis is somewhat divided but favourable reports are given. It seems probable that regular drug taking leads to increased susceptibility if the drugs are discontinued. This may be due to loss of immunity.

PARROT *et al* (p 422) found that the daily administration of quinine reduced spleen rates and brought parasite and gametocyte rates to zero. Quinacrine was less successful probably owing to under-dosage. In both the gametocyte rate followed the curve of the parasite rate and the authors think that both drugs have some action on young gametocytes.

MEZINCESCU *et al* (p 422) in 1935 observed a village of 271 inhabitants. In 101 given atabrin prophylactically the parasite index was 1.9 per cent. in 99 given quinine 1.8 per cent. in 71 controls 15.1 per cent. There were practically no cases of clinical malaria in the treated groups. In 1936 no drugs were given in this manner and in the atabrin group there were 33 cases of malaria, in the quinine group 26 and in the controls 18. FIELD, NIVEN and HODGKIN (p 36) gave atabrin (0.2 gm. on two successive days of each week) and quinine bihydrochloride (0.4 gm.

daily) to two groups of persons on a plantation in the Federated Malay States. A third group acted as control. Smaller doses were given to children. The groups were observed for 15 months and during the last six the reduction in malaria in the treated groups amounted almost to elimination, but when the drugs were stopped malaria rapidly reappeared and was almost twice as frequent in the treated groups as in the controls. The action of the drugs was, in effect, to prolong the incubation period up to as long as one year. Atebrin was more potent than quinine and the risks are very slight.

RACHINA *et al.* (p. 33) conclude that the usefulness of both acríquine and quinine prophylactic courses is most evident if they are begun a few days before the annual wave of benign tertian relapses. Acríquine is rather more successful than quinine. HILL and GOODWIN (p. 37) in America treated groups with atebrin (1½ grains thrice weekly) and quinine (10 grains daily). The percentages of new infections were atebrin group 1.8, quinine group 5.5, control group 31.6. LAVERGNE (p. 562) considers the synthetic remedies better than quinine for collective prophylaxis.

CLARK and KOMP (p. 806) in Panama found that quinine, atebrin and plasmoquine prophylaxis does not give promising results. Carriers are missed at each survey and are enough to keep up transmission. Some natural immunity may be destroyed by treating subclinical cases. Immediate treatment of clinical cases is a most useful measure where the elimination of *Anopheles* is impossible.

FARINAUD and MOREAU (p. 167) find in Indo-China that in a few areas of moderate endemicity with a marked and limited seasonal prevalence the use of synthetic remedies as the sole measure of prophylaxis has given good and lasting results. In hyperendemic areas they are insufficient, and almost continuous treatment is neither practicable nor desirable.

MOSMA and CANALIS (p. 28) in a well controlled experiment, found that atebrin administered 0.2 gm. twice weekly (adult dose) to a section of the population of a village in Sardinia appeared to exert a very considerable prophylactic influence both during the period of administration and for six months afterwards. Daily atebrin was also successful but to a lesser extent. WINCHESTER (p. 567) in the Southern United States gave atebrin daily to 428 persons. No malaria occurred in the season but in a control group of 202 the incidence was 24.3 per cent. Parasite carriers were not found in the prophylactic group but in the control group they numbered 19.6 per cent. The common infection is *falciparum*. JALALYAN and KARASEVA (p. 33) found that 3.1 per cent of 127 persons taking atebrin had attacks of malaria as against 13.2 per cent. of 114 controls.

WINCHESTER (p. 658) considers that using atebrin one can control, if not eradicate malaria in the Southern United States but that anti-mosquito and anti-larval measures should also be used. HOORS (p. 659) in Malacca, gives two tablets of atebrin twice weekly for four weeks and two tablets once weekly thereafter. This can suppress clinical manifestations where anti-larval measures are only partially effective.

OGANOV *et al.* (p. 32) found that 0.4 gm. acríquine given every 10 days had a good prophylactic effect. By successfully suppressing clinical symptoms, which are bound up with the appearance of gametocytes, it may be used to lower the infectivity of mosquitoes. SICAUT and MESSERLIN (p. 421) remark that for clinical prophylaxis

among a population living in a moderate or severe endemic zone and consequently premunized, it suffices to treat the children and the sick. Quinacrine and praequine are given every 8, 10 or 15 days according to the intensity of the prevalence of anophelines and of gamete carriers. In insufficiently premunized communities threatened with unusual outbreaks the whole population should be treated in the same way. The state of premunition is determined by the relation of the parasite index of children to that of adults and by the splenometric index.

CIUCA *et al* (p 899) found that with a six months atebirin and plasmoquine prophylactic treatment 1.3 per cent of the treated and 8.1 per cent of the untreated or irregularly treated suffered from malaria. Splenic splenometric and parasite indexes had fallen considerably at the end of a six months course and were considerably lower than before the experiment after a period of two years during which only clinical cases were treated. SICAULT and MESSERLIN (p 421) in Morocco for the eradication of malaria gave quinacrine 0.3 gm. and praequine (plasmoquine) 0.03 gm weekly to all infected persons identified either clinically, serologically or haematologically. Anti-larval measures are also conducted. BLOMMINI (p 810) found that atebirin and plasmoquine administered each Saturday and Sunday in Italy gave encouraging results. Clinical attacks were less frequent in the treated group than in the rest of the population.

Senior WHITE and ADRIKARI (p 567) report that no delay caused by malaria was experienced in a labour camp where each person received a course of atebirin followed by a weekly dose of plasmoquine. Previously malaria had been a serious matter.

FARINAUD (p 562) found in Madagascar that two courses of quina-crine and rhodoquine cleared the blood of 94 per cent of children who had previously shown parasites, when examined up to one month after completion of the treatment. DUBOUX *et al* (p 566) gave premaline (a tablet containing quinacrine, rhodoquine and praequine) regularly to 27,097 persons in Tunis over a period of 5½ months. Spleen, parasite and gamete indices fell remarkably and clinical relapses were rare. The authors are enthusiastic about the results.

CHOPRA and BASU (p 569) found that plasmoquine in doses of 0.02 gm was effective in preventing the development of crescents in *A. stephensi* but atebirin and malarcan prevented the development of gametocytes of *P. malariae* and quinine arrested development of oöcysts in *ritax* infections. TIBOURSKAJA (p 35) advocates that all gametocyte carriers should be given 0.03 gm plasmocide thrice daily every third day until a few days after the gametocytes have disappeared in order to render them incapable of infecting mosquitoes.

(b) Other measures

General—DECOURT (p 898) discusses the limit of benignity or the degree of malaria infestation above which pernicious forms appear. In most regions there are virulent areas which maintain dangerous strains of parasites and conserve active malaria. Antiplasmodial measures should include chemoprophylaxis for the virulent areas and areas of moderate endemicity, sanitary barrages, the search for and treatment of cases and hygienic prophylaxis. EARLE (p 21) shows that in Porto Rico the malaria prevalence was not affected until the mosquito density had been brought down to and maintained at an extremely low figure. SICAULT and MESSERLIN (p 421) realize that in

Morocco attempts at the eradication of malaria are only possible in places where anopheline infestation is moderate and the disease not widespread.

ROUBAUD (p. 568) shows that improvement in housing conditions and social progress favour the development of zoophilic deviation of Anopheles. This deviation is a vast biological phenomenon and the first necessity seems to be a general transformation in the conditions of human life. GROOTINGS (p. 903) advocates, in those parts of the Dutch East Indies where increased malaria has followed house improvement inaugurated as a protection against plague that drainage channels and the water surface of ponds should be cleaned, swamps should be drained and dried and stalks cut and burned after the harvest fish should be introduced to eat pond vegetation and possibly that mosquito curtains should be distributed. The Malaria Advisory Board of the Federated Malay States (p. 20) draws attention to the necessity for filling in holes left by uprooting trees on rubber estates. CORRADETTI (p. 573) in Italy found that *A. cius* was present in abundance where bonification had either not been or had only imperfectly been carried out and its prevalence diminished in direct proportion to the progress in bonification achieved.

DR PALMAS and SANCZ (p. 281) detail the measures which succeeded in converting a very unhealthy military post in Tonking into a comparatively healthy station. These include clearing and levelling drainage and oiling, the use of mosquito nets and prophylactic quinine.

WATSON and SPAIN (p. 188) in Alabama think that the creation of lakes by the impounding of the water of the Tennessee would lessen rather than increase malaria transmission if modern anti-larval measures are carried out through the breeding season. CARR (p. 900) reports that the shading of watercourses by planted *Ficus benjamina* is an important measure in the eradication of larvae of *A. albimanus* in Cuba.

HILL (p. 23) in Portugal records that intermittent irrigation of rice fields has proved successful experimentally in the control of breeding but screening of labour barracks and improvement in agricultural methods are necessary. SMALT (p. 427) found in Bali that draining rice fields for two successive days every nine days reduces the number of larvae of *A. aconitus* to one-third or less of the figure found previously without serious loss of produce. SCHARFF (p. 98) finds shading or finishing and agitation of the water surface to be useful measures of control in Malaya.

Drainage.—RECTOR (p. 812) describes control in Mississippi. Ditch lining receives most attention. A round bottom invert with the banks of the ditch covered with Bermuda sod gives the best results. Wood ash is used as a fertilizer for the sod. HARKNESS and SAMARA (p. 98) used dynamite in the excavation of drainage canals in Palestine. They describe the method, which is not suitable for dry soil or semi-liquid marsh. Excavation by hand labour costs ten times as much. Oiling.—WATSON (p. 258) considers that the killing power of a larvicide may be best estimated by noting the interval which elapses between the entry of oil into the breathing tubes and the moment when the heart muscle finally ceases to contract. This may be determined by the cessation of tracheal movements. Paris green behaves in larvae as in man as a gastro-intestinal poison. MURRAY (p. 654) discusses the stability of oil films. The conclusions cannot be further abstracted. MANSO (p. 811) describes a method of oiling streams in

Assam which consists of an oiled gunny mat which is unrolled on to the surface of the water. The method is cheap and effective.

Dusting—BRASIER-CREAGH (p 725) describes the dusting with Paris green of flooded land near Delhi by means of a D.H.83 Fox Moth aeroplane. Slow and low flights should be made and the pilot should know the ground and the day to day changes in the position of the flood water. WATSON HIKER and JOHNSON (p 512) find that aeroplane dusting of Paris green is useful in somewhat open water with low emergent vegetation but not where there is dense horizontally locking vegetation. The usual height of flying is 25 feet. HIKER *et al* (p 805) show that one pound of Paris green per acre in a 20 per cent by volume mixture gave good results when distributed from an aeroplane on Lake Wheeler Tennessee. It is not successful in areas of dense vegetation. RAO and SWIFT (p 97) used 1 per cent of Paris green in road dust and wood ash for dusting rice plots in Mysore. Over a period of three years no evidence was found of any adverse influence on the yield of rice or straw.

PIVOVAROV and GUTERMAN (p 512) describe the results of using anabasin, a powder insecticide of the nicotine type. KALANDADZE and LEIMER (p 573) investigated chloropicrin as a larvicide. It is successful when used to moisten sawdust which is then broadcast. It is expensive.

Larvivorous fish—MORIN and MARTIN (p 38) give practical details concerning larvivorous fish. They are seldom adequate alone but form a valuable supplement to other measures such as the use of Paris green. MORIN and MOREAU (p 188) consider that small larvicidal fish may be of great value in the centre and south of Annam but that in the north larger omnivorous varieties are necessary. COLLIGNON *et al* (p 261) report that increased attention is being paid to *Gambusia* as a larvicide in Algeria.

Spraying—COVELL, MULLIGAN and AFRIDI (p 901) report very encouraging results from the regular spraying of native houses with Pyrocyde 20 diluted with 19 times its volume of kerosene. At first 2 cc. per 1 000 cubic feet of air space was used, later the quantity was halved. Rooms were closed for half an hour after spraying. Various communities and two villages were treated in this fashion twice a week or oftener. Cowsheds were also sprayed. The results (which are given in the abstract) were remarkably good and the cost was about fourpence per head for the malaria season. GINSBURG (p 260) reports favourably on the protection of outdoor gatherings against mosquitoes by the production of a cloud of atomized dilute emulsified kerosene pyrethrum extract.

Screening—BLACKLOCK (p 259) points out that since a certain proportion of *A. funestus* and *Aedes* can pass through a 14-mesh screen-cloth made of wire of 30 Imperial S.W.G. It is unsafe to use this gauze without experimental proof of its efficiency in each locality. CHIRILOVA and SCHLONOVA (p 36) found in Russia that the use of metallic screening combined with mosquito nets gives considerable protection but the necessity of killing all adult mosquitoes in dwellings should not be overlooked. BESSLER (p 656) compared 19 metallic gauzes over a period of 7 years. The best results were seen with steel, aluminium, bronze, Monel metal and galvanized iron. All were durable except galvanized iron even in coastal regions.

GORE (p 199) describes a simple mosquito trap.

Research

CRUCA *et al.* (p. 28) dissected infected salivary glands of *Anopheles* in solutions of basic quinine and atabrin each in 1 in 2,500 concentration. The sporozoites were in contact with the drugs for 15 minutes. One patient of four in the atabrin and two of four in the quinine experiment became infected after receiving injections of the suspensions.

RAFFAELE (p. 100) shows that the blood of canaries injected intravenously with large numbers of sporozoites of *P. praecox* is not infective until after three days. Human findings are similar. The sporozoites probably enter the reticulo-endothelial cells.

MISSIROGLI (p. 599) from observations on the (so called) sporozoites of *P. praecox* (*velicium*) injected into canaries concludes that they are in reality immature sporocysts which continue their development in the lymph spaces and give rise to sporozoites, not more than eight from each.

YORLI (p. 732) has succeeded in infecting *Anopheles* by inducing them to feed through a membrane prepared from the skin of a rabbit's ear stretched over a tube containing gametocytes in defibrinated blood kept for five hours at 23 to 27°C or for 72 hours in the ice box.

GARCIA (p. 816) for the study of parasites puts up malaria infected blood as for culture and keeps it at 10°C instead of 37°C. SIMONS (p. 814) describes a rapid method of staining blood films in which saponin is used for haemolysis and methylene blue for staining. MATUMOTO and HIRASAKI (p. 815) describe a method for the simultaneous staining of large numbers of films.

Malaria in Monkeys and Birds

MOSKA (p. 731) tested various African monkeys as hosts for *P. knowlesi*. None was as satisfactory as the Indian *M. rhesus*.

JOLLY LAVERGNE and TANGUY (p. 107) found the cycle of *P. knowlesi* to be 20 hours instead of the usually accepted 24. Passage through man reduces the virulence so that in *Cynocephalus papio* only mild chronic infection is produced.

RODHAIN and VAN DEN BERGHE (p. 107) describe *P. gonderi* of monkeys which, in view of its 72 hours cycle they regard as a distinct species. SINTON had previously regarded it as the variety *gonderi* of *P. swinsii*.

RODHAIN and MUYLLE (p. 816) failed to infect three patients with the virus (one patient) and *falciparum* (two patients) types of the species of *Plasmodium* of chimpanzees though no difficulty was found in the transmission of infection to other chimpanzees.

WEYER (p. 107) found that complete development of *P. knowlesi* in *P. cynomolgus* and *P. swinsii* takes place in *A. maculipennis* although injection of apparently normal sporozoites from the salivary glands did not produce infection. The reason for this is not clear.

MALANOS (p. 108) studied immunity in monkeys. A high degree of acquired immunity can be produced by repeated super-infections. It is strictly specific and limited to homologous strains of the same parasite. It breaks down if splenectomy is performed or if the R.E.S. is blocked but even then it may be produced by reinfection, and disappears after treatment and complete eradication of the parasites to the extent that reinfection can be carried out, but the decreasing intensity of subsequent infections in certain cases indicates that some degree of immunity remains. Natural immunity is very rare. Das

GUPTA (p 732) found that in monkeys immunity to *P knowlesi* persisted only as long as parasites remained in the body With complete eradication of infection the immunity was lost

COGGESHALL (p 109) found in monkeys that the greatest degree of splenomegaly was associated with the milder and more slowly developing infections and was accelerated by repeated injections of parasites

MALAMOS (p 108) noted auto-agglutination of red cells in one of 200 monkeys infected with *P knowlesi* A large number of the cells in each clump contained half-grown parasites The phenomenon persisted after atebirin treatment

COGGESHALL and KUMM (p 109) demonstrated that the serum of monkeys with chronic infection has a depressing effect on the course of the disease if injected into monkeys with an acute attack [See also LORANDO and SOTERIADES above]

MANWELL (p 731) working on cross immunity with nine species of bird malaria parasites found that *P elongatum* did not protect against any other and conversely Four small parasites like *P rouxi* protected against each other and against *P cathemerium* but not against *P praecox*

MANWELL and HEWITT (p 104) cultured *P praecox* of birds in capillary tubes at 25°C. A small quantity of heparin was added to prevent coagulation

BRUMPT (p 105) gives a list of birds susceptible to and of those refractory to infection by *P gallinaceum* In fowls up to 90 per cent of red cells may harbour parasites without there being signs of illness until about two days before death *Aedes aegypti* and *Aedes albopictus* are vectors. KIKUTH (p 729) confirms the work of BRUMPT on *P gallinaceum* and its development in *Aedes aegypti* He observed the pigmentless schizonts described by JAMES and TATE in *P gallinaceum*, *P cathemerium* and *P praecox* infections. The number found bears no relation to the intensity of the infection. They may be found in the brain kidney lung liver heart and bone marrow 72 hours after sporozoite injection KIKUTH and MUDROW (p 729) however state that the number of these forms in the internal organs increased with the severity of the blood infection They do not think that these schizonts belong to parasites other than those of malaria. RODHAIN (p 899) found endothelial non pigmented schizonts in penguins in Antwerp infected with *P praecox* These occur not only in the fixed endothelial cells but also in the monocytes and histiocytes of the blood and the author considers them to be derived directly from the sporozoites of mosquito infection BRUMPT (p 104) considers that the irregularity of the occurrence of schizonts of *P gallinaceum* within endothelial cells points to accidental ingestion rather than an essential stage in development

HEGNER and WOLFSON (p 730) however consider that further work is necessary before it can be concluded that endothelial schizonts actually belong to the malarial parasites and not to toxoplasms which are relatively common parasites of birds.

GAMBRELL (p 729) studied gametogenesis in *P cathemerium* and *P relidum* var *matulinum* infections Pregametocytes appear at each schizogony (which takes place at 24 hour intervals) and reach maturity 6 to 10 hours later Strains vary in their capacity to produce gametocytes A strain started from a single cell by STAUBER produced

AMOEBIASIS

PRECIS OF ABSTRACTS IN THIS SECTION

Vlassani (p 283) describes an outbreak of amoebic dysentery on a torpedo boat. Two members of the crew were cyst passers

ARCHETTI (p 283) notes that the disease is widespread in Italian East Africa.

TCHALAJA (p 284) shows that in culture the variation in the long and short diameters of vegetative amoebae extends from 5 to 48 μ and 5 to 33 μ respectively

PAVLOVA (p 284) found that locomotion and the formation of ectoplasmic pseudopodia cannot alone be used as differential criteria between *E. histolytica* and *E. coli*

DESCHENS (p 284) finds that bilirubin like haemoglobin is a stimulant to the growth of *E. histolytica* in culture but (with DOPTER, p 285) that bile at 1 in 1 000 dilution checks development and at 1 in 100 kills the amoebae Bile salts and cholesterol similarly retard development

TSUCHIYA (p 285) induced encystment of *E. histolytica* on Loeffler's slants covered with Ringer's solution to which starch is added, but these cysts had apparently lost in culture their pathogenicity for kittens PAVLOVA (p 286) describes simple and efficient culture media of salt phosphate buffer solution horse serum and starch. DOPTER and DESCHENS (p 286) show that *E. histolytica* grows much more easily on coagulated horse serum slopes when human serum is added to the Ringer's solution with which the slopes are covered. Serum from amoebic dysentery patients is only half as good as that from normal persons but serum from jaundiced patients is better than normal.

PAVLOVA (p 287) found that in culture *E. histolytica* only ingested human red cells between pH 5.8 and 6.5 Findings suggested that thermolabile factors inhibiting phagocytosis exist in horse serum DESCHENS (p 287) found that the pathogenicity for cats of *E. histolytica* maintained in culture is 50 per cent. between 56 and 124 days and only 20 per cent. between 542 and 652 days This loss is attributed to changes in the accompanying bacteria.

WESTPHAL (p 288) considers that *E. histolytica* is capable of both intra and extra-cellular digestion Proteolytic ferments but no toxins, are produced. Normally it exists as a harmless amoeba in the lumen of the gut (*mulina* form) and the extent to which it may become pathogenic depends on the tissue resistance of the host which may be broken down by bacteria. In the tropics conditions favour the reproduction of *E. histolytica* and virulent strains therefore ensue BENZONI (p 289) also accepts the view that it is normally harmless.

SWARTZWELDER (p 290) showed that unencysted *E. histolytica* could produce dysentery in dogs when administered by the mouth. Gastric juice was therefore not an efficient barrier DESCHENS (p 290) showed that a strain of *Bact. coli* capable of producing simple enteritis in cats increased, when added to a culture of *E. histolytica* the virulence of that organism more than twofold. The simple enteritis is apparently a predisposing factor He (p 290-291) further showed by animal experiment that certain groups of bacteria enable *E. histolytica* to give rise to amoebic dysentery and supports this view by epidemiological observations. Similarly DESCHENS and DECOURT (p 292) found that a toxic enteritis caused by croton oil

[April, 1930]

gametocytes in the normal manner showing that they are offshoots of asexual forms.

CHORNE (p 730) found in fowls infected with *P. gallinaceum* a slight diminution in blood englobulin and a marked increase in pseudoglobulin. In human malaria there is a great increase in englobulin.

MASIROLI (p 104) showed that sporozoites of *P. fovear* (*redicium*) from the body cavity and mature malarial cysts of mosquitoes are infective. Maturation in the salivary glands is therefore not necessary but SANDICCHI (p 816) points out that in the dissection of mosquitoes heavily infected salivary glands may rupture and liberate mature sporozoites into the body cavity. This may explain why sporozoites from the body cavity have been held to be infective.

OESTERLE (p 103) found that the activity of methylene blue which is a gametocidal agent is due to its action on the respiratory metabolism of the cell that of plasmoquine is increased by products of glucose which play an important part in cell respiration that of quinine is unaltered by the addition of such respiratory metabolic products. These studies were made in birds. ALBAICHT and METWEXBUTTE (p 106) found that methylene blue (intramuscularly) combined with quinine is much more effective in *P. fovear* infection of birds than quinine alone. He suggests its use in human malaria.

BITTLE *et al* (p 731) found that changes in the viri side chain in quinine and quinidine do not alter the antimalarial action, but that any interference with the central -CHOH group partially or completely destroys it.

COGGESWELL (p 897) found that sulphanilamide was capable of preventing the onset of malaria or of producing a chronic low grade infection in rhesus monkeys infected with *P. knowlesi* and was useful in prophylaxis. Sulphanil-sulphonate has therapeutic, but no prophylactic value. Neither drug has any value in *P. calomacrum* or *P. leptarai* infections in canaries or young chicks. CHOPRA and DAS GUPTA (p 800) found salmepastine to be a specific for *P. knowlesi* infections in monkeys.

RONHAUX and HENDRIX (p 106) found that "*Paludex*" had no favourable action in infections by *P. calomacrum*, *H. oregonense*, *P. knowlesi* and *P. gonderi*.

AMOEBIASIS

PRÉCIS OF ABSTRACTS IN THIS SECTION

MASSANI (p 283) describes an outbreak of amoebic dysentery on a torpedo boat. Two members of the crew were cyst passers.

ARCHETTI (p 283) notes that the disease is widespread in Italian East Africa.

TCHALAJA (p 284) shows that in culture the variation in the long and short diameters of vegetative amoebae extends from 5 to 48 μ and 5 to 33 μ respectively.

PAVLOVA (p 284) found that locomotion and the formation of ectoplasmic pseudopodia cannot alone be used as differential criteria between *E. histolytica* and *E. coli*.

DESCHENS (p 284) finds that bilirubin like haemoglobin is a stimulant to the growth of *E. histolytica* in culture but (with DORTER, p 285) that bile at 1 in 1000 dilution checks development and at 1 in 100 kills the amoebae. Bile salts and cholesterol similarly retard development.

TSUCHIYA (p 285) induced encystment of *E. histolytica* on Loeffler's slants covered with Ringer's solution to which starch is added but these cysts had apparently lost in culture their pathogenicity for kittens. PAVLOVA (p 286) describes simple and efficient culture media of salt phosphate buffer solution horse serum and starch. DORTER and DESCHENS (p 286) show that *E. histolytica* grows much more easily on coagulated horse serum slopes when human serum is added to the Ringer's solution with which the slopes are covered. Serum from amoebic dysentery patients is only half as good as that from normal persons but serum from jaundiced patients is better than normal.

PAVLOVA (p 287) found that in culture *E. histolytica* only ingested human red cells between pH 5.6 and 6.5. Findings suggested that thermolabile factors inhibiting phagocytosis exist in horse serum. DESCHENS (p 287) found that the pathogenicity for cats of *E. histolytica* maintained in culture is 50 per cent. between 56 and 124 days and only 20 per cent. between 542 and 652 days. This loss is attributed to changes in the accompanying bacteria.

WESTPHAL (p 288) considers that *E. histolytica* is capable of both intra- and extra-cellular digestion. Proteolytic ferments but no toxins are produced. Normally it exists as a harmless amoeba in the lumen of the gut (*minuta* form) and the extent to which it may become pathogenic depends on the tissue resistance of the host which may be broken down by bacteria. In the tropics conditions favour the reproduction of *E. histolytica* and virulent strains therefore ensue. BENZONI (p 289) also accepts the view that it is normally harmless.

SWARTZWELDER (p 290) showed that unencysted *E. histolytica* could produce dysentery in dogs when administered by the mouth. Gastric juice was therefore not an efficient barrier. DESCHENS (p 290) showed that a strain of *Bact. coli* capable of producing simple enteritis in cats increased, when added to a culture of *E. histolytica* the virulence of that organism more than twofold. The simple enteritis is apparently a predisposing factor. He (p 290-291) further showed by animal experiment that certain groups of bacteria enable *E. histolytica* to give rise to amoebic dysentery and supports this view by epidemiological observations. Similarly DESCHENS and DECOURT (p 292) found that a toxic enteritis caused by croton oil

favoured the establishment of the amoeba in the cat's intestine GAUDUCHEAU (p. 292) transformed latent amoebic infection into dysentery in animals by inoculating a bacillus and a virus.

SARATISSJAK (p. 292) concludes from experiments that amoebae from symptomless carriers are identical with pathogenic *E. histolytica*. FRYE and MELENKY (p. 293) conclude from experiments that a small race of *E. histolytica* exists which is relatively fixed in its size and activity and that it possesses a low power of invasion of the tissues of man and experimental animals.

WILKINSON (p. 293) concludes that sigmoidoscopy is useful for the confirmation of diagnosis in a small proportion only. BOWEN (p. 294) uses a histidine cutaneous test. He infers that there is a distinct affect and is reduced by treatment. He infers that there is a distinct affect of general and local protein metabolism. PAULSON and ANDERSON (p. 294) found that the complement fixation test is unreliable in the individual case and not so valuable as microscopic faecal examination. CRAIG and SWARTZWELDER (p. 294) found that four monkeys infected with *E. histolytica* all gave positive complement reactions. This result did not agree with previous findings by MELENKY and FRYE. MANSON BARR (p. 295) found *E. histolytica* in the discharge from the ulcerated abdominal wall around a colostomy opening. Emetine and yatra treatment was successful and the colostomy wound was finally closed. PIZRI *et al.* (p. 295) discuss a case of a cyst of the lung associated with, but not proved to be caused by, an amoebic liver abscess. WU (p. 295) found amoebae in a nasopharyngeal polyp. Fusiform bacilli were also present. It could not be decided whether the amoebae were *gigas* or *histolytica*. LOUZEZAS *et al.* (p. 296) describe a patient whose neuritis (with paralysis) cleared up when emetine was given for an attack of amoebic dysentery.

SAUTET (p. 296) points out that obscure hepatic conditions in the tropics and subtropics are often due to amoebiasis. Previous history of dysentery does not always occur.

HUARD LOYO and GRAHAM (p. 296) describe a series of 48 liver abscesses, of which only three were amoebic seen in Indo-China. Open operation was the usual treatment in the bacterial cases, but in amoebic cases they gave emetine intravenously and use adrenalin to counteract depressant effects. A table of mortality from many authors is given. WIJERAMA (p. 298) records 48 patients of liver abscess of whom 34 gave a history of previous dysentery. Treatment with emetine with or without aspiration was very successful. One died after operation. PEIRIS (p. 298) describes the clinical picture in 28 cases of liver abscess. Treatment was by emetine and aspiration. The commonest complication of untreated abscess was rupture. BROWN and HODGSON (p. 299) found that 18 per cent of liver abscesses at the Mayo clinic were due to amoebiasis. They gave the symptoms, methods of diagnosis and treatment and stress the importance of emetine. TRAUB and RASCH (p. 300) describe the symptoms in a case of amoebic hepatitis. These disappeared under emetine treatment but an increasing leucocytosis remained, possibly indicating abscess.

DAVIS (p. 300) records a patient whose symptoms and X-ray suggested a pneumonic condition. No fluid was found in the pleural cavity and faecal examination was negative. Treatment was unsuccessful until emetine was tried as a shot in the dark when rapid improvement occurred.

MATTEI (p 301) details the alimentary urinary and circulatory premonitory symptoms of emetine poisoning. Polyneuritis and cardiac insufficiency are symptoms of established poisoning. He recommends caution in dosage.

HAKANSSON (p 302) gives the results of treatment with Carbarsone. An intensive 10 day course in which 5 to 10 gm. were given in all produced the best results. GRASSO (p 303) recommends 75 mgm per kilo body weight over a period of at least 10 days in the use of Fenarsone (the Italian equivalent of Carbarsone). The drug is valuable. PYMAN (p 303) tested derivatives of harmol as amoebicides in cultures and in animals. They are less effective than emetine in the treatment of amoebic infections.

HILLEMANN and GAUBE (p 304) deal with treatment in general.

BOVAIN and ARETAS (p 304) found that emetine resistance could be induced by growing *E. histolytica* in media containing emetine. This persists to some extent after 10 subcultures in emetine-free media. VALETTE and ROLLÉ (p 304) observed by ultraviolet illumination that quinine enters *Amoeba dubia* and fixes itself to certain inclusions or vacuoles in greater concentration than in the surrounding solution.

DESCHENS and PROVOST (p 305) experimentally infect cats directly into the ileum during laparotomy. C W

MASSANI (R. M. Mario) Osservazioni su di una piccola epidemia di amebiasi intestinale manifestatasi a bordo di una torpediniera. [A Small Outbreak of Amoebic Dysentery on a Torpedo-boat.]—*Ann di Med Nav e Colon* 1938 July-Aug Vol 44 No 7-8 pp 301-305

At the end of September 1937 on two successive days a patient from a torpedo-boat reported sick with symptoms of dysentery and examination of the stools revealed *E. histolytica* both vegetative and cyst forms. Examination of others of the ship's complement showed nine to be infected and details of each of these are given. Five of them presented definite symptoms passing mucus and blood one merely ordinary diarrhoeic stools three appeared to be in good health but were cyst passers. Two of the last had suffered from gastrointestinal disturbance in Crenalea previously. When these patients were properly dealt with no further cases occurred. To avoid such occurrences it is suggested that care should be taken to examine those who have lived in Africa before being accepted in the service to keep a record of those who have suffered from amoebiasis clinically and been cured to examine such periodically and particularly to keep watch on those engaged in the handling of food. SORGE (Giuseppe) *Epidemiologia e profilassi dell amebiasi logy and Prophylaxis of Amoebiasis*.—Reprinted from *Epidemiologia e Profilassi* 1938 Apr. No. 4 18 pp [84 refs.]

TCHALAJA (L. E.) [Morphological Study of a Pure Line of *Entamoeba histolytica* in Culture].—*Mémoires Parasit. & Parasitic Dis.* Moscow 1938 Vol. 7 No. 1 [In Russian pp 85-109 With 15 figs. on 2 plates & 3 diagrams. French summary p. 109.]

The author records the results of a detailed morphological study of a pure line strain of *Entamoeba histolytica* grown in culture on a fluid cardiac [?] medium. From measurements of stained specimens taken at different intervals the long and short diameters of the vegetative amoebae were found to vary from 5 to 48 μ and 5 to 33 μ respectively (mean $21 \times 15 \mu$). The amplitude of variation in the dimensions increased with the age of the culture the maximum coinciding with a higher rate of multiplication of the amoebae. The nucleus varied in size (diameter) from 2 to 7 μ . The majority of nuclei had the typical structure deviations from this structure are attributed to the physiological state of the organism. The paper is illustrated by graphs and figures.

PATLOVA (E. A.) [Comparative Study of Locomotion in *Entamoeba histolytica* and *E. coli*].—*Mémoires Parasit. & Parasitic Dis.* Moscow 1938 Vol. 7 No. 1 [In Russian pp 110-118. With 8 figs. French summary p. 118.]

Working with cultures and faecal forms the author has made comparative observations on the locomotion of *Entamoeba histolytica* and *E. coli* under various conditions, the object being to ascertain whether locomotion can serve for the differential diagnosis of these species. In the case of both amoebae it was found that the greater activity was manifested at pH 8.5 the rate of locomotion being higher at body temperature than at room temperature. Neither of the amoebae when freshly isolated from the faeces or culture and observed at 37°C., showed a sharp differentiation between ectoplasm and endoplasm, and locomotion in both took place without the formation of hyaline pseudopodia. On the other hand amoebae of both species produce such pseudopodia some time after isolation, *E. histolytica* retaining its motility and pseudopodia for a longer period than *E. coli* on account of which the formation of these ectoplasmic outgrowths is more commonly attributed to the dysentery amoeba. It is concluded that the differential diagnostic importance of ectoplasmic pseudopodia is only relative and can only be used if allowance is made for the freshness of the material, and in conjunction with other characters. The movements of the amoebae are illustrated by a series of figures.

DESCHEUX (R.) *Affinité alimentaire de l'amibe dysentérique pour la bilirubine* (Alimentary Affinity of the Dysentery Amoeba for Bilirubin).—*Bull. Soc. Path. Exot.* 1938. July 6 Vol. 31 No. 7 pp 626-633 With 2 figs. on 1 plate.

The author finds that the addition of bilirubin in crystalline form or in solution to culture medium for *E. histolytica* is a stimulant to growth.

Moreover the amoebae ingest with avidity the crystals which appear to be utilized as a nutriment. If both rice starch and bilirubin are added to the culture tubes the cultures behave as regards development of the amoebae with a great regularity. The stimulating action of bilirubin is compared with that of haemoglobin which has also been shown by the author to be beneficial to growth. The liking of the amoebae for bilirubin may explain to some extent the frequency of amoebic abscess of the liver in connexion with amoebic dysentery.

C M Henyon

DOTTER (Ch.) & DESCHIENS (R.) Action de la bilirubine et de la bile totale sur les amibes dysentériques [Action of Bilirubin and of Bile on Dysentery Amoebae].—*C R Soc Biol* 1938 Vol. 129 No 30 pp 626-628

The authors find that the addition of bilirubin in crystalline form or in solution to culture media for the growth of *E. histolytica* has a stimulating action on the amoebae. Bile on the other hand in concentrations of 1 in 1 000 upwards checks the development while with a concentration of 1 in 100 all the amoebae are killed.

C M H

DOTTER (Ch.) & DESCHIENS (R.) Action des sels biliaires et du cholestérol sur les cultures d'amibes dysentériques [Action of Bile Salts and Cholesterol on Cultures of Dysentery Amoebae].—*C R Soc Biol* 1938 Vol 129 No 30 pp 628-632

Having shown that bilirubin acts favourably on *E. histolytica* in culture while bile has the opposite effect it seemed of interest to test the action of bile salts and cholesterol. It was found that these substances did not stimulate the growth of the amoebae and in certain concentrations actually retarded development. It would appear therefore that the good effect on the growth of the amoebae of adding to the medium the serum from cases of jaundice as previously reported is attributable to the presence in such serum of bilirubin.

C M H

TSUCHIYA (H.) Observations on Induced Encystment of *Entamoeba histolytica* in Vitro.—*Jl Lab & Clin Med* 1937 Dec Vol 23 No 3 pp 261-268 [16 refs]

The author shows that *Entamoeba histolytica* cultivated on S.C. medium, i.e. nutrient broth starch and charcoal with or without Dorsett's egg medium (see *Jl Lab & Clin Med* 1933-34 Vol 19 p 495) in which encystment does not occur will readily encyst when transferred to a medium consisting of Loeffler's slants covered with Ringer's fluid to which some starch has been added. The maximum encystation occurred after incubation at 37°C for 48 to 51 hours. It was found that at refrigerator or room temperature uninucleate or binucleated cysts continue to develop to the 4 nucleate stage. At the same time the chromatoid bodies tended to disappear. Kept at 37°C. the cysts degenerated. Though apparently normal in every way these

induced cysts orally administered failed to produce lesions in kittens or rats, though harmless infection with amoebae resulted in some cases in these animals. The original pathogenicity of the cysts from the human case as had been proved by administration to kittens, had been lost on culture. As judged by their power to excyst in suitable media it was found that the cysts survived for 40 to 45 days at refrigerator temperature and for 6 to 8 days at room temperature. C M IF

PAVLOVA (E. A.) Sur les méthodes de la culture d *Entamoeba histolytica* [Culture Methods for *Entamoeba histolytica*].—*Med Parasit. & Parasitic Dis Moscow* 1933. Vol. 7 No. 2. [In Russian pp. 224-227 (16 refs.) French summary p. 227]

The author maintains that for the successful culture of *E. histolytica* it is quite unnecessary to use complicated media with Locke or Ringer solutions or extract of heart muscle. A simple medium consists of a solution of sodium chloride to which is added a phosphate buffer such as that of SORESENSEN at pH 6.5 horse serum to a strength of 1 in 20 and a little starch. In such a medium both primary cultures and subcultures succeed and the amoebae can be maintained indefinitely by subculturing every 72 hours. For each test tube the following quantities are used —

1	Solution of NaCl 0.9 per cent	9 cc.
2	Phosphate buffer of Sorensen pH 6.5	2 cc.
3	Horse serum	0.5 cc.
4	Rice starch	1 loopful.

As an alternative the following may be employed —

1	Disodium phosphate ($\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$)	0.3564 gm.
2	Monopotassium phosphate (KH_2PO_4)	0.6354 gm.
3	Sodium chloride solution (0.9 per cent)	1 litre.

After sterilization in the autoclave and distribution in quantities of 10 cc. in tubes horse serum (0.5 cc.) and rice starch (one loopful) are added to each tube.

The cultures can be kept alive for longer periods than 72 hours if 0.5 cc. of buffer solution is added each day.

[Sorensen's standard phosphate buffer solution of pH 6.468 at 18°C is made as follows —

1	$\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$	11.678 gm. per litre.
2	KH_2PO_4	9.078 gm. per litre

Three parts of 1 to seven parts of 2.

DORTCH (Ch.) & DESCHENS (R.) Action comparée du sérum humain normal et du sérum humain icterique sur les cultures d'amibes dysentériques. [Comparative Action of Normal and Icteric Human Serum on Cultures of Dysentery Amoebae.]—*C. R. Soc Biol* 1937 Vol. 128 No. 33. pp. 869-872.

Employing as culture medium for *E. histolytica* coagulated horse serum slopes covered with a mixture of serum and Ringer's solution

in the proportion of 1 to 7, to which 0.05 grams of sterile rice starch had been added for each tube the authors have previously shown that the growth of amoebae is five times greater when the serum in the Ringer mixture is human serum than when it is horse serum. They have also shown that the growth in the presence of serum from cases of amoebic dysentery is only half as good as in the presence of normal human serum. In the present paper they describe tests on the action of serum from cases of jaundice which have shown that as compared with normal horse serum the growth of amoebae is six times as great. It has already been shown that amoebic growth is aided by the presence of haemoglobin so that it is possible that the related bilirubin in the icteric serum is also a stimulant. On the other hand it may be that the increased cholesterol content is responsible for the better growth. This requires investigation.

PAVLOVA (E. A.) [Factors affecting the Phagocytosis of Erythrocytes by *Entamoeba histolytica* in Cultures.]—*Med Parasit & Parasitic Dis* Moscow 1938 Vol. 7 No 1 [In Russian pp 119-122 French summary p 122.]

The author studied the effect of pH of the medium upon the capacity of *Entamoeba histolytica* to phagocytize human red cells and tested FRYE and MELENER's contention that heated horse serum favoured this phenomenon. A drop of culture medium with amoebae was mixed with a drop of saline emulsion of red cells the reaction was set at different pH by the addition of HCl NaHCO₃ or phosphate buffers and the preparations were examined at 37°C. It was found that the amoebae ingested the red cells only at pH 5.6 to 6.5 whereas no ingestion took place at higher values of pH. It is noted that this reaction corresponds to that found in human dysenteric stools and in the colon of experimentally infected kittens. The author confirmed the observation that heated horse serum when added to the medium was more favourable to the ingestion of the erythrocytes by the amoebae than fresh serum thus pointing to the presence in the serum of thermolabile factors inhibiting phagocytosis.

DESCHENS (R.) Nouvelle observation de réduction du pouvoir pathogène pour le chat d'une souche d'amibes dysentériques en culture [Further Observations on the Loss of Virulence of a Strain of Dysentery Amoebae during Culture.]—*C R Soc Biol* 1938 Vol. 127 No 11 pp 939-941

The author refers to earlier experiments of various authors, including himself who have shown that the virulence of *Entamoeba histolytica* as judged by its power of producing infection when injected into the small intestine just above the ileo-caecal valve of cats is decreased by continued cultivation in artificial media. In the present paper he shows that a strain of amoeba isolated from a case of dysentery in Morocco produced infection in 50 per cent. of cats inoculated when the culture had been maintained for 56 to 124 days and in only 20 per cent when the culture period was 542 to 652 days. This loss of virulence is in the author's opinion probably associated with changes which occur in the bacteria which accompany the amoebae in the medium.

Westphal (Albert) Die Pathogenese der Amöbenruhr bei Mensch und Tier I Das Wesen der pathogenetischen Wirkursache der Ruhr amöbe. II Die Pathogenese der Amöbenruhr beim Menschen. [The Pathogenesis of Amoebic Dysentery in Man and Animals. I The Nature of the Pathogenic Action of Dysentery Amoebae. II The Pathogenesis in Man.]—Arch f Schiffs u Trop Hyg 1933. Aug & Oct. Vol 42 Nos. 8 & 10 pp 343-349 441-459 With 2 figs [41 refs.]

There are two views generally held regarding the pathological processes in tissue invaded by *Entamoeba histolytica*. One school believes them to be due to fermentative toxic action. The toxic theory is founded mainly upon the similarity of the necrotic processes in the surrounding tissues as observed in men as well as in animals.

Naturally, in assessing complicated interactions between host and parasite it is necessary to discount secondary infections and in the case of an intestinal parasite it is quite impossible to avoid them. It is only in bacteria free metastatic abscesses that the true process can be observed and even here it is not quite clear whether the bacteria were originally present or were subsequently removed by the leucocytes. The best uncomplicated picture of tissue-invasion by amoebae is to be obtained from a study of the submucosa of the human large intestine. The penetration of the muscularis is effected through various gaps in the muscular fibres. The nests of amoebae flourish in the submucosal tissues usually uncontaminated by bacteria and, as is well known, the cellular response to the presence of amoebae is minimal. The amoebae themselves lie in lacunae of histiocyte cells and it is worthy of note that this histolysis occurs in the absence of leucocytic infiltration and that necrosis follows but does not precede the amoebae. Tissue destruction is the result of fermentative processes and takes place in man and in animals in the absence of any parasites, but it is accompanied by leucocytic invasion which is singularly free from leucocytes. We are driven to the conclusion that the amoebae are capable of *extra-* as well as *extra-cellular* digestion. The formation of actual channels in the invaded tissue can only be explained on the assumption that free proteolytic ferments are produced. On the other hand no evidence is forthcoming of any toxin-production. If the amoebae were surrounded by a toxic necrosis, one would expect to find that the dead tissue could be demonstrated in the entoplasm of these parasites. On the other hand, digestion in these protozoa takes place in intracorporeal vacuoles in which usually bacteria can be demonstrated.

Further evidence of the absence of toxins is seen in the absence of fever in uncomplicated amoebiasis, as well as in the absence of toxic manifestations in the patient, such as are usually seen in association with bacillary dysentery. In a personal infection Westphal induced in his own body and in which the incubation period was 23 days [this Bulletin 1933 Vol. 35 p. 596] he did not experience the slightest toxic disturbance and even after the onset of amoebic dysentery the sense of well-being was maintained.

Absence of toxins has also been established by intravenous injections of amoebic-culture extracts in rabbits [Morewitz this Bulletin 1933 Vol. 30 p. 28 HEATHMAN Ibid p. 25] Even in extracts used by

CRAIG [this *Bulletin* 1928 Vol 25 p 228] for complement-deviation no toxins can be demonstrated but proteolytic ferments were present. Even the production of a positive complement fixation does not necessarily indicate the active presence of a toxin.

Moreover, necrosis under aseptic conditions can be brought about by the liberation of proteolytic ferments from the leucocytes.

Westphal is of the opinion that in man *E. histolytica* exists normally as a harmless amoeba (*minuta* form) in the lumen of the gut and in this stage forms cysts. The *minuta* form is nourished by osmosis and phagocytosis and the nutriment is digested in the entoplasmic vacuoles. At this stage the amoeba can excrete a proteolytic ferment and become a pathogen. The extent to which the invasion of the bowel wall takes place depends upon the tissue-resistance of the host.

The breakdown of the resistance may be in the first instance due to bacterial spoiling which causes damage to the cells and functional disturbance of the bowels. After the formation of amoebic lesions a secondary alteration of the intestinal flora takes place and this is especially liable to ensue in tropical and sub-tropical climates. It is stipulated that a change in the life cycle of the amoeba then takes place so that it is no longer able to form cysts. The following effects are noted in man —

(1) An acute bacterial disease in which the amoeba plays a small part and death occurs within a few days.

(2) Pure amoebic dysentery in which bacteria play a transient part.

(3) Chronic amoebic dysentery which is chemotherapeutically more difficult to cure.

As regards therapy it is thought that the rectal or oral administration of iatren and allied compounds can penetrate to a limited extent into the bowel wall but on deep seated abscesses or metastatic lesions it has no action at all. On the other hand the parenteral injections of emetine are diffused throughout the body and these penetrate the deeply hidden amoebae but do not touch the *minuta* forms in the bowel lumen. Rectal injections do not reach the more highly situated amoebic lesions and often result in establishing the carrier state.

So many factors are concerned in the production of amoebic dysentery that they must all concur at the same moment before an epidemic of amoebic dysentery can result and that is why it is so rare.

The sequelae of amoebic dysentery are not due to the activities of the organisms but to the scarring of the bowel wall and the dysfunctions which result from their former presence. In tropical regions where intestinal upsets commonly occur conditions are produced which favour the reproduction of *E. histolytica* and thereby virulent strains of the organism ensue whilst in temperate climates where these extraneous factors are absent amoebic dysentery becomes a relatively mild disease.

BENZONI (G.) Il problema dei portatori in amebiasi la sede nell'intestino e la virulenza dell' *Entamoeba histolytica* [Carrier Problem in Amoebiasis. Situation in the Intestine and Virulence of *E. histolytica*]. — *Patologica* 1938, Feb 15, Vol. 30, No. 556, pp. 47-52. [29 refs.] English summary (10 lines).

The paper is a general discussion of views on the pathogenicity of *Entamoeba histolytica*. It is argued that that of REICHENOW, which

[April, 1909]

supposes that *E. histolytica* is normally a small harmless amoeba of the intestine reproducing in the lumen and producing cysts, is the correct one. Under certain conditions penetration of the intestinal wall takes place resulting in the large tissue-invading amoebae and symptoms of amoebic dysentery.

SWARTZWELDER (John Clyde) Studies on the Infection of Dogs with Trophozoites of *Entamoeba histolytica* by the Oral Route. A Preliminary Report.—*Public Health Rep.* 1907 Oct. 15 Vol. 52, No. 42. pp 1447-1451 [12 refs.] C M IV

The experiments described in this paper were designed to test the possibility of producing *E. histolytica* infections by the oral administration of trophozoites. In the first place it was determined, by sacrificing dogs 15 minutes to one and a half hours after the oral administration of 5 to 10 cc. of material aspirated from the large intestine of an infected dog, that trophozoites were able to survive in the stomach and to pass alive into the small intestine. Of 13 dogs which were given orally 3 to 7 cc. of material containing only trophozoites of *E. histolytica* five became infected, with incubation periods of 3 to 24 days. As regards the presence of free acid in the stomach it was found that viable trophozoites could occur after exposure for one hour to amounts of free HCl requiring from 12 to 40 cc. of N/10 NaOH to neutralize 100 cc. of gastric juice. It is evident that in the dog oral ingestion of unencysted amoebae may be followed by amoebic dysentery. C M IV

DESCHREWS (R.) Nouvelles données sur le rôle de la flore associée à l'amibe dysentérique dans l'amibiase expérimentale. [The Influence of the Flora associated with the Dysentery Amoeba in Experimental Amoebiasis].—*C. R. Soc. Biol.* 1908 Vol. 127 No. 12. pp 1078-1079

Continuing experiments on the lines of others which he has previously carried out the author shows here that the virulence to cats of a culture of *E. histolytica* is increased to the extent of producing infections in 45 per cent. in place of 20 per cent. of animals inoculated in the addition to the culture of a pathogenic strain of *Bact. coli*. The strain of *Bact. coli* inoculated to cats alone produced in 70 per cent. of the animals a simple enteritis which appears to be a predisposing factor in the establishment of an amoebic infection. It is noted that the amoebic infection in young cats is represented by an inflammatory and necrotic process over the greater part of the surface of the mucosa of the large intestine. It is only rarely that the deep circumscribed ulcers so characteristic of amoebic dysentery in man are observed. C M IV

DESCHREWS (R.) Le rôle de la flore bactérienne associée à l'amibe dysentérique, dans l'amibiase. [Rôle of the Bacterial Flora in Amoebic Dysentery].—*Ann. Inst. Pasteur* 1908. July Vol. 61 No. 1 pp. 5-32. With 10 figs. (4 on 2 plates) [13 refs.]

In this article the author discusses the relationship of certain groups of bacteria to *Entamoeba histolytica* in the production of amoebic dysentery a subject upon which he has made many experiments and

upon which he has written a number of papers [this *Bulletin* 1935 Vol 32 p 778 1937 Vol. 34 p 325 1938 Vol 35 p 580] In the first place clinical and epidemiological observations have suggested to various workers that bacteria play some part in enabling the dysentery amoeba to produce actual dysentery. Thus in countries or districts where the incidence of amoebic dysentery is greatest in the hot season it is then that the bacterial flora pollute drinking water most intensely. When in one country amoebic dysentery is especially prevalent in certain districts it is found that here faecal contamination of soil and water is occurring regularly. Similarly outbreaks of amoebic dysentery occurred during the great war in France and Belgium amongst groups of people who were subject to the rigours of war when in spite of the strictest measures contamination of soil and water by faecal bacteria could not be avoided. Residents in the colonies who have suffered repeatedly from amoebic dysentery on return to their homeland tend to become mere amoebic carriers without dysenteric symptoms just as symptomless amoebic carriers occur commonly amongst persons who reside permanently in the home countries. From these various observations it can be deduced that the dysentery amoeba alone is a somewhat inoffensive organism which however can be so biologically changed by alterations in the bacterial content of the intestine that it assumes pathogenic properties and produces amoebic dysentery.

In support of this point of view the author reviews a long series of experiments he has already described in earlier papers. The object of these has been to gauge the pathogenicity of certain culture strains of amoebae by observing the percentage of 20 cats acquiring amoebic dysentery when inoculated directly into the ileum exposed by laparotomy. Having established this percentage which in the case of some strains was low the bacterial content of the culture was altered by transferring to it the bacteria from more virulent strains. It was possible then to determine that the percentage of animals contracting dysentery had considerably increased. By a long series of experiments carried out by the standard technique which was first introduced by FRYE and MELENEY in 1933 [this *Bulletin* 1934 Vol 31 p 284] and which the author describes in detail in this paper it was possible to demonstrate that certain bacteria or groups of bacteria enable *Entamoeba histolytica* to give rise to amoebic dysentery. The study of the pathological anatomy of the intestine in amoebic dysentery reveals in the destructive process a bacterial element in addition to an amoebic one without however enabling one to decide which of these is to be regarded as the primary cause. It seems safe to conclude however that the intestine can be prepared for amoebic invasion by bacteria.

The paper is a long and carefully reasoned one and exposes fully what may be regarded as the modern view of the etiology of amoebic dysentery.

DESCHIEUX (R.) Le rôle des bactéries dans l'amoebiose intestinale [Rôle of Bacteria in Intestinal Amoebiasis].—Reprinted from *Paris Méd* 1938 June 4 8 pp

This is a general account of experiments carried out by the author to demonstrate that just as dysentery amoebae require bacteria to enable them to develop and multiply in the culture tube so do they depend

[April, 1909]

on certain pathogenic bacteria to enable them, when in the intestine, to penetrate the intestinal wall and produce the conditions which are grouped under the term amoebiasis. The various papers describing these results have already been reviewed in earlier numbers of the Bulletin.

DESCHIEUX (R.) & DECORRY (Ph). Action favorisante d'une colite toxique sur l'adaptation pathogène de l'amibe dysentérique [Pathogenicity of Dysentery Amoeba favoured by a Toxin Colitis].—*C. R. Soc. Biol.* 1908 Vol. 128 No 23 pp 1018-1019

One of the authors has shown by previous experiments that the establishment of a colitis in kittens by the administration of certain bacilli, living or killed, favours the development of amoebic infection when cultures of *E. histolytica* are injected directly into the small intestine after laparotomy according to the authors' technique. In the present paper experiments are described which indicate that a colitis caused by an irritant such as croton oil likewise favours the establishment of the dysentery amoeba in the cat's intestine.

GAUDICHEAU (A.) Sur la pathogénie de l'amibiase [Pathogenesis of Amoebiasis].—*Bull. Soc. Path. Exot.* 1907 Oct. 13 Vol 30 No 8 pp. 858-859.

The author mentions his experience with a dog and a monkey which were experimentally inoculated with a bacillus and a virus. In both cases the injection transformed a latent amoebic infection into an active amoebic dysentery. A cultivable free-living amoeba has been shown to grow actively only in the presence of certain bacteria, while its power of phagocytizing staphylococci depends upon the simultaneous presence of *Bact. coli*. It is obvious that both pathogenic and free-living amoebae depend upon certain bacteria for their satisfactory development.

SARKISJAN (M. A.) [Pathogenicity to Kittens of Various Strains of *Entamoeba histolytica* from Healthy Human Carriers].—*Med. Parasit. & Parasitic Dis.* Moscow 1908 Vol 7 No 1 In Russian pp 123-128. French summary p 123.

Experiments were conducted with the view of verifying the existence of virulent strains of *Entamoeba histolytica* such as "E. dispar." Four strains of amoebae were isolated from different persons whose present and past history showed no symptoms of any intestinal disorder. Kittens were inoculated *per os* (4) with washed cysts from the faeces and *per rectum* (22) with cultures. Out of 26 kittens, infection resulted in 6 (2 1 1 2 with the respective strains). The passed amoebae with ingested red cells, while the histopathological picture was similar to that found in kittens infected from human dysentery cases. It is concluded that the amoebae from symptomless carriers are identical with the pathogenic *E. histolytica* from which they are morphologically indistinguishable.

C. A. Howe

FRYE (William W) & MELEKEY (Henry E) The Pathogenicity of a Strain of Small Race *Endamoeba histolytica*—*Amer Jl Hyg*, 1938 May Vol 27 No 3 pp 580-589 With 5 figs. on 1 plate. [14 refs]

The paper discusses the strains of *E. histolytica* which produce cysts under 10 μ in diameter. The observations recorded were based on stool examinations carried out in the Department of Preventive Medicine and Public Health of the Vanderbilt University School of Medicine during the years 1930-1937. The specimens examined 9 449 in number gave 325 or 3.44 per cent positive for *E. histolytica*. Of these 85.2 per cent. were the large race with cysts over 10 μ in diameter 13.5 per cent were the small race and 1.2 per cent were mixed large and small races. It is noteworthy that before the beginning of 1935 only seven instances of infection with a small race were detected whereas since then there have been found 37 cases. It was not possible to account for this increased incidence which was a real one. One of the small races was successfully cultivated. During maintenance by subculture the amoebae remained constantly small in size and showed no tendency to ingest red blood corpuscles when these were added to the medium. The few cysts which were produced in cultures were constantly small in size. Culture was injected into the terminal ileum after laparotomy in 22 kittens only five of which became infected. The amoebae which were small in size showed less tendency to invade the tissues than did large races such lesions as were produced being very superficial in character. Complement fixation tests carried out with a large race antigen on 14 carriers of small race amoebae gave a positive result in five. The patient from whom the small race was cultivated gave a positive complement fixation reaction which became negative after treatment. It is concluded that a small race of *E. histolytica* exists which is relatively fixed in its size and activity and that it possesses a low power of invasion of the tissues of man and experimental animals.

WILKINSON (W) An Investigation Into the Value of Sigmoidoscopy Examination as an Aid to Diagnosis of Chronic Amoebic Infection in Man.—*East African Med Jl* 1938 Dec. Vol. 15 No 9 pp 295-299

The author has analysed a hundred patients with abdominal complaints of considerable duration examined by sigmoidoscope either by himself or by Dr BRAIMBRIDGE during the past year. He divides his cases into two groups according as there were clinical signs of amoebiasis or not. Of the former there were sixty. Twenty were found to have a normal mucosa, 17 an extensive hyperaemia, 3 had haemorrhagic areas 12 had ulceration and 8 leucoplakia. Details of the findings in each of these subgroups are given. *E. histolytica* was found in 17 of the 60 and the author concludes that no case of amoebiasis was discovered by sigmoidoscopy which had not been diagnosed clinically or by examination of the stools and that consequently in chronic cases sigmoidoscopy is of value as confirmatory in a small proportion only.

H H S

BOVENIGRO (A.) La coltreazione all'istadina nella colite amebica. (Cutaneous Histidine Reaction in Amoebic Colitis).—*Riv. Sanitaria Sicilia* 1938, Vol. 15, No. 22, pp. 1279-80. 1283-4 1287-8 1291-2, 1295.

For this test the author employs 0.1 cc. of a 10 per cent. solution of histidine. The immediate result is local pallor of 0.3 cm. diameter in positive cases after 1-2 minutes a reddening appears over the area of a 20-lire piece and lasts for 40-45 minutes and often shows dendritic prolongation at the periphery. If the reddening is not observable in 5-8 minutes, the reaction is regarded as negative. The author has studied the reactions in 72 cases and finds that in chronic amoebic colitis the skin reacts to amino-acids with greater intensity than in cases of gastro-enteritis, or non-amoebic infections. treatment of the condition reduces very greatly this reaction, and it is inferred that in chronic amoebiasis of the intestine there is a distinct affection of general and local protein metabolism.

PARTSON (Moses) & ANDREWS (Justin) Complement Fixation in Amoebiasis. A Comparative Evaluation in Clinical Practice.—*Arch Intern Med* 1938, Apr Vol. 61, No. 4, pp. 552-573. (13 refs.) H H S

The authors have attempted to estimate the true value of the complement fixation test as a diagnostic procedure for amoebiasis. Sera from 150 cases which had been studied clinically and parasitologically were submitted to one or more laboratories where the amoebic complement fixation test was being carried out with one or more antigens. When the results were tabulated it was found that the positive results occurred more frequently amongst those cases in which amoebic infection had been determined macroscopically than in others but the numerous falsely positive results show that the test is unreliable in the individual case. It is pointed out that the test as carried out at present is merely a diagnostic aid and that in spite of the many disadvantages of macroscopic faecal diagnosis this method is still more reliable than complement fixation. CALVO, who has done so much to develop the complement fixation test for amoebiasis, has admitted that when adequate faecal examinations can be carried out the test is unnecessary.

KAIG (Charles F) & SWARTZWEIDER (John Clyde). Observations upon the Complement-Fixation Test in Monkeys Infected with *Entamoeba histolytica*.—*Proc. Soc. Exptl. Biol. & Med* 1938, Jan Vol. 37, No. 4, pp. 671-673. C M W

MELLEVET and FITE (this Bulletin, 1938 Vol. 35 p. 583) have reported that monkeys (*Macacus rhesus*) naturally or experimentally infected with *Entamoeba histolytica* did not give complement fixation reactions with one exception, and showed no macroscopic or microscopic lesions at autopsy. The authors of the present paper noted that a monkey infected with a human strain of *E. histolytica* consistently gave a four-plus complement fixation reaction for amoebiasis. To investigate the matter further a strain of *E. histolytica* occurring naturally in a monkey was used to infect three other monkeys. This monkey

vol 36 No 4]

strain was identical morphologically with strains occurring in men while cysts fed to a dog produced infection associated with typical lesions in the caecum and colon. The three monkeys which were infected by feeding them with cysts all gave a positive complement fixation reaction. All the four monkeys were examined post mortem and lesions in the caecum and colon were found in three. The one exception was an animal in which the complement fixation reaction had become doubtful 27 days before death. In view of the previous positive reaction it seems probable that this monkey was recovering spontaneously. C M II

JANSON BAIER (Philip) Amoebic Invasion of the Skin and Subcutaneous Tissues.—*Trans Roy Soc Trop Med & Hyg* 1938 Aug 25 Vol. 32. No 2. pp 223-227 With 5 figs on 1 plate. [28 refs.]

The case described is that of an ex-soldier from India aged 25 years on whom colostomy was performed owing to the sigmoidoscopic appearance of the rectum suggesting carcinoma. Extensive ulceration of the abdominal wall around the colostomy opening followed. Ultimately *Entamoeba histolytica* and trichomonas were found in the discharge from the ulcerated area. Amoebae were also found in portions of the tissue removed from the ulcer while amoebic ulceration of the rectum was observed by sigmoidoscopy. Response to emetine treatment was immediate though final recovery was delayed by complications such as perforated appendix, pelvic abscess and pneumonia. Finally after a course of auremetine and yatrein which rid the patient of his persisting amoebic infection the colostomy wound was successfully closed. C M II'

PIERI SARDOU & BOUDOURESQUE Maladie kystique du poulmon chez un amibien. [Cystic Disease of the Lung in a Case of Amoebiasis] —*Bull Soc Path Exot* 1937 Oct 13 Vol 30 No 8 pp 659-664

A patient who had on two occasions suffered from amoebic abscess of the liver was again admitted to hospital for an obscure condition of the lung which was ultimately diagnosed as pulmonary cyst rupturing into the pleural cavity. On no occasion was it possible to demonstrate amoebae in the material coughed up or aspirated from the pleural cavity nor did any response to emetine treatment occur. The clinical aspects of the case are discussed in some detail. C M IV

WU (S D) Amoebic Infection of a Nasopharyngeal Polyp.—*Chinese Med J* 1938. Mar Supp No 2. pp 217-220 With 2 figs. on 1 plate [19 refs.]

The specimen examined was from a tumour the size of an orange removed from the back of the nose of a Chinese, aged 28 years. Its structure was that of a muco-fibrous polyp with localized areas of ulceration and in the necrotic patches with granulation tissue were fusiform bacilli and amoebae. Unfortunately all material available for examination had been sent in formalin so there was no opportunity to examine living amoebae from fresh material. No history could be obtained of amoebiasis, the patient's stools were free of amoebae or their cysts. Since fusiform bacilli were present also the ulceration

cannot be attributed solely to the protozoan. The question arises as to whether the amoeba was *A. histolytica* or *gargalis*. Bacteria were found within them in this case—a point more in favour of *gargalis* but red corpuscles were also found—a point in favour of *A. histolytica* and strongly against *gargalis*. They measured from 8-17 microns in diameter. Since only preserved material was available no final decision could be made. H H S

LOUBEYRE (J) TOLLIER (H) & FOISSAUX (J) Polynévrite des membres inférieurs apparue au décours d'une paratyphoïde B et d'une amibiase intestinale, et guérie par un traitement émétiq. Neuritis in Association with Paratyphoid Fever and Intestinal Amoebiasis cured by Emetina. *Bull. et Mém. Soc. Méd. Hôp. de Paris*. 1938. Dec. 12. 54th Year 3rd Ser. No. 33. pp 1702-1708

A commercial traveller 32 years of age suffered from an attack of paratyphoid B and neuritis of the legs, and some months later had a haemoptysis. There was no sphincter involvement. No cause was discovered for this haemoptysis, but on a subsequent occasion a diagnosis of "pulmonary hepatic and intestinal amoebiasis" was made when diarrhoea, 8-10 stools a day led to faecal examination and discovery of *E. histolytica*. Electrical treatment had failed to benefit the paralysis but on the exhibition of emetine for the amoebiasis the paralytic symptoms also cleared up. The authors note that GRALL DIOT (in Morocco) and ROGER (of Marseilles) have noted that polyneuritis does occur as a complication—though a rare one—of amoebiasis. H H S

ENDERLE (Lario) Sindromi neuropsichiche nella amebiasi cronica (Nervous and Mental Syndromes in Chronic Amoebiasis). *Arch. Ital. Sci. Med. Colon e Parasit.* 1938. Sept. & Oct. Vol. 18. Nos 9 & 10. pp 513-558 5 refs. H H S

SAUTET (Jacques) A propos des abcès amibiens du foie (Amoebic Abscess of the Liver). *Rev. Prat. Malad. des Pays Chauds*. 1938. July 17th Year Vol. 18. No. 7. pp 323-4 327

The author stresses the fact that obscure hepatic conditions in the tropics and subtropics are probably more often due to *E. histolytica* than is generally believed. The fact of the pus from a liver abscess being sterile or in an earlier stage, a hepatitis of obscure origin should lead to a very careful and, if necessary, repeated examination of the faeces. It is not, he thinks, sufficiently appreciated that cysts may be found and hepatitis and even abscess occur without there being a history indicative of a previous attack of true dysentery. H H S

HUARD (P) LONG (M) & GRAEYAT (R) Réflexions sur une nouvelle série de 48 abcès du foie. (Reflections on a Further Series of 48 Liver Abscesses). *Rev. Méd. Française d'Extrême-Orient*. 1938. Mar. Vol. 18. No. 3. pp 170-217 [Refs. in footnotes.]

This is a valuable paper emphasizing that in Indo-China a large proportion of abscesses of the liver show primary or secondary bacterial infection, necessitating more frequent resort to open operation and drainage.

The authors now add records of 48 new cases to the 150 previously recorded by them. They quote figures of 99 cases in eight years in Tonking as well as data from other countries. They also quote evidence that some cases are caused by bacterial infection and not by amoebae and the former appear to be more frequent in Indo-China than in India and elsewhere. Such bacterial and especially streptococcal and staphylococcal infections may be secondary to amoebic abscesses. They also note that such organisms may be found by haemoculture. A table of the data of seven series of cases by other workers in the Far East shows 90 amoebic and 7 non-amoebic cases but the author's own figures showed among 42 Tonking cases only 3 amoebic and 39 non-amoebic cases. Such a remarkable difference has naturally led them to adopt different treatment from that found most effective in other countries. They quote the old French contention that the amoebae carry to the liver the bacteria that cause the abscess although the reviewer has never seen any explanation of why such septic organisms die out of the liver alone and leave so many amoeba-containing abscesses sterile as regards bacteria. They also refer to other very rare causes of liver abscess such as worms distoma gallstones and hydatids.

The symptoms are next discussed and the frequency of different signs recorded in accordance with general experience. The rarity of definite jaundice is emphasized except that due to pressure of a large abscess on the hepatic ducts as in the case quoted from ROGERS. More important are the complications met with which are discussed at length. Intraperitoneal perforation may be spontaneous or follow on puncture or drainage operations and the authors quote published records of cure obtained in sterile cases by simple aspiration of the abdominal pus combined with emetine treatment which they will be tempted to try in future. Recent data collected by SANTAVELLI showed in localized peritoneal infections 13 cures and 9 deaths and in generalized ones 5 cures and 18 deaths. In a table of 690 liver abscess cases they record 88 with rupture into the peritoneal cavity. Multiple and recurring abscesses are next dealt with and their serious import noted.

Under diagnosis they record further successful use of the method of injecting lipiodol collargol or tenebryl into the abscess cavities, to detect their extent and complications through spread to neighbouring organs such as the lung or some part of the gastro-intestinal canal.

The results of treatment in a number of eastern countries are summarized in Table 7. They show great variations in the mortalities but only two deal with a considerable number of cases. The very high death rate of 80 to 90 per cent in the non amoebic cases of Yoshitake is noteworthy. The Indian Army with only 12 per cent mortality among 83 cases doubtless largely in amoebic cases presents a great contrast. In an analysis of their own cases the authors point out that nearly all their fatalities occurred in cases showing bacterial infection, and very few in purely amoebic cases. This is in accordance with Indian experience. Owing however to the much larger proportion of bacterial infections in their series they naturally adopted the open operation as a rule. In cases suitable for emetine treatment they prefer to give the drug intravenously. They find adrenalin of value as a safeguard to the heart against the depressing effects of the former drug.

Tropical Diseases Bulletin.
Table showing the Mortality from Liver Abscess in Various Statistics of
Indo-China and the Far East.

[April, 1935]

Sources	Number of abscesses observed	Number of Deaths
Military statistics from the Dutch Indies (1934-1936)	17	3 (17 per cent.)
Military statistics from the Dutch Indies (1920-1925)	268	76 (28.7 per cent.)
Military statistics from British India (1930-1935)	83	10 (12 per cent.)
Military statistics from British India (1935)	4	1 (25 per cent.)

Wijerama (E. M.) *Tropical Abscess of the Liver.*—*J. Ceylon Branch Brit Med Assoc* 1933 Mar Vol 35 No. 5 PP 263-267

During a period of 21 months among 4,070 patients admitted to the author's wards were 48 with liver abscess, i.e. about 12 per mille. Those in the fourth decade were twice as numerous as in any other corresponding period only one was under 20 years, eight between 20 and 30 years and for the succeeding decades 19, 10 and 10 the oldest patient being 58 years. All, without exception, were males. A history of previous dysentery was obtained in thirty-four (but the interval between the dysentery and the onset of symptoms of liver abscess for hepatitis) is not stated. It is interesting to note the treatment adopted. Forty-three received injections of emetine only adults 1 grain daily for twelve days with an interval of two days between the sixth and seventh injections. Four patients were aspirated as well as being given emetine one being aspirated once two twice and one three times. These forty-seven all did well. One patient was transferred to the surgical ward and died after operation. H H S

Prinks (M. V. P.) *Tropical Abscess of Liver.*—*J. Ceylon Branch Brit Med Assoc* 1933 Sept. Vol 35 No. 5 PP 381-384.

The author's remarks are based on a very small number of cases, 28 and he excludes the inflammatory condition preceding actual abscess. [It is a pity that with so small a total as 28 percentages are given throughout in place of actual figures they are very apt to mislead.] Eighty per cent. [22 cases] were of obscure onset with moderate fever up to 101°F only no sweats or rigors a history of dysentery

or diarrhoea was obtained in less than half 45 per cent. [? 13] The author found that alcohol in moderate quantities was taken by 24 per cent. [? 6 or 7] and concludes that it is likely that toddy was the medium of infection in these cases. He adduces however no other evidence for this generalization. Pain in the right upper abdomen was present in 60 per cent. [? 17 cases] tenderness over the liver in 95 per cent. jaundice in 4 per cent. [presumably a single case]. Sweats were uncommon loss of weight marked with large collections of pus leucocytosis ranged from normal to 18 600 per cmm with an average about 12 000 pus withdrawn usually sterile.

The author recommends the giving of emetine for three days before aspiration is undertaken. He warns against the use of the knife for incision of the liver over an abscess because of the risk of uncontrollable haemorrhage also of a long needle for exploring because of the danger of puncturing the inferior vena cava.

The commonest complication of untreated abscess was rupture. Of twelve such cases under the author's observation four ruptured into the lung and pleura two through the chest wall two into the peritoneum and four through the abdominal wall. He states that abscesses rupturing into the peritoneum set up acute and extensive peritonitis although ordinary pus-forming organisms were absent and proved invariably fatal if operative treatment was undertaken early and shock was profound. Nevertheless at exploratory laparotomy two such cases were found to be ruptured tropical abscesses. Both patients recovered when the matter in the peritoneal cavity was mopped out and the abdomen was drained. [These statements are not easy to reconcile is a negative omitted from the first?]

BROWN (Philip W) & HODGSON (Corrin H) Late Results in Treatment of Amebic Abscess and Hepatitis of the Liver — *Amer Jl Med Sci* 1938 Sept Vol. 196 No 3 pp. 305-313

This is an important contribution from the Mayo Clinic to the incidence of amoebic hepatitis and liver abscess in the North Temperate Zone climate of the United States.

Invasion of the liver by amoebic infection from the large bowel is a serious affection as shown by the high mortality prior to the introduction of the emetine treatment. A review of 18 years Mayo Clinic records shows 18 actual cases of liver abscess and 17 with clinical signs of hepatic involvement. The amoeba was found to be the cause in 18 (14 per cent.) of 125 liver abscess cases in this temperate zone area. Only 4 of the 35 cases were in women and these were all among the 17 non-surgical cases none of the 18 surgical cases were females. Even a history of diarrhoea was absent in 8 of the 35. Pain in the lower right thorax was the most frequent symptom it also occurred in the right shoulder in 8 and in the left in one. Fever was present in all but four. Leucocytosis is present but may be minimal during a quiescent phase. Tenderness on pressure over the liver is common. X-rays may reveal liver enlargement and fixed right diaphragm. The stools were positive to amoebae in 26 cases and in 8 more that organism was found in the liver abscess pus. Three cases were recognised by the characteristic response to emetine. In 7 of 17 proctoscopic

[April, 1935]

with a six day interval between them. Up to one year 5 mgm. a day up to a total of 5 cgm. from 1 to 2 years, 1 cgm. daily total 10 cgm. from 3 to 5 years 2 cgm. a day total 20 cgm. from 6 to 9 years, 3 cgm. daily total 30 cgm. from 10 to 13 years, 4 cgm. daily total 40 cgm. For the last age group five weeks for the others four weeks suspension of emetine treatment is observed after the last dose. The doses mentioned refer to the hydrochloride of emetine for other compounds the dose is proportional to their emetine content. In the acute stage of bismuth and emetine or auremetine (28 per cent of emetine) are given in capsules. Of the latter he gives four capsules of 1 grain each daily up to a total of 60 grains. Congestive amoebic hepatitis yields rapidly to emetine and he is convinced that typical hepatic abscess may undergo resorption under this treatment.

That failures with emetine treatment occur he allows. Apart from cases treated with insufficient doses mixed infections of bacterial and amoebic dysentery and cases complicated by a *Leishia* or other protozoal infection he finds that 5 per cent of acute cases resist emetine. In such cases arsenicals must be employed. Insufficient dosage with emetine—less than 6 cgm a day in the adult—produces emetine-resistant amoebae. The author finds that anaphylactic symptoms are not infrequent in attendants and pharmacists but rare in patients. They are vesiculo-erythematous rashes of face and hands. In the sick extensive erythema oedema and arthralgia have occurred in patients previously treated with ipocuanha. As to whether it is permissible to speak of cure the author is very reserved. A useful paper deserving of careful study by those practicing in the tropics.

J B Davy

HAKANSSON (E G) On the Effectiveness of Carbarbons as a Remedy for Amoebiasis.—*Am J Trop Med* 1933, May Vol. 18, No 3 pp 245-269 [24 refs.]

A careful analysis of the results obtained in 43 cases of amoebiasis by treatment with Carbarbons given in capsules by mouth.

The cases are separated into four groups in which varying dosage was employed—(i) 12 gm. in four weeks (ii) 18 gm in five weeks (iii) 11 25 to 16 gm in ten days (iv) 5 to 10 gm in ten days. In the last two groups dosage was proportional to body weight. In all cases divided doses two or three times daily were given after meals. The cases comprising groups (i) to (iii) were asylum inmates those in group (iv) laboratory technicians and their families. Among the former were six of acute dysentery the rest were all carriers.

The patients were on ordinary diet and no other drugs were employed except for a few of the acute cases in which exhaustion compelled rest in bed, the patients were up and about.

During the twelve months following treatment, at least 31 thorough microscopical examinations of the faeces of each case were made. The sugar flotation method of YORKE and ADAMS was employed when examining stools of normal appearance. The test of cure was therefore, a stringent one.

In one instance only were toxic symptoms seen. This was a woman weighing only 88 lbs. who developed jaundice and glycosuria after a course of 10 gm. in 23 days. The toxic symptoms cleared up in a fortnight.

Vol 36. No 4]

There was no vomiting complained of by one patient. The faeces were negative throughout the year of observation. 19 of the 43 cases following treatment and in one of seven submitted to a second course of treatment after relapse. The intensive 10 day courses gave the best results. All the cases in group (iv)—laboratory technicians and their families—passed the test although a low dosage was employed in this group.

As Hakansson points out it is probable that some of the failures in the asylum cases were actually reinfections for no precautions against this were possible and an earlier survey by C M Jönsson revealed that there was an *E histolytica* incidence among the inmates of this asylum of 35 per cent.

The immediate result in carriers was the disappearance of cysts from the stools in three days. In the acute cases the stools were free of *E histolytica* and of blood and mucus in two to four days. Hakansson is rightly cautious in drawing wide conclusions from this small but exhaustively investigated series of cases and concludes his paper with useful suggestions on the precautions to be observed in prescribing this valuable drug.

J B Darcy

GRASSO (Rosario) Sul valore terapeutico dell'acido p carbamidico fenalarsonico (Fenarson) nella colite amebica (Fenarson in Amoebic Colitis)—*Riv Sanitaria Siciliana* 1933 Aug 15 Vol. 26 No 16 pp 921-930 [10 refs]

Fenarson is the Italian equivalent of Carbarsone. The author has employed it in treating forty patients giving 50 cgm daily for ten days. He found that the entamoeba both vegetative and cystic forms disappeared early it might be in two days but usually within a week. Twelve of the patients examined at intervals up to eight weeks afterwards were still found negative and the drug was well tolerated by all.

In discussing the dosage the author states that American physicians prescribe for an adult 75 mgm per kilo body weight over a period of three weeks the minimum and maximum doses found effective being 29 and 204 mgm per kilo without giving rise to toxic symptoms. The general dosage recommended is 75 mgm per kilo over a period of at least ten days and given in two doses a day. It has proved efficacious but not so completely in infections by *E coli*, *E nana*, *Iodamoeba butschlii*, *Chilomastix* and *Giardia*. [See also this Bulletin 1934 Vol. 31 p 282 1936 Vol. 33 p 543] H H S

PYMAN (F L.) Chemotherapy of Amoebicides.—*Nature* 1937 Nov 13 Vol. 140 No 3550 pp 832-834 [10 refs]

In this paper the author reviews work that he has carried out on derivatives of harmol with a view to the discovery of amoebicidal drugs. The various derivatives were tested on cultures of *E histolytica*. A series of compounds of the general formula $RR'N(CH_2)_xNRR'$ was prepared and it was found that of these the most active were α -tetra n -amylidiaminodecane ($R,R' = n$ -amyl $x=10$) and α -tetra- n -butylidiaminodecane ($R,R' = n$ -butyl $x=10$). The first of these in

to 1923 which was the last year in which epidemic plague occurred. Many interesting statistical facts are recorded in tables—table I standardized death rates for census years and crude death rates for each year table II age-mortality of plague deaths in 1901 because this was a census year table III plague deaths expressed as a percentage of deaths from all causes in their age groups and table IV seasonal distribution of plague 1894–1923. Other tables follow with calculated coefficients of correlation between plague and the five main climatic factors—relative and absolute humidity monthly mean temperature, rainfall, and barometric pressure. It is not easy to ascribe the diminution in the severity of plague to improved sanitation since the severity of plague has diminished everywhere in South China with or without sanitation betterment. Conclusions are come to which appear somewhat contradictory—

“Climatic conditions favour the spread of plague in Hong Kong in the spring and early summer. When the mean temperature rises to 83° the relative humidity to 83° and the tension of aqueous vapour to 0.500, epidemics are likely to occur. When these factors approach respectively the values of 82° , 83° or more for three to four months and 0.900, the disease tends to die out. Inasmuch as these factors have often prevailed in non-epidemic years, and indeed when there has been no case of plague

it is necessary to look for other causes which may govern the appearance of plague either in epidemic or sporadic form in Hong Kong.”

W F H

Buxton (P. A.) Quantitative Studies on the Biology of *Xenopsylla cheopis* (Siphonaptera)—*Indian J. Med. Res.* 1938. Oct. Vol. 26 No. 2. pp. 505–530. With 3 figs. & 2 graphs. [22 refs.]

The biology of tropical rat-flea has been studied by insect physiologists under laboratory conditions and the “flea count” in the field has been thought to provide a rough guide to the state of natural populations from time to time. But more exact studies in population growth, making use of laboratory technique for breeding the fleas and the control of climate though leaving the rodent-flea relationship as natural as possible, have only recently been attempted. The present paper describes the results of 27 experiments made in order to discover the climatic conditions under which fleas live and multiply most easily.

The apparatus, which is quite new and which with slight modifications may perhaps be used for other problems, is described in great detail. It consists essentially of a “synthetic mouse-hole”—a rectangular glass chamber 18 cm. \times 12.5 cm. \times 13 cm. with a copper lid waxed into position and carrying inlet and outlet pipes for air thermometer hygrometers, etc. Into this chamber which is kept in an incubator at constant temperature, are placed a mouse and its bedding together with the fleas (*Xenopsylla cheopis*). Air brought to the required humidity by either KOH or H_2SO_4 solutions is passed through the chamber. Many difficulties in the control of humidity have been overcome and are described. Among other precautions it is necessary to use a mouse of standard weight and to maintain a constant rate of air flow. Then in spite of the water given off by the mouse it is possible to control humidity so that there is no more than an 8 per cent. variation in different parts of the chamber. It is thought that the humidity in the bedding is very little in excess of that of the atmosphere above it.

When the mouse has occupied the apparatus for three days adult fleas, from 15 to 50 of each sex, are introduced (P (parental) generation). They feed on the mouse and breed in the bedding. After a definite period from 7 to 18 days in these experiments the fleas are counted and the bedding incubated at the temperature and mean humidity of the experiment until all the first filial generation (F) adults have emerged. Many P fleas are eaten by the mouse but assuming their decrease to be logarithmic an estimate of the number surviving at any day can be made and experiments of different duration compared. It is stressed that owing to the small number of experiments the conclusions are tentative they may be briefly summarized as follows —

P generation

A high mortality is due to fleas being eaten by the mouse but survival was affected neither by temperature nor humidity over the ranges used (24° to 32°C. 30 per cent. to more than 90 per cent. R.H.) It is thought that in dry air water loss is compensated by frequent blood-meals. The original density of population has no effect on the proportion surviving. When an experiment is concluded the proportion of fleas on the mouse is determined. This may vary between 4 per cent. and 23 per cent. of the total and it is affected neither by temperature nor humidity. When the sexes are present in equal numbers significantly more females than males have been found on the mouse.

Production of F fleas

Eighty per cent. of the emergences occur between the 24th and 33th day after the commencement of the experiment and they tend to be sooner at higher than at lower humidities. The production of F fleas per P♀ day is greater at higher humidities and at high temperatures. At very high humidities mould appears and there is a total mortality in the F generation. It is probable that low humidity is unfavourable during larval life when spiracular control is less efficient and when water may be lost through the cuticle. Possibly the larvae feed only when the proportion of water in the bedding exceeds a certain value.

In conclusion the author calls for a more critical study of the flea count for his experiments suggest that as yet it gives no reliable estimate of the fluctuations in the total flea population since it assumes that the population of fleas on the rat bears a constant relation to the total population. It is urged that the climate in rat-holes and harbourages should be studied, for it would be interesting to know if mortality of fleas is high in nature in view of the nearly saturated atmosphere found by the author in rat-holes [this *Bulletin* 1932 Vol. 29 p 838].

It is important to know also about the temperature in the holes since fleas may possibly tolerate a drier atmosphere at the higher temperatures for then the adult stage with its greater tolerance of humidity variations is reached more quickly.

It is hoped too that the "synthetic mouse-hole" will be used in the future with rats and that the period of the experiments will be extended to cover the whole life of the P generation. Very high relative humidities should be studied, with a drainage system (plaster of Paris on

the floor of the chamber?) similar to those occurring in natural rat holes. The use of baby rodents has also been tested the mortality among adult fleas is then very slight (but we understand that the fleas lay few eggs)

C G Johnson

RAMOS DÍAZ (Arquimedes) Epidemiología de la peste bubónica en la sierra del Departamento de Lambayeque. [Epidemiology of Plague in the Mountainous Region of Lambayeque.]—*Boletín Semanario Panamericano*. 1938 Sept Vol. 17 No. 9 pp 778-781

A small epidemic of plague occurred in a small village in the mountainous region of Lambayeque in Peru. It has formed the basis of a study of the mode of transmission of plague in that district. The disease was proved to be human plague by disintering the body of a fatal case two months after burial and examining the bone marrow from a rib microscopically by culture and by animal inoculation. In the region of the epidemic the presence of *Rattus rattus* which is the common reservoir of plague on the Peruvian coast, has been demonstrated together with its plague vector *X. cheopis*. In the mountains however rodent plague is found in the *cui*, a species of guinea pig. Contact is made between *cui*s and rats, which accounts for epizootics in the former. Now the flea *Pulex irritans* has adapted itself as a parasite of the *cui* and it is this flea which is considered to have transmitted plague in this instance to human beings.

LAUBAUER (E.) Rapport sur la peste dans l'île de Hainan. [Report on Plague in Hainan.]—*Bull Soc Path Exot*. 1938 Oct 12 Vol 31 No 8 pp 752-760

GRAND (G.) Identification du bacille pesteux par l'inoculation au cobaye des séroités de ponctions diluées dans l'eau salée (à propos des remarques formulées par M. BROQUET). [Identification of the Plague Bacillus by Inoculation of the Guinea-pig with Puncture Material Diluted with Salt Solution.]—*Bull Soc Path. Exot.* 1938, July 6 Vol. 31 No 7 pp 660-677

The point made in this communication and illustrated by experimental data is that more certain and quicker results are given by subcutaneous injection of a suspension of test material in salt solution than by application to the shaved skin. One advantage of the salt solution over more nutrient fluids is that post-mortem organisms do not multiply in it.

W F H

ESKRY (C. R.) Fleas as Vectors of Plague.—*Amer Jl Public Health* 1938, Nov Vol. 28, No 11 pp 1305-1310

Many important data regarding the conditions under which plague is transmitted to man by fleas are contained in this article. These are presented in condensed form and can only be still more concisely summarized.

It is only shortly before the death of an animal that the blood septicaemia is sufficiently intense to infect fleas. In the flea itself which has taken up plague blood, infectivity is not developed as long

as that blood can still pass into the stomach. Only the "blocked" flea—that is one in which bacterial proliferation has occurred in the proventriculus with obstruction—is infective by the regurgitation of organisms into the wound made by the insect bite. In the course of experiments fleas have transmitted plague as early as five days and as late as 147 days after they had ingested *P. pestis*. On the other hand the period of infectivity is short for the flea does not usually survive obstruction more than 24 to 48 hours.

The species of rat flea *Xenopsylla cheopis* is the most active and dangerous of the flea vectors but *Nosopsyllus fasciatus* is also highly capable of transmitting plague. Although all species of fleas do not have the same ability to transmit plague it is probable that any flea regardless of species feeding on septicaemic blood may become infected and may be a potential vector.

It used to be held that man might be infected with plague by means of flea faeces rubbed into the wound. While this view has been discarded for man in favour of regurgitation infection, it probably holds good for the rodent and it is well to remember that *P. pestis* may retain its virulence as long as four weeks in dried faeces.

Sylvatic plague has assumed considerable importance of recent years for epizootic spread and yet there is little knowledge regarding the facility with which wild rodent fleas will attack humans. It would seem probable that all rodent fleas have to be starved before they prefer human blood to that of their natural hosts and that wild rodent fleas are not nearly so dangerous to man as the domestic rat fleas *Xenopsylla cheopis*. W F H

MAYFIELD (R. B.) Rat-Fleas in Plymouth.—*Parasitology* 1938
Sept Vol. 30 No 3 pp 314-319 With 1 fig

The investigation related only to a certain section of the docks in Plymouth which were separated by town dwellings from other dock premises. More extensive surveys in Liverpool have shown that *Xenopsylla cheopis*, *Nosopsyllus* (*Ceratophyllus*) *fasciatus* and *Leptopsylla musculi* were the prevalent species there. In London the most common species was *Nosopsyllus fasciatus* although *Leptopsylla musculi*, *Ctenophthalmus agyricus* and *Ctenocephalus felis* were present in fair numbers. In conducting the research the live rats were chloroformed and the fleas obtained by combing the rat. Three species were found—*Nosopsyllus* (*Ceratophyllus*) *fasciatus*, *Xenopsylla cheopis* and *Leptopsylla segnis* (*musculi*). The findings of *Xenopsylla cheopis* were almost entirely confined to a certain grain store. W F H

PISTONI (Ferruccio) Fauna murina in Eritrea e nello Scioa. Ricerche parassitologiche. [Murine Fauna in Eritrea and in Scioa.]—*Arch Ital Sci Med Colon e Parassit* 1938 July Vol 19 No 7 pp 388-394

A survey has been made by the author of the rats together with their ecto- and endoparasites in the seaport of Massana in Asmara a town in the highlands of Eritrea and in Addis Ababa. In Massana out of 200 rats captured 187 were *Mus rattus rattus* and 13 *Mus rattus*. No rats of the species *Mus norvegicus* (*decumanus*) were caught. In the

highlands of Eritrea and of Selom there was a slight preponderance of *Mus rattus* over *Mus rattus rattus* and *Mus musculus*. Ectoparasites in the plains of Eritrea were represented by *Xenopsylla cheopis* and *Nosopsyllus fasciatus* but the parasitic index was low during the hot weather whereas it was higher and more constant in the hills. The endoparasites specially noted in both hills and plains were *Giardia* and *Trypanosoma lewisi*.

ALI (P. Mohamed). A Rat-Flea Survey of Mattarahery (Goshin) (1937).—*Indian Vet Gaz* 1938 July Vol 73 No 7 pp 409-412

OTOMO (T.) KOGA (S.) & TANAKA (I.) Les rats et leurs puces dans les entrepôts douaniers de Kôbé. [The Rats and their Fleas in the Customs Depot of Kobe].—*Bull. Office Internat. d'Hyg. Publique* 1938, July Vol. 30 No. 7 pp 1435-1436.

It is to be expected that the species of rats found on board ship will differ significantly from those on shore. The storage depots of the Customs have an intermediate position in this respect, as the present incomplete investigation lasting from 1st to 25th October shows. A proportion of 70 marine to 30 shore rats was found. According to species there were in percentages, *Rattus rattus alexandrinus* 71.57 *Rattus norvegicus* 11.20 *Rattus rattus rattus* 9.90 and *Mus molossinus molossinus* 7.26. The fleas found on the rats were in the percentage proportions *Xenopsylla cheopis* 75.62, *Ceratophyllus fasciatus* 21.07 *Ceratophyllus anisus* 1.36 *Leptopsylla musculi* 0.56 and *Echidnophaga gallinacea* 1.36. The *cheopis* index in the depots was about 4.2.

RISTORCELLI (A.) Les rongeurs sensibles à la peste dans la région du Neftzoua. [Rodents Susceptible to Plague in the Region of Neftzoua].—*Arch. Inst. Pasteur de Tunis* 1938 Sept. Vol. 27 No. 3 pp. 296-303 With 1 map

The region of Neftzoua in Tunis is a strip of country stretching from beyond the salt lagoon of Shott el Djerid in the North to Ghadames in the South and having the Algerian frontier on the West. Rodents found in this territory are the dormouse *Psammomys* and merions, gerbils *Mus musculus* *Rattus alexandrinus* *jerboa* and *Ctenodactylus gundi*. Gerbils and *Psammomys* predominate. Although human plague has not been known since the French occupation it is said to have decimated the district a century ago. Epizootics are described by the natives and are said to be due to ticks of the genus *Hyalomma*. If epizootic plague did make its appearance it would probably spread rapidly.

MORGAN (M T) Mémoire publié par le Ministère Britannique de l'Hygiène sur la méthode à suivre pour l'examen des rats au point de vue du diagnostic de la peste. [Departmental Method of examining Rats for Plague]—*Bull Office Internat d'Hyg Publique* 1938. July Vol 30 No 7 pp 1437-1439

(1) Attach the dead rat to a board belly upwards (2) Reflect the skin from the jaw to pubis and search for cervical axillary and inguinal lymph nodes not forgetting that there are sex glands in front of the pubis which may normally contain numerous small bipolar bacilli. (3) Note the presence of subcutaneous haemorrhage or congestion (4) Dissect out every suspicious lymph node and section it. (5) Make films and examine microscopically if any sectioned surface suggests necrosis. (6) Open the abdomen and remove small pieces of tissue from liver and spleen after sterilizing the surface by cauterization (7) Fix films made from suspicious lymph nodes in the flame treat with absolute alcohol stain with carbol thionin under gentle heat and wash in tap water (8) Examine for bacilli with bipolar staining (9) Take portions of tissues such as nodes, liver spleen, etc., in any case which has shown bipolar bacilli for test culture and inoculation into a guinea pig (10) Sow the fragments of tissue without making into suspension directly on well dried ordinary nutrient agar plates. (11) Inoculate the guinea pig subcutaneously at a shaved spot on the abdomen to the left of the middle line (12) Send material such as the rat organs or culture which have proved suspicious of plague infection to the Ministry of Health Laboratories, London whose duty it is to confirm the suspicion (13) Take all precautions to have this material, in a carefully corked wide-mouthed bottle surrounded with sawdust, packed in a tin box (14) Send a telegram in advance to notify the Minister of Health. W F H

ROBIC (J) & MINEC Note sur un cas de peste bubonique compliqué de pyomyosite à bacille de Yersin (Case of Bubonic Plague complicated by Plague Abscesses in Muscles.)—*Bull Soc Path Exot* 1938. July 6 Vol. 31 No 7 pp. 679-682.

The patient was a young man of 21 years who developed plague and buboes in both inguinal regions. That on the left side opened spontaneously and discharged abundant pus. The iliac lymph nodes were secondarily affected and supplicated also. Death occurred suddenly 17 days after the appearance of the first bubo from haemorrhage due to ulceration into the femoral or iliac artery. There is nothing very extraordinary in this history. What was quite unusual, however was the development of intramuscular abscesses in both upper and lower extremities. Two of these were aspirated before they had opened and yielded in the one case a pure culture of *Past pestis* and in the other *Past pestis* along with *Staph albus*. A reference is made to the presence of this latter organism either in the category of a contaminant or as having a more causative rôle. The case may be described as one of plague pyomyositis. W F H

ANCHEZAR (Benjamin V) Estudio bacteriológico y anatomopatológico de la infección experimental con *Pasteurella pestis* (Cepa E.V. avirulenta de Girard.) [Experimental Study of Plague Strain E.V.]—*Rev Inst Bacteriológ* Buenos Aires 1938. Aug Vol. 8. No 2. pp 196-227 With 5 figs. on 3 plates [27 refs.]

A strain of plague was isolated by GIRARD in Madagascar which is not merely avirulent but can be used as living vaccine in man. The

present study has been directed to following out the effects of this living E.V. strain on the very susceptible guinea-pig. Conclusions arrived at are 1 The E.V. strain which was isolated from a patient with bubonic plague is identical in all respects with *Pest. pestis*. 2 The living E.V. strain is avirulent for the guinea-pig in small or medium doses whether administered subcutaneously intraperitoneally intratracheally or by the mouth. 3 In large doses (of 250,000 million organisms) it causes death in guinea-pigs and rats by toxic action. 4 Experimental infection has shown that E.V. bacteria (a) have selective effect on the lymph nodes and spleen, (b) are temporarily present in the blood and bone marrow and (c) persist for a considerable time at the site of inoculation. 5 The inoculation gives rise to localized inflammatory lesions, such as regional adenitis and peritonitis and temporarily to more general lesions of infective type. *W F H*

GIRARD (G) & ROBIC (J) Vaccination antipesteuse par germes vivants (virus vaccin E.V.) Trois années d'application à Madagascar [Plague Prophylaxis with E.V. Living Vaccines].—*Bull Acad Méd* 1938 July 5 102nd Year 3rd Ser Vol 120 No 26 pp. 54-60 With 1 chart.

Many communications by the authors have been noticed on this subject (this *Bulletin* 1934 Vol 31 p. 885 1935 Vol 32, p. 850 1936 Vol 33 pp. 366 877 1937 Vol 34 p. 408 1938 Vol 35 p. 209). The summary here given is A huge programme of plague prophylaxis by means of living avirulent E.V. vaccine has been carried out during the past three years and over 2,000,000 vaccinations have been performed. The killed vaccine which was originally used had given mediocre results. With living vaccine on the other hand an 80 per cent reduction of mortality is claimed. *W F H*

PASSA Prophylaxie de la peste à Madagascar [Prophylaxis of Plague in Madagascar].—*Bull. Office International d'Hyg. Publique* 1938 July Vol 30 No. 7 pp. 1440-1441 With 1 chart.

Plague has been present on the High Plateau since 1921. From the year 1935 large scale prophylactic inoculation of living plague vaccine has been carried out with the result that in the three years 1935 to 1937 there were performed 500,000 711,039 and 815,453 single dose vaccinations respectively and corresponding reported cases of plague were 3,493 2,007 and 918. This represents a notable reduction. *W F H*

ROBIC (J) Film cinématographique sur la vaccination antipesteuse à Madagascar [Cinematograph Film of Anti-plague Measures in Madagascar].—*Bull. Soc. Path. Exot* 1938 Oct. 12 Vol 31 No. 8 pp. 660-661 With 1 fig.

A film of plague work has been shown in country districts of Madagascar with the final projection on the screen of a graph to illustrate the results of vaccination with the living E.V. strain of plague bacillus. This graph is reproduced below and shows for the five years 1933 to 1938 the number of cases of plague to have been 3,493 3,605 3,035 1,376 and 596 respectively. The E.V. vaccine first introduced in November 1935 has in three separate campaigns of inoculation

made as is shown graphically a solid impression on the case incidence of plague. The final figure (596) for 1937-38 is to be compared with a mean annual incidence of plague for the years preceding the vaccination campaign of 3,500. It will be interesting to see how much lower the graph may descend.

Course of plague in Madagascar in the five years 1933 to 1938, showing the results of vaccination with the living E V strain between 1935 and 1937

MEYER (K F) Sylvatische Pest. [Sylvatic Plague]—*Schweiz. Med. Woch.* 1938 Aug 6 Vol. 68 No 32 pp 925-928.

The history of plague in San Francisco and California is one of ebb and flow but never of final disappearance. Here too the importance of sylvatic plague was discovered and the importance of persisting though sometimes latent infection among ground squirrels. Some twelve species of wild rodents have been incriminated in sylvatic plague species of the genera *Citellus*, *Marmota*, *Peromyscus*, *Neotoma*. It is depressing to read though probably true that no doubt remains that North America from now on will remain a permanent plague focus.

MEYER (K. F) Sylvatic Plague—*Amer. J. Public Health* 1938 Oct. Vol. 28, No 10 pp 1153-1164. With 1 fig
This article is a report on the subject of sylvatic plague by the chairman of the Sylvatic Plague Committee. Two human cases of

W F H

plague, contracted presumably from wild rodents, are described. In the one case the rodent was not identified although "fleas carrying plague bacilli were discovered in the region." The other case gave a history of having been bitten by a chipmunk (*Callospermophilus* (*Citellus*) *chrysodermus*) and it was reported that an epidemic disease had been prevalent among the rodents of the area. Some of the recommendations made as a result of the occurrence of human cases are the use of lymph node punctures for diagnosis in doubtful cases the use of antiplague serum rodent proofing of summer houses warning to residents "not to touch or play with chipmunks or other rodents" reporting of noteworthy rodent mortality prohibition of sale of chipmunks, golden mantled squirrels or other rodents until after two weeks quarantine.

Special consideration is given to latent rodent plague and to the method of its detection by mass inoculations of fleas or fleas by the pool method. Reference is made also to the skin tests and serological procedures used by Russian investigators to detect invisible plague in rodents.

Under the heading scientific investigations some important results are listed —

"(a) The rodent population in a plague area in the California mountains varies from 27 to 117 individuals per acre. Trapping small areas is followed within two months by recovery to a considerable fraction of the original numbers. (b) Rodent control over a narrow belt is soon followed by re-invasion. (c) Experimental studies have shown that methylbromide administered at the rate of 10 cc. per burrow opening, is very efficient in controlling both burrow rodents and their fleas. The fumigant of course must be used with the customary care accorded to all highly toxic gases."

DE LA BARRERA (JOSE MARIA) & CORICA (PABLO). Peste rural en Mendoza. (Rural Plague in Mendoza).—*Polis Biol. Buenos Aires*. 1933 Feb-Mar. Nos. 83-84 p. 353

STEWART (M. A.) & MACKIE (D. B.). The Control of Sylvatic Plague Vectors.—*Amer J Hyg*. 1933. Nov. Vol. 28. No. 3. pp. 469-480 [14 refs.]

The flea is not only a vector of plague but may be a reservoir also so that measures for the eradication of sylvatic plague must aim at killing off not only the rodents concerned but their fleas as well. Much of the work already done on this subject has been directed to the burrowing rodents and to the disinfection of their burrows. In methyl bromide apparently a substance has been found which will kill both the rodent and its fleas whereas hydrocyanic acid has not been so efficient in this respect. Experiments were undertaken to test a number of fumigants in a specially constructed apparatus ethylene dichloride ethylene oxide propylene oxide dicotynal malate sulphur dioxide methyl bromide hydrocyanic acid gas carbon monoxide 1,4-diethylene oxide di-chlorethyl ether carbon disulphide and chloropicrin. Because of the deficiencies of hydrocyanic acid gas and since methyl bromide was next highest in efficiency in the laboratory tests, all further investigations were confined to the latter. The fleas used were taken from the Douglas ground squirrel

(*Citellus beecheyi*) and belonged to the species *Diamanus montanus* and *Hoplopsyllus anomalus*. In the field about 10 cc. of liquid methyl bromide per burrow opening is used. It is well to recognize however that methyl bromide is colourless and odourless and has poisonous action. Care must be taken then by the trained operators in using the fumigant lest they come accidentally in contact with the chemical and receive burns or breathe its fumes which are to some extent toxic. The authors have experimented with gram and tests show that food materials are not rendered toxic by the fumigant. It is probable therefore that methyl bromide could be used satisfactorily for the fumigation of cargoes.

W F H

HELMINTHIASIS.

PRELIS OF ABSTRACTS IN THIS SECTION

KAUFMAN (p. 319) shows that *Ascaris* is found in 3 per cent. of corpses in Bresden. WINFIELD and CHIN (p. 319) emphasize the importance of the pollution of the household environment in both urban and rural districts in China, in the maintenance of *Ascaris* infestation. FOSTER (p. 320) compares the infestation by children in London with a recent comparison by children in the United States that the improvement in worm infestation shown in a recent comparison is due to mass treatments.

BARRETO & ARIDO (p. 320) found that the improvement in worm infestation shown in a recent comparison is due to mass treatments. SANG (p. 321) shows that a watery extract of *Ascaris* contains a protease which inhibits the action of trypsin. LONGLIN (p. 321) describes an ascariasis in the oesophagus removed through the mouth. MULLAN and NERPOLO (p. 321) a case of suffocation due to these worms in the trachea, ZABAWI (p. 321) a case of intestinal obstruction and RAJAHAM (p. 321) one of multiple liver abscesses due to *Ascaris*. KÖ (p. 322) saw a girl of 2½ from whose umbilicus 16 of these worms escaped.

MAPLESTONE and MUKERJI (p. 322) discuss the treatment of ascariasis by oil of chenopodium combined with santonin. Chenopodium in doses graded in the usual way according to age is less successful for children than for adults. DOUBROW (p. 322) describes hookworm disease in the miners in the Loire. Most show no symptoms but some are gravely ill. Treatment is by thymol. DÍAZ (p. 323) found helminth infestation in 41 per cent. of children in Resistencia (Chaco). Hookworm was the most frequent. PESSOA and PASCALE (p. 323) working on estates in São Paulo found 80.5 per cent. infected by *Necator*. Heavier infection was found in those whose dwellings had no latrines than in those possessing them. Treatment was by tetrachlorethylene and other drugs.

SCOTT (p. 324) shows that overt blood loss leads rapidly to iron deficiency. Available iron stores are equivalent to about half the haemoglobin and may repair anaemia from blood loss quickly but this can only happen once and thereafter even small haemorrhages may produce anaemia rapidly unless the iron store is replaced. This explains why anaemia and amount of hookworm infection are often not parallel. The commonest cause of overt blood loss is probably hookworm disease.

CASTILLO ODESA (p. 325) shows the importance of treating children for ankylostomiasis in the schools in the Argentine. AKETAGAWA (p. 325) concludes that canine hookworm larvae, when swallowed, penetrate the wall of the alimentary canal. V. BRAND and OTTO (p. 325) found a low glycogen content in *A. caninum* and that infection had no effect on the carbohydrate metabolism of the host.

KHALIL (p. 326) believes that the periodicity of the microfilariae of *W. bancrofti* in the blood depends upon the site of the adults in the human body and that day and night postures are factors in controlling

lymph flow. An explanation of the common occurrence of *W. bancrofti* in the lymphatics of the spermatic cord depending on the warmth of the tissues, is given.

GALLIARD (p 328) in two post-mortems found no evidence to support the view that autoinfection by *Strongyloides* is common.

RAMOS E SILVA (p 328) gives a local treatment of chenopodium wintergreen and gomenol for larva migrans.

JONES (p 328) gives instructions for the use of the cellophane NIH swab in the diagnosis of *Enterobius* infection but REARDON (p 328) calls attention to artifacts resembling the ova which frequently occur in the cellophane. She also (p 329) gives numbers of eggs counted in the gravid females. MARSHALL and WOOD (p 329) consider that *Enterobius* caused an ischio-anal abscess in a boy. WRIGHT and BRADY (p 329) found gentian violet efficient in treatment of thread worm infection. C W

KAUFMANN (W) Ueber Wurmerkrankungen [On Helminth Diseases].—*Med Klin* 1938 June 17 Vol. 34 No 24 (1747) pp 810-811

As to *Ascaris* it is noted that in Dresden it is found in 3 per cent of corpses at most. The work of MAY at Lahr in Baden showed about a quarter of the people there infected [this *Bulletin* 1938 Vol. 35 p 668]. The difference is considered. In the treatment of thread-worms in which the fingers are emphasized as conveyors of eggs from anus to mouth an ointment of percaene with menthol is advised as well as the anointing of the anus before a stool with zinc ointment and the taking of slops as food. Evidence of their value is not offered.

Clayton Lane

WINFIELD (Gerard F) & CHIN (Ta-hsiung) Studies on the Control of Faecal-borne Diseases in North China. VI. The Epidemiology of *Ascaris lumbricoides* in an Urban Population.—*Chinese Med J* 1938 Sept Vol. 54 No 3 pp 233-254 With 1 graph

The environmental studies indicated that the pollution of the household environment is probably the most significant factor in maintaining the *ascaris* infestation of the city just as it is in the country. It seems to me that the part children play in polluting the environment cannot receive too much emphasis.

The stools were from 2 751 civilians in and around Tsinan and from 393 soldiers of the Shantung provincial forces. The following figures show in order the class of person examined, their numbers and the percentage of infection discovered by Stoll's egg counting method for *Ascaris* hookworm and *Trichuris*. Children in 6 primary schools 895 percentages 43.9 11 3.2 students in the Provincial School of Dramatics aged 7 to 30 total 133 percentages 44.4 12 7 3 middle schools students mostly aged 10 to 19 total 503 percentages 22 7 3.6 college students total 173 percentages 15.6 1 7 10.9 nurses total 47 percentages 38 3 0 10.6 hospital patients total 416 percentages 31 7 8.4 5 5 in city families total 584 percentages 39 7 1.9 2 1 soldiers 393 percentages 8 1 26 7 4 2.

For studies of environment 37 families were selected in Tsinan 15 lightly and 22 heavily infected with total members of 77 and 116 the infection rates for *Ascaris* being 14.3 and 68.4. Of soil samples

taken for examinations the percentages of those positive for *Ascaris* eggs were—in courtyards 37.5 and 75 in rooms 33.5 and 57.1 in streets 83.5 and 40. Most latrines had as receptacle a small brick walled pit cleaned every 5 or 6 days. "one family had a septic tank into which they flush their sewage by means of a bucket of water poured into the latrine and this family was one of the most heavily infected. In no latrine was the pit covered, flies were seen in all but 4 and dogs and chickens had access to all but 6. Of the 22 heavily infected families 12 had children who defaecated in the courtyard from the 15 lightly infected families no such report came. C. L.

DEMPSTER (G. O.) Intestinal Parasites in Western Samoa.—*New Zealand Med. J.* 1933, Aug. Vol. 37 No. 200 pp. 214-218. With 1 fig.

The results are given of a faecal survey of racially pure Samoans in Western Samoa by a slightly modified Willis technique of salt flotation."

The undescribed modification showed no infection by hookworm or *Trichuris* and almost none by *Ascaris* in babies under 1 year old. For these infections there was a sharp rise during childhood reaching 50 to 60 40 to 50 and 18 per cent respectively in adult life.

"Attention is drawn to a discrepancy between the rates of *ascaris* and *trichuris* infestations, which theoretically should be similar.

An improvement on the previous state is shown. This may be partly due to the less accurate technique than that of Hopkins, but for all practical purposes it is accurate enough. An individual infestation with one hookworm is of academic interest only.

Improvement must be due to mass treatments, as sanitary conditions in Samoa are static and have been for some centuries. Any improvement must be due to mass treatment, which therefore appears to be justified as regards expense and the only method at present at our disposal for the control of this disease.

All authorities are agreed that the Willis technique is more accurate [than D.C.F.] in demonstrating ova of *ascaris* and *trichuris*." (As a worker not as an authority LANE found (this *Bulletin* 1926, Vol. 23 p. 281) that using the same quantity of centrifugal precipitate from the same faecal suspension, and floating with a salt solution of s.g. 1.200 the number of *Ascaris* eggs collected by one spin of D.C.F. averaged 1 415 (1 156 to 1 740) by Willis technique as used by Lambert 230 (32 to 596) by Willis technique when the eggs lost during Lambert's reversal of the slide were caught 333 (36 to 946) For *Trichuris* eggs in the same conditions the average for D.C.F. was 15 (12 to 18) for Lambert a modification of Willis 3.5 (0 to 10) and for the total Willis collection 9.8 (0 to 23)] C. L.

BASQUEYO (José G.) & ANIDO (Vicente) Conteo de huevos de helmintos. [Counting Helminth Eggs].—*Rev. Med. Trop. y Parasit. Habana*. 1938 Mar-Apr. Vol. 4 No. 2 pp. 85-87.

The technique consists of suspending faeces in 1 per cent hydrochloric acid by the aid of glass beads and shaking putting the suspension through a sieve and counting an amount of it representing 0.0025 gmt. of faeces. In an example given four such preparations showed *Trichuris* eggs varying between 3 and 6 and *Necator* eggs between 0 and

5 [The accuracy of the technique is in no way tested and apart from the variation in eggs reported in the paper itself, it will be remembered that the mere straining of a suspension removes eggs] C L

SANG (James Henderson) The Antiproteolytic Enzyme of *Ascaris lumbricoides* var *suus*.—*Parasitology* 1938 June Vol. 30 No 2. pp 141-155 With 7 figs. [30 refs.]

A point for medical men is that *in vitro* a watery extract of *Ascaris* contains a readily diffusible protease namely ascarase which combines with trypsin and inhibits its action an effect which presumably explains the inability to digest protein which may be present in this infection C L

VOEGTLIN (Walter L.) Some Novel Manifestations of Ascariidiasis.—*Northwest Med* 1938 June. Vol 37 No 6 pp 182-183

The unusual symptom was as of something crawling up through the chest to the level of the larynx and being stopped by rapid swallowing. Finally on reaching to the back of her throat this woman of 26 pulled out a 7½ inch *Ascaris*. Caprocol brought away five worms and the symptoms persisting hexylresorcinol two more after which they ceased Excessive hunger had also been present C L

MILLAN (Justo M) & NESTOLO (Juan F V) Obstrucción traqueal por áscaris [Tracheal Obstruction by *Ascaris*.]—*Prensa Méd Argentina* 1938. June 1 Vol 25 No 22 pp 1070-1072. [28 refs.]

A child of 11 months died of suffocation the result of several adult *Ascarids* in the trachea. There were also many in the stomach and intestine. C L

ZAHAWI (Shawkat) Intestinal Obstruction and Atrophic Lesion of the Appendix caused by *Ascaris*.—*Jl Trop Med & Hyg* 1938. Oct. 1 Vol. 41 No 19 pp 316-318. With 2 figs.

Some two pounds weight of *Ascaris* caused the death by intestinal obstruction of a boy of 10

Though the obstructing worms lay in the small intestine the appendix was enlarged to a length of 12 cm and a breadth of 3.9 cm. [from the photograph figured this latter was presumably measured with the appendix flattened] and contained four *Ascarids*, its wall being markedly thinned with the mucosa absent C L

RAJAHRAM (S G) A Case of Abscess of the Liver due to *Ascaris lumbricoides*.—*Jl Malaya Branch Brit. Med Assoc* 1938. Sept Vol. 2. No 2. p 103.

A girl of 6 died with five *Ascaris*-containing abscesses in her liver. One had opened in the epigastric region leaving a sinus from which three ascarids had escaped while she was under observation in hospital at which time she had emaciation fever and an enlarged liver. At autopsy there were still two worms in the cavity into which the sinus ran. The dilated and inflamed bile ducts showed other worms and there was one in the duodenum though santonin during life had not led to the passage of worms. C L

h.5 (Tōm) Ein Fall von Ausschlüpfung der Ascariden durch die Mitte der Nabelgrube hindurch. [Escape of Ascarids from the Navel.]—*Tarzan Igakkei Zasshi* (*Jl Med. Assoc. Formosa*) 1938. Apr. Vol. 37 No. 4 (397) [In Japanese pp. 758-762. With 4 figs. on 1 plate. German summary p. 763]

A peasant girl, aged 2½, complained of abdominal pain for some two months. After the appearance at the umbilicus of a serous discharge ascarids began to worm their way out of it to the number of 16 during 35 days. She had no fever apart from malaria, and no colic. C. L.

MAPLESTONE (P. A.) & MUKERJI (A. K.) The Treatment of Ascariasis. —*Indian Med. Gaz.* 1938. June. Vol. 73 No. 6. pp. 326-328.

Treatments were by oil of chenopodium of B.P. standard and combined with santonin in varying doses.

The standard adult dose of oil of chenopodium was ℥ xv and in general the efficiency of treatment as judged by an unstated technique lessened as its dose was diminished below 12 to 10 minims, and when the two drugs were given together its dose when reduced had a far greater effect in lessening the success of the treatment than had santonin. The lessening of the dose of oil of chenopodium for age that is size of a patient as is the usual custom for drugs, is not successful, and it is pointed out on the one hand that the worms which are to be poisoned are of the same size whatever the size of the host, but that, the child's intestine being smaller the reduced dose should give a proportionate concentration of the poisonous drug round the worm. A second suggested explanation is that as most intestinal helminths more readily infect young than old animals, it may be a matter of power to maintain position. [A third explanation is that after absorbing ascaridole the host's body produces from it as it seems to do from santonin and thymol, the real anthelmintic substance, and that in the child these activities are less marked than in the adult. That the host's body does absorb and change ascaridole is shown by the report that after the administration of oil of chenopodium it disappears from the intestinal contents and that in the urine there is present glycuronic acid and a smell of thyme (CAIUS & BHASKAR *Indian Jl Med Res.* 1920 Vol. 7 pp. 570-609)] C. L.

DOUBROW (S.) L'ankylostomose en pathologie du travail [Ankylostomiasis in Industrial Pathology]—*Arch. Maladies Professionnelles* Paris 1938 Sept.-Oct. Vol. 1 No. 4 pp. 298-305 With 2 figs.

In France ankylostomiasis is a disease of underground workers in Algeria and elsewhere in the French Colonial Empire it has no relation to industry. The infection cannot then be listed internationally as an industrial disease.

The paper deals essentially with French miners in the Loire and reports that of some 7 000 of them examined by the [uncontrolled] modification of Telemann's diagnostic method [this *Bulletin* 1932, Vol. 29 p. 756, and 1933 Vol. 30 p. 267] 1,236 infections were discovered. Of these 1,032 (83 per cent.) had no symptoms 204 were anaemic, 31 of them gravely so the other 173 being unfit for full work. Cure of the anaemias closely follows expulsion of the worms it however not being stated what amount of haemoglobin the author

considers to be normal. Treatment is by freshly powdered thymol in cachets three doses of 1 gram each at hourly intervals on each of three consecutive days or 9 grams (135 grains) in all with a purge on the 4th day. Treatment is given in hospital and all stools after admission to hospital are kept each man's in his own bucket and sieved on the fifth day. Surface latrines permit of the miner easing himself before going underground. Apparently there are no underground latrines. C L.

DIAZ (Benito) El índice anquilostomiasico en la ciudad de Resistencia (Chaco) [The Hookworm Index in the City of Resistencia (Chaco)] —*Bol Sanitario* Buenos Aires 1938 Apr Vol 2 No 4 pp 279-310 With 8 graphs & 3 charts

Faecal examinations were made on 1 102 children in nine schools in the city of Resistencia. Percentages of detected infections were as follows: any helminth 41.1 hookworms 29.3 (11.1 to 43.8) *H. nana* 11.7 *Trichuris* 7.9 *Enterobius* 1.8 *Ascaris* 0.7 *T. saginata* 0.4

Faecal examinations for presence of infection were by the Willis technique for egg counting by that of Stoll using 0.075 cc. With the intensity of infection present the Stoll technique missed over 20 per cent. of them. On the method of calculation used 30 per cent. of the children harboured ten and over 70 per cent. less than a hundred parasites. There was no correlation between the estimated weight of infection and the anaemia induced. The clay subsoil of the Chaco favours hookworm infection. C L.

— & — V Observações sobre o tratamento da ancylostomose pelo tetrachlorethileno baseadas em contagens de ovos antes e depois da administração do remédio [V Treatment of Necator Infection by Tetrachlorethylene based on Pre-Treatment and Post-Treatment Egg Counts.]—Reprinted from *Folia Clin et Biol S Paulo* 1937 Vol 9 No 6 pp 165-169

III In 626 persons from whom 0.005 gm. of faeces were examined by the Stoll-Hausheer caustic soda solution method, this technique displayed necator infection in 80.5 per cent. The greatest weight of infection, judging by egg counts was between 15 and 19 years the diminution after 20 being held to be evidence of acquired age resistance. This method of examination disclosed 81.4 per cent. of men infected with an average of 2,276 eggs per gm. the figures for women being 79.4 and 2,736

The few figures available suggest that those who do and those who do not work in the plantations are equally infected.

IV In Fazenda Vassoural the percentage found infected was 62, with an average of 1,684 eggs per gm. The inhabitants were divided into two groups those whose dwellings had no latrines of any kind and those in which latrines of a simple and absorbent type [presumably pit latrines] were provided. In the former the average eggs per gm. were for men and women 2,960 and 2,326 and in the latter 1,551 and 890. As to race in white men the percentage of infection detected was 84.1 of 354 examined and in women 60.8 of 364 the corresponding figures for negroes were 84.2 of 56 and 70.4 of 81. In 61 white men in whom no eggs were detected by the Stoll-Hansaer technique the percentage of haemoglobin was 75.3 in 125 in whom eggs were less than 5,000 to the gram it was 73.3 and in 25 in whom eggs were 5,000 or over 67.4 the corresponding figures for negroes were in 16 75.7 in 12, 73.6 and in 1 53 per cent. there was then no direct relationship between detected egg numbers and the percentage of haemoglobin.

V To the Stoll-Hansaer diagnostic technique there were percentage decreases in necator egg numbers (after tetrachlorethylene given in an adult dose of 3 cc.) varying from 46 to 49 after one treatment and from 78 to 84 after two. It is well to note that after 2 cc. of this drug the number of *Ascaris* eggs was increased by 9 per cent. Figures are given for other treatments.

C. L.

Scorr (R. Bodley) The Iron-Deficiency Anaemias.—*Lancet*, 1939, Sept. 3 pp 549-552.

Under "Overt blood loss" come these words: "In a world-wide census the commonest cause would probably be blood loss due to infestation by the hookworm."

[There runs through hookworm literature surprise, expressed or implied, that anaemia and the weight of hookworm infection do not run parallel. The following sentences from this paper put the matter with admirable clarity for it is not the number of hookworms that determine the onset and degree of hookworm anaemia, but the host's iron reserve.]

"The total amount of iron in a healthy adult is between three and four grammes and it exists in three main forms. First, the iron of the circulating haemoglobin which has an average total of 2.5 g. secondly iron stored in the liver bone-marrow and spleen which is available for conversion into haemoglobin should need arise. Clinical experience shows that a healthy man may reduce his haemoglobin to 60 per cent. and subsequently repair the anaemia without administration of iron so it may be taken that the available iron stores are equivalent to about half the haemoglobin-iron or 1.15 g. Thirdly a small amount exists in the tissues in an unavailable form."

"Overt blood loss will rapidly lead to a state of iron deficiency. It is recognised that an adult may lose about half his total blood volume and yet mend the consequent anaemia completely without the administration of iron but this may only happen once, for the repair of the anaemia will have exhausted the whole of the available iron store in the body and thereafter every milligramme of haemoglobin lost is haemoglobin which cannot be replaced until the patient be given more iron. Once the iron reserve has been depleted in this way anaemia will develop rapidly from

what may seem trivial loss of blood and will persist after the haemorrhage has stopped because the raw material for manufacture of haemoglobin is lacking

CASILLLO ODENA (Isidro) Papel que desempeña la escuela en la profilaxis de la anquilostomiasis en la República Argentina [Schools in the Prevention of Ankylostomiasis in the Argentine]—*Bol Sanitario* Buenos Aires 1938. Feb Vol. 2. No 2. pp 136-144 With 2 graphs

The fourth South American Conference on Hygiene Microbiology and Pathological Anatomy held in 1928 urged the importance in any antihookworm campaign of treating children while attending school.

In 1935 1936 and 1937 treatment was given to children in 269 296 and 356 schools respectively. In all 30 708 treatments of which 27 073 were first ones. Of 13 622 children who went barefoot the percentage of detected infection (the technique seems nowhere to be stated) was 49.6 of 12,254 whose homes were without latrines it was 59.4. Tallquist and faecal examinations were made in about 10 per cent of those reported on. The toxicity of anthelmintics and the value of iron are noted

AKETAGAWA (Hiroshi) Some Experimental Contributions on Oral and Cutaneous Infection of Hookworms.—*Japanese Jl Experim Med* 1938. June 20 Vol. 16 No 2 pp 85-107 With 5 charts & 6 figs. on 1 plate [11 refs.]

It is concluded that infective canine hookworm larvae when swallowed penetrate the wall of the alimentary canal and do not remain in its lumen.

A casual reference found in the paper shows that the author was dealing with the infective larvae of *Ancylostoma caninum*. From 72 to 96 hours after an infective feed there were collected from the bodies of pups about half the number of larvae which the feed had contained but if examination were delayed for 10 days 98 per cent. of these larvae were accounted for. In adolescent dogs the position was reversed—40 per cent being collected at the earlier and 32 at the later time. In old dogs this change was exaggerated, 24 per cent after 72 hours and 3.7 later. In a pregnant bitch the young were infected nearly all larvae being in their lungs, the quantity being described as up to nearly 30 per cent. of the number of larvae found in the mother's intestine.

C L

V BRAND (Th) & OTTO (G F) Some Aspects of the Carbohydrate Metabolism of the Hookworm, *Ancylostoma caninum* and its Host.—*Amer Jl Hyg* 1938 May Vol 27 No 3 pp 683-699 [18 refs.]

The total glycogen found in the dog hookworm (*A. caninum*) during these studies was much less than that so far reported for other intestinal helminths. Furthermore the total glycogen content of the worms was unchanged by short periods of starvation or alimentary hyperglycemia of the host. These facts may be related to the extraordinary blood-sucking habits of these worms which conceivably permits an oxidative type of metabolism and further insures a more or less continuous food supply

without the necessity of storing nutrient material. The severe but sub-lethal hookworm infections of a month's duration had no apparent effect upon the carbohydrate metabolism of the host. C. L.

- i. KHALIL (M.) The Site of the Adult Filaria in the Human Body is the Determining Factor in the Microfilaria being Periodic or Non-Periodic even in the Same Species.—*Jl Egyptian Med Assoc* 1938. Aug Vol. 21 No. 8. pp 502-505

- iii. — Thermotropism in Filariasis the Basis of the Clinical and Pathological Manifestations and the Rational Methods of Treatment.—*Ibid* pp 597-602

i. The title shows the scope of the paper. It refers to *Wuchereria bancrofti*

In the South Pacific Islands the intermediate host is *Aedes* a day biter mostly of the upper extremities, the adults grow up in the corresponding lymph vessels, their microfilariae pour directly into the veins of the neck or the terminal portion of the thoracic duct and they show no periodicity in the blood. Elsewhere the intermediate host is *Culex* which bites the lower limbs, especially in the evening before bedtime the adults grow up in the corresponding lymphatics and their young pass into the thoracic duct. The author adds that the adult *Wuchereria bancrofti* generally inhabits the lower parts of the body in most countries but in the South Pacific Islands a third to three-quarters of the worms inhabit the upper extremities. This is borne out by the fact that in Fiji Manson Bahr extracted adult worms from six cases, of whom three had worms in the upper limb. A second factor in causing periodicity is the lymph flow—in this way. In the daytime man's position is mainly upright and gravity keeps in the lower part of the thoracic duct and in its tributaries the microfilariae from the lower limbs when he lies down at night this attitude coupled with the maximum flow of chyle which it is said takes place 12 to 13 hours after a meal, is held to bring them into the blood about midnight.

[This note seems hasty for 17 per cent of it has been rewritten as corrigendum. Doubtless in the more extensive paper promised controls will be published and the results of infections of the male genitalia considered, for in both types of infection the lymphatics from these open into the thoracic duct. The statement regarding Bahr's work (1912) (*Jl London School Trop Med* 1911-12, Vol. 1 Supp. No. 1) is incomplete and refers to his Appendix V only for his Appendix XXIV shows that he found dead or living adult worms in all of six enlarged epitrochlear glands and in ten of eleven enlarged groin glands it being said of the eleventh the gland had been preserved in formalin thus making dissection a difficult task. In these non-periodic cases, then, the habitats of adult worms showed no perceptible discrimination in favour of the arm. Buxton's work (1928) [this *Bulletin* 1929 Vol. 23 p. 436] in the South Pacific is apposite for it covered both types of infection symptoms referable to worm infections of the male genitalia were noted in 40 per cent. of 1103 persons examined in Samoa where infection is non-periodic and in 30 per cent. of 318 persons in the New Hebrides, where it is periodic (Table 23). As to enlarged lymph nodes, to whose relationship with

the presence of worms BARR a quoted work testifies BUXTON in the cited table reported for the non periodic Samoan infection enlarged inguinal nodes in 45.8 per cent and enlarged epitrochlear nodes in 47.6 per cent while the corresponding figures for the periodic New Hebrides infection were 26.1 and 17.3 The locality of enlarged and presumably infected nodes had then no obvious relationship to the type of infection.]

ii Such a migration from the capillaries into the lymphatics was proved by experiment in [the sheathless] *Microfilaria immitis* of dog (Augustine and Drinker 1935)

This paper corrects two statements made in the earlier papers of his series. The first is a further addition to the long corrigendum in (i) as to the flow of chyle after food

In consulting the original paper of Munk and Rosenstein I found that this figure refers to the flow in 12 hours after food

It was mentioned in the last paragraph in the article referred to that all microfilariae in man live for a few hours while it is meant "a few days" [The original corrigendum had altered this to "for a limited time."] Then there is the *ex cathedra* statement regarding migration from blood capillaries into the lymphatics

In these repeated journeys through the lymphatic system the microfilariae pass into the blood circulation at a time determined by the lymph flow and posture in man. On the whole this tends to accoustuate nocturnal periodicity as the thoracic duct drains the major part of the body

iii. A series of statements held to support the hypothesis found in the title

ROSSI reports that from excised tissue containing adult *Wuchereria* the worms come out into warm saline if the lymphatics are patent. The spermatic cord region is the warmest in the body its lymphatics are the first in which valves lose their functions so there is direct communication between them and the pelvic and abdominal lymphatics and the worms migrate back and forth between them and the genitalia while most patients suffer no symptoms. But if too many worms get into and partly block a vessel it dilates into a lymphatic cyst this bursts or leaks internally and causes filarial lymphangitis and is the basis of the allergic filarial skin reaction. This explains all the known facts of Filariasis namely the common occurrence of *W. bancrofti* in the lymphatics of the spermatic cord and epididymis an absolute relief from periodic lymphangitis and elephantoid fever by removal to a cold climate the periodicity of the lymphangitic attacks seeing that the hole in the lymphatic closes and the cycle is repeated again at practically equal intervals and the attacks have a severity proportionate to the amount of fluid which escapes. A cold application chases the worms away if the passage for escape is clear if not it depresses their fecundity

Filarial lymphangitis, elephantoid fever Calabar swellings, the various skin manifestations in *Oncocerciasis* and *A. persians* infection are different grades of the same phenomenon. Bacteria may come in as a secondary infection or they may precipitate an attack by providing a focus of a high temperature attracting the adult filariae to it. The reported value of vaccine therapy is understood not as due to a specific *Streptococcus* but any kind of vaccine will have a similar effect. Adrenaline will be useful.

[The promised definitive report will presumably aim at justifying these *ex cathedra* statements]

GALLIARD (Henri) L'auto-infestation au cours de la strongyloïdose humaine. [Autoinfestation by Strongyloides in Man.]—C. R. Soc Biol. 1938. Vol. 128. No. 20 pp 572-574

The conclusion that autoinfestation by Strongyloides is common is a hasty one and the statement that any delay of over a few hours during passage through the intestine implies formation of infective larvae is contrary to fact.

Three fatal cases of infection are noted. Of one it is merely said that filariform larvae were present in large numbers in fresh stools so that if they had been present in the intestine, they could have pierced the wall. In a second, who was in a state of extreme cachexia earlier at autopsy the interval between which and death is unstated, there were females and eggs in the lumen of the glandular crypts of the mucosa with no sign of penetration in numerous ulcers, and a very few degenerate filariform larvae. In a third there were no Strongyloides larvae but many rhabditiform ones on the surface of epithelium and of an ulcer but these seemed to have no tendency to penetrate. Cachexia and approaching death will favour formation of filariform larvae.

RAMOS E SILVA (J.) Sobre o tratamento da larva migrans. [The Treatment of Larva Migrans.]—Hospital 1938. Sept. Vol. 14 No 3 pp 465-468. With 1 fig

For creeping eruption the local treatment advised is an anthelmintic dressing consisting of oil of chenopodium 50 drops, essence of winter green 5 grams, gomenol 10 per cent. [? in olive oil] 50 grams. It soothes the irritation, quiets secondary inflammation and immobilizes the larva. The objection to freezing is that the larva may be beyond the viable tunnel. The other treatments and the kind of larva which may cause the lesion are noted.

JONES (Myrna) The Diagnosis of Pinworm Infestation.—Rev Med Trop y Parasit Habana. 1938 May-June. Vol 4 No 3 pp 147-149

The Cellophane NIH swab [see HALL, this Bulletin 1937 Vol 34 p 878] is described and considered by a member of the U.S. Public Health Service. The following are clear instructions for its use — The cellophane covered tip of the glass rod is used much as a cotton swab might be used, with outward strokes along the anal folds and about the anus. The folded edges of the cellophane pick up sticky debris and eggs, or even worms when present. The swab is not inserted into the rectum. A considerable surface should be covered since the worms may migrate some distance before eggs are deposited. The cellophane may be removed from the swab and examined microscopically immediately after use or several days later with equally good results.

REARDON (Lucy) Studies on Oxyurias. X. Artifacts in "Cellophane simulating Pinworm Ova."—Am J Trop Med 1938. July Vol. 18. No. 4 pp 427-431 With 2 plates.

Artifacts which simulate ova of Enterobius are frequently found in the Cellophane of the NIH swab described by Hall (1937) [see this Bulletin

1937 Vol 34 p 878) used in diagnosis of pinworm infection. Attention is called to these artifacts in order to avoid possible confusion of them with pinworm ova. These artifacts are not superficial but are imbedded in the cellulose film and cannot be dislodged by surface scratching. They consist of a definite hyaline outline usually ovoid sometimes rounded enveloping a dark, amorphous mass, the whole structure markedly similar to a pinworm egg. The hyaline outline which appears to be composed of several layers, resembles the transparent shell layers of the egg of *Enterobius*. The central mass is irregular brownish or greenish with usually a clear space between it and the hyaline outline. Size variation is great but usually falls within the range of the pinworm egg so that size and appearance constitute a potential source of error in diagnosis of oxyuriasis.

REARDON (Lucy) Studies on Oxyuriasis. XVI. The Number of Eggs produced by the Pinworm, *Enterobius vermicularis* and its Bearing on Infection.—*Public Health Rep* 1938 June 17 Vol 53 No 24 pp 978-984 With 2 figs. [14 refs.]

Counts made by rather precise techniques, of the eggs present in 20 gravid females of *Enterobius vermicularis* show from 4,672 to 16,888 eggs per worm. The arithmetical mean is 11,105 and the mean of the extremes is 10,780. These figures in connection with studies on the recovery of pinworm eggs from households, afford some explanation of the familial nature of oxyuriasis, and the status of pinworms as the most common of all the pathogenic worm parasites of man.

C L

MARSHALL (George R.) & WOOD (Q. L.) Ischioanal Abscess caused by *Oxyuris vermicularis*.—*Northwest Med* 1938 June Vol. 37 No 6 pp 180-182. With 2 figs. [18 refs.]

A boy kicked in the anal region developed a right ischioanal abscess which burst externally closed had to be reopened and which it was later discovered, was also in communication with the rectum. On reopening it was found to contain many threadworms and their ova [That the threadworms may well have got into the abscess through the opening (at first undetected) by which it burst into the rectum and were not the cause of the abscess is not considered.]

C L

WRIGHT (Willard H.) & BRADY (Frederic J.) The Treatment of Oxyuriasis.—*Rev Med Trop y Parasit* Habana, 1938 May-June. Vol. 4 No 3 pp 151-153

As controlled by the NIH swab gentian violet is apparently highly efficient in treating threadworms and it has many advantages.

Of 163 patients completely treated over 90 per cent. have become negative. The course advised is two periods of eight days with an interval of seven days. The dose for adults is two enteric-coated tablets [this term is not explained] each containing half a grain of gentian violet given three times a day before meals for those under 15 years it is 1 centigramme a day for each year of apparent age. Of the patients 103 showed no reaction there was nausea in 24 vomiting in 23 diarrhoea in 17 griping in 15 constipation or dizziness each in 2 headache in 1. The course is relatively cheap and is easy to give an important point when many in a household have to receive treatment.

C L

MOREAU (P) Valeur des pulvérisations insecticides dans la lutte antimalarienne. [Value of Insecticidal Sprays as an Anti-Malarial Measure.]—*Rev Méd Française d'Extrême-Orient* 1938 Mar Vol. 16 No 3 pp 264-274. With 2 figs.

The author gives a résumé of recent work on insecticidal sprays for the destruction of adult anophelines in dwellings and pays special attention to the work of Park Rosa [this *Bulletin* 1937 Vol. 34 pp 59-60] in Natal, which he visited. He describes experiments carried out in the laboratory and in the suburbs of Hué Annam. As there are local grave disadvantages in the use of an inflammable solvent for pyrethrum preparations the author made use of a watery emulsion of pyrethrins prepared by a French firm. It is put up as a concentrated extract in tins its pyrethrin content is 5.5 per cent. Diluted with water it forms a stable, homogeneous suspension that is easy to spray. As pointed out by SHERROD and WATTS [this *Bulletin* 1936 Vol. 33 p. 255] better results are obtained with high temperature and low humidity. A daily spraying, about 5 p.m. with a 1 per cent. dilution of the concentrated product enabled one to pass the night, after the second day in a treated house without being bitten. Whereas before treatment two persons were able to catch upwards of 100 mosquitoes in this house, in an hour daily attempts at catching mosquitoes after the third day of treatment were invariably negative. The native house in question had the door and its three windows open the greater part of the day and there was an air space between walls and roof. In spite of these conditions one litre of the diluted insecticide for each 200 cubic metres of space was sufficient to secure the absence of mosquitoes for 24 hours.

The spraying apparatus used was Geneste and Herscher's disinfectant spray such as is used in large hospitals for formalin spraying etc. The container holds ten litres. The jet is powerful and diffusion perfect.

The author concludes that such a method should be used if and when it is necessary to break temporary contact between a community and a hyperinfecting domestic anopheline fauna. Thus it could be used to cut short a localized epidemic or to protect a camp in an epidemic area. It does not replace, but is a valuable addition to classic methods of prophylaxis.

N W

WASSILIEFF (A.) La lutte antilarvaire, en Tunisie, doit-elle être saisonnière ou continue? [Ought Antilarval Measures in Tunis to be Seasonal or Continuous?]—*Arch. Inst. Pasteur de Tunis* 1938. Mar Vol. 27 No 1 pp 31-41

In Tunis *Anopheles* breed the whole year through. Anti-larval measures must therefore be carried on without intermission but the nature of these measures should be modified from time to time as determined by biological observations carried out in each locality. For example, floods following heavy rains clear the ovals or water courses of larvae. These larvae may be carried far afield to where temporary breeding places are formed in ditches, ravines or any low-lying ground. These temporary breeding places then call for the attention that was previously given to the water-course. Photographs taken from an aeroplane have been of value by indicating all collections of water left by floods that need attention. There are

also permanent breeding places especially in the oases. Here antilarval measures if persistently carried out should be most successful the breeding places in many cases are not numerous and the nearest outside breeding places may be tens or hundreds of kilometres away *Gambusia* have been of the greatest value To obtain the best results with *Gambusia* it is necessary to keep the water free from too dense an algal growth and to remove other obstacles such as dead rushes which may prevent the fish from obtaining access to larvae During floods when no larvae are found in water-courses adult anophelines may be found in unusual numbers in houses bordering the streams An attack on adult *Anopheles* in these conditions may be productive of good as indeed at other times

COLLIGNON (E) Une grande mesure antilarvaire l'assèchement du lac Halloula. [A Major Antilarval Work the Draining of Lake Halloula.]—*Arch Inst Pasteur d'Algérie* 1938 June Vol. 16 No 2 pp 166-175 With 4 figs. on 2 plates & 2 text figs

Sixty two kilometres west of Algiers is a small village Montebello three kilometres from the sea from which it is separated by a range of hills Montebello has a population of 169 and has had an unenviable reputation for malaria Lake Halloula close to the village afforded plentiful and inaccessible breeding grounds for anophelines The lake has been drained by means of a tunnel through the hills with the result that the spleen index which was 60 in 1932 had been reduced to 7 in the corresponding period of 1937 The canal began to function in the spring of 1935 During the progress of the work large labour forces caused a temporary increased prevalence of the disease

N IV

DEBUSK (C K.) Water Conservation a New Problem in Malarial Control—*Texas State Jt of Med* 1938 Apr Vol. 33 No 12, pp 826-828. [Summary taken from *Public Health Engineering Abstr* Washington 1938 Nov 5 Vol. 18 Signed Fred G KALLMEYER.]

Pioneers in Texas through necessity conserved water in rain barrels for themselves and in stagnant ponds for their live stock and thus created additional breeding places for mosquito millions.

There is a justifiable apprehension on the part of some that this is about to be repeated on a large scale due to the great water conservation program throughout Texas Projects under construction and contemplated will create about thirty-five major reservoirs with possibly thousands on the tributary streams. Backing the water up and spreading it out into the lowlands along the river valleys may lead to an acute problem in the matter of malaria control threatening to destroy the results of so much time and energy which have been devoted to the task of eliminating mosquitoes and their breeding places. Improper impoundment of water has been known to bring a return of malaria to sections that for years have been free of the disease.

There is a serious need for the conservation of water for beneficial uses including irrigation and to protect the health of the people by

preventing through proper conservation methods the pollution of these waters to an extent that will render them unfit for human use. The conservation of surface waters is of extreme importance also from the standpoint of the underground supply. In all sections of our State there has been a serious recession of the water level and in many sections of the State it has fallen as much as 150 feet.

If the necessary antimalarial measures are taken, there should be no danger of increasing the extent of malaria or introducing it into new areas. Dams should have gates and flash boards to permit lowering of water levels at the proper time. The basin should be cleared of all trees and brush should be piled and burned to prevent the storage of trees and brush should be cut back a sufficient distance from the high water contour to permit inspection and to prevent these growths along the shallow water edges from holding storage. It is recommended that the water level be maintained at this maximum elevation during the winter and early spring in order that the edges of the reservoirs may be flooded to prevent the early growth of land vegetation. Then later on in the summer the water level should be lowered quickly to strand storage and larvae in the shallow areas and wave action in the deeper portions of the lake should prevent anopheline breeding. Larvicides of various chemical content, oil, kerosene or other sprays can be used in special locations. *Gambusia* commonly known as *top minnows* are very helpful.

In East Texas the contemplated region-wide program will eliminate a large portion of the swamp areas where water now stands for long periods and creates ideal mosquito-breeding conditions. It is intended to make mosquito control an integral part of the Sabine Naches conservation district program and to embody preventive measures in the plans, construction and maintenance of the project.

(Discussion Dr. Henry Tucker) I am very hopeful that a plan of impounding the spring floods in large reservoirs of rippling sun-reached water whose level can be controlled and where it can be released through proper channels to prevent the accumulation of dead and stagnant surface and back water will produce a permanent condition similar to that which now exists only in the driest months, and prove to be a big forward step in malaria control in East Texas.

HENMAN (E. Harold) Biological Effects of Fluctuation of Water Level on Anopheline Breeding.—*Am. J. Trop. Med.* 1938. Sept. Vol 18. No. 5 pp 483-495 With 5 figs & 2 graphs.

In reservoirs in Alabama *Anopheles quadrimaculatus* breeds in great numbers if there is much dead floating material or much growth of vegetation in the shallow water round the edge. If the level of the water is caused to fluctuate once a week much of the vegetation is killed, and some of the floating material is stranded, so that the shore line becomes nearly clean and breeding places are much reduced. The intention is mainly to render much breeding of *Anopheles* impossible. It is not claimed that if breeding is going on many of the larvae can be killed. Artificial raising and lowering of water level should, therefore, be undertaken in spring before the insects multiply.

It seems that no catching stations were in use and no measure is given of the reduction in mosquitoes which resulted from what was done.

P. A. Buxton

EJERCITO (Antonio) Biological Control of *Anopheles funestus minimus* Subgroup breeding in the Philippines, I. A Critical Study on Biological Control of *A. minimus* var *flavirostris* as an Anti-Malaria Measure at the Hacienda Tala, San Jose del Monte, Bulacan.—*Jl Philippine Islands Med Assoc* 1938 July Vol 18 No 7 pp 415-435 With 1 map & 1 folding graph

This is an account of the control measures undertaken in a hacienda in which extensive breeding of *A. flavirostris* in numerous streams was responsible for high malaria incidence among a floating population. The biological control measures consisted of clearing or sun exposure of breeding places, construction of a series of dams to cause stagnation of the water, sloping of stream banks with straightening of edges at water level and channelling. The work was begun in January 1935 and continued to the end of 1936 when the Hacienda Tala had to cease operations owing to lack of financial support. In the meantime there was decreased anopheline breeding, decreased adult anopheline prevalence and decreased malaria incidence results which the author attributes to the measures undertaken, incomplete though they were. He endeavours to justify this conclusion at very great length. N W

TILLI (Pietro) Le moderne tecniche agricole impongono l'estensione della disanofelizzazione con calciocianamido [Use of Calcium Cyanamide to combat Anophellinae].—*Riv di Malarologia* Sez I 1938 Vol 17 No 3 pp 225-230 With 3 figs French summary (8 lines)

This is a discussion of an American agricultural method of treating arid soils by the construction of barrage-reservoirs. Deep parallel trenches are dug to capture and retain the rain. In malarial countries this may provide facilities for anopheline breeding. To combat this danger the author advocates the use of calcium cyanamide, a powerful larvicide and a useful fertilizer. N W

AMBIALET (R.) Sur un essai de destruction de gîtes à larves d'anophèles par la méthode de Williamson (herbage cover) [Attempted Destruction of Anopheles Breeding by Herbage Cover].—*Arch Inst Pasteur d'Algérie* 1938 June Vol 16 No 2 pp 161-165 With 2 figs. on 1 plate

This is a description of an attempt at eliminating the breeding of *A. maculipennis* in a water-course close to a village in the Department of Constantine, Algeria, by WILLIAMSON'S Herbage Cover Method [this *Bulletin* 1935 Vol 32 pp 429-430]. In this village the malaria season is from June to November at which period the water-course is a streamlet linking up a series of pools. At the end of April two kilometres of this water-course were treated as recommended by Williamson. The author's experience indicates that the method does not lend itself to a wide application in Algeria. There was certainly a disappearance of anopheline breeding coinciding with the period of fermentation of the herbage cover, this was of limited duration, however, less than two months. Subsequently there was a recrudescence of anopheline breeding. The disadvantages, a nauseating stench and an abundance of culicines, are certainly not negligible for dwellers in the vicinity. N W

BLACKLOCK (D B) A Device for applying Oil or Other Liquids to Flushing Cisterns.—*Amer. Trop. Med. & Parasit.* 1938, Aug. 2, Vol. 32, No. 2 pp 109-114 With 3 figs. [Summary appears also in *Bulletin of Hygiene*]

Although the introduction of piped water supplies and water carriage sewerage in the tropics offers a most important means of eliminating various diseases which depend upon human excreta for their propagation it is attended with the risk of mosquito breeding in the flushing cisterns for water closets, urinals and slop sinks. This paper describes various attempts which have been made to mosquito-proof these water cisterns and describes what is claimed to be a very effective device for discharging the necessary quantity of an oil on to the surface of the water in the cistern as soon as the "flush" of the cistern has taken place. The oil used consists of 88 parts of fuel oil, 10 parts of kerosene and 2 parts of castor oil and the charge amounts to 15 drops of this mixture at each pull of the chain.

The apparatus has been tested with anopheline and culicine larvae and has proved effective in killing them. *H T Calvert*

ROY (D N) A Note on Shute's Technique of enumerating Sporozoites in an Emulsion of Salivary Glands.—*Jl Malaria Inst of India.* 1938 Sept. Vol 1 No 3 pp. 335-337

The author's experience with Shute's method of counting sporozoites in emulsions of salivary glands has not been satisfactory. Having determined the sporozoite content of the emulsion by counting in a Thomas Zeiss counting chamber dilutions were made with sterile salt solution. The number of sporozoites in the dilutions bore no proportionate relationship to each other nor to the sporozoite content of the original emulsion. Similar discordant results were obtained with sporozoites killed with formalin made up to a 1 per cent formalin emulsion and diluted to various strengths. The author's explanation of these results is that the sporozoites have a tendency to adhere to the inner surface of the glass utensil used. The result is that an emulsion leaving a syringe may contain a considerably smaller number of sporozoites than the estimated dose. *N W*

HAWITT (Redginal) The Cultivation of *Plasmodium calhamerium* for One Asexual Generation on Inactivated Egg and Rabbit Serum.—*Amer Jl Hyg* 1938 Mar Vol 27 No. 2 pp 341-344

The author has introduced into a medium consisting of inactivated whole egg slants covered with 10 cc. of 0.9 per cent. saline containing 0.5 per cent. dextrose and serum of a bird or rabbit, blood from a bird with a heavy infection of *Plasmodium calhamerium* and has noted that if incubated at 37°C. the young intracorpuseular parasites grow into fully formed schizonts, though less rapidly than they do in the blood of control birds. The merozoites formed do not appear to leave the host cells in the culture tubes. *C M Weyon.*

HERMAN (Carlton M) Mosquito Transmission of Avian Malaria Parasites (*Plasmodium circumflexum* and *P. cathemerium*)—*Amer Jl Hyg* 1938 Mar Vol. 27 No 2 pp 345-350

The author has tested the transmitting powers of a number of mosquitoes (*Culex pipiens* *C. apicalis* *Aedes sollicitans* *A. canadensis* *A. cantator* *A. vexans* and *Theobaldia melanocera*) with *Plasmodium circumflexum* and *P. cathemerium* of birds. Of the mosquitoes the last named successfully transmitted *P. circumflexum* while *P. cathemerium* was transmitted by *C. pipiens* and *A. sollicitans*. From the differences in susceptibility of *A. sollicitans* to different races of *P. cathemerium* it seems that one or more varieties may be included under the one name. C M W

KIKUTH (Walter) & MUDROW (Lilli) Die endothelialen Stadien der Malaria-parasiten in Experiment und Theorie [The Endothelial Phases of Malarial Parasites in Experiment and Theory]—*Zent f Bakl* I Abt. Orig 1938, Aug 18 Vol. 142, No 3/4 pp 113-132. With 15 coloured figs. on 2 plates. [36 refs.]

The authors results deal mostly with *P. cathemerium* infections in canaries as well as with other bird plasmodia. Following sporozoite infection of these birds unpigmented forms (E forms) were found in the endothelium of inner organs and in brain capillaries and their numbers increased with increase of parasites in the blood. These E forms could be transmitted to fresh birds by inoculation with suitable blood or organ emulsions. The liver and brain were found to be richest in E forms but a positive result did not depend on the tissue used (brain lung liver spleen). More positive finds were made the later up to a point the inoculation from previously infected birds was made except where the canary was killed immediately following sporozoite inoculation and its blood used. The mortality amongst the birds was greater and the duration of infection longer in the presence of E forms. As the blood infection dies out the E forms become fewer and may appear in fresh birds inoculated with material negative as regards such forms. The question whether erythrocytic forms can give rise to E forms or whether a chance E form gradually acquires greater virulence has to be considered.

The presence of E forms with one or more nuclei following inoculation of canaries with different strains and types of bird plasmodia was substantiated including those of *Pr. praecox* (*P. relictum*) strains isolated from a crow greenfinch and magpie. These pigmented forms were similar to those of *P. cathemerium* and were present in the same types of cell, being however less numerous and present over a shorter period of time. The *Pr. praecox* strain from a crow could not be passaged in canaries while a circumflex strain isolated by the first author and passaged by blood inoculation failed to give rise to E forms.

Canaries inoculated with *P. cathemerium* sporozoites and killed at definite intervals showed single or multiple nucleated E forms earliest at the site of injection and similar E forms in the liver and in monocytes of lung while pigmented forms were still absent from the blood. Similar findings were made in canaries treated by suitable antimalarial compounds to delay blood infection. Later the brain contained more E forms in its capillaries than the liver and this is

true of *P. gallinaceum* from the start. The unpigmented forms in large monocytes or macrophages of the lung did not suggest degeneration, and often several occurred in the same cell with, in cases, another parasite. The host cell and nucleus were at times enlarged.

The fact that all over the world unpigmented forms were noted accompanying different types of plasmodial infection suggests that these E forms did not arise from a mixed infection. While these forms in the different cases are morphologically similar they differ in time and duration of appearance as well as in cell habitat and in numbers present. The forms are absent in healthy birds and there is no support for the view that a virus infection may play a part. Controlled infection by insect vectors led to the same view.

The author is of the opinion that these E forms play a definite rôle in the malaria cycle. The view that they belong to the toxoplasma group is refuted, since the latter group is not specific as regards the host whereas E forms are host-specific. Moreover no toxoplasma forms were found in malaria vectors and further their appearance is different from that of E-forms.

The literature is reviewed regarding the early developmental cycle of bird plasmodia and it is noted that early descriptions of pigment free forms agree with those of the present E-forms whose nature, habitat and persistence in different plasmodial infections is recorded. Pigment-free forms have been described as occurring in monkey and human malaria, and those of the latter resemble the forms which are found in bird malaria. The embryology of the various parasites is discussed and also the question of relapse in malaria in relation to E-forms. It is not yet certain whether erythrocytic forms can return to endothelial cells.

HEGWER (Robert) & ESKRIDGE (Lydia) Susceptibility of Young Red Cells to the Merozoites of Avian Plasmodia.—*Amer. J. Hyg.* 1938 Mar Vol. 27 No. 2 pp. 471-492. With 10 coloured figs on 1 plate. [38 refs.]

In the study of bird malaria very little attention appears to have been paid to the age of the red cells into which the merozoites penetrate. The author has studied infections of *Plasmodium relictum*, *P. circumflexum* and *P. elongatum* from this point of view in canaries, pigeons and chickens and in a wild red-winged blackbird. As regards age the red corpuscles of the bird are divided into five categories recognizable from the character and shape of the cytoplasm and the nucleus. It is found that in over 90 per cent. of cases the merozoites enter the young cells of the second or third category. The five categories of cells, infected and uninfected, are illustrated in a coloured plate.

YOUNG (Martin D.) Comparative Pathology of Infections of *Plasmodium rouxi* in Canaries with Other Malarías of Birds, Monkeys, and Man.—*Amer. J. Trop. Med.* 1938 Jan. Vol. 18 No. 1 pp. 85-99 [12 refs.]

The pathological changes produced in canaries by the mild *Plasmodium rouxi* infections have been compared with those following

the more severe *P. cathemerium* infections in those birds. The severe infection produces a more rapid response on the part of the spleen, liver and bone marrow. Thus there is in the spleen in the case of the severe infection a rapid activation of the lymphoid follicles and lymphocytes and an increase in the mononuclear cells of the red pulp whereas in *P. rouxi* infection the activation is limited to the mononuclear cells of the red pulp. Similarly there was less immediate activation of the bone marrow and liver in the case of the mild infection. In consequence of the milder response the organs in the case of *P. rouxi* infections remained in a state of hyperplasia for longer periods after the crisis an indication of the less intense immunity response which was reflected in the inefficient resistance to superinfections. The pathological changes brought about by malarial infections in monkeys and man correspond more closely with those in canaries infected with *P. cathemerium*. It appears that the resistance to superinfection is correlated with the degree of phagocytosis carried out by the macrophages during the acute phases of infection. Where there is a very acute infection there is much phagocytosis and a resulting well developed immunity to superinfection. C M W

JAMES (S P) & TATE (P) Exo-Erythrocytic Schizogony in *Plasmodium gallinaceum* Brumpt, 1935 — *Parasitology* 1938 Jan Vol. 30 No 1 pp 128-139 With 18 figs. on 2 plates [24 refs]

In this paper the authors describe observations they have carried out on the endothelial schizogony or what they suggest calling it the exo-erythrocytic schizogony of *Plasmodium gallinaceum* of fowls. They have noted that these schizonts are not discoverable in the young chicks infected by mosquito inoculations till intra-erythrocytic forms are present in the blood. They first make their appearance in the brain and then extend to other organs the spleen being next in importance to the brain in the number of exo-erythrocytic schizonts it contains. The schizonts appear not only after infection by sporozoites but also after blood inoculations. Observers who have found similar forms in birds infected with *P. relictum* have noted that as far as present observations go they occur only after infections due to inoculation of sporozoites. The close resemblance of the exo-erythrocytic schizonts of species of *Plasmodium* to those of species of *Haemoproteus* is emphasized. The size of the schizonts varies considerably and in consequence the number of merozoites produced, thirty to fifty five or more. During growth of the schizont division into a number of cytomeres occurs the merozoites being formed from the surface of the cytomeres. It is noted that there are two types of schizont the one staining deeply and possessing little chromatin and the other staining a pale blue with Giemsa and having much chromatin. The number of exo-erythrocytic schizonts in the capillaries of the brain may be so great that the fowls die with symptoms of general paralysis. This may also occur in birds which appear to have been cured of the peripheral infection by quinine treatment.

The paper is illustrated by two excellent plates while the records of other workers are discussed in the light of the authors own observations. C M W

CHROME (V) Modification quantitative des protéides sériques au cours de l'infection due au *Plasmodium gallinaceum* chez les poules. [Quantitative Change in Proteids in *P. gallinaceum* Infection of Fowls.]—*C. R. Soc. Biol.* 1938. Vol. 127 No 5 pp 391-393

During the course of *Plasmodium gallinaceum* infections in fowls the blood shows a progressive increase in total proteins (10 to 40 per cent.) which is due chiefly to an increase in the globulins though the albumin is also increased in amount. Sometimes the albumin is slightly decreased during the acute phase of the infection. C M H

CHRISTOPHERS (S. Rickard) & FULTON (J. D.) Observations on the Course of *Plasmodium knowlesi* Infection in Monkeys (*Macacus rhesus*) with Notes on its Treatment by (1) Atabrin and (2) 1-11 Normal Undecano Diamidine, together with a Note on the Action of the Latter on Bird Malaria.—*Ann. Trop. Med. & Parasit.* 1938 Oct. 12 Vol 32. No 3 pp 257-278. [10 refs.]

The authors have recorded a number of observations of interest and practical importance made on 150 monkeys infected with *P. knowlesi* during routine laboratory procedure in maintaining the strain and providing material for experiment. The fatal character of the disease has not altered during six years continuous transmission by blood inoculation. The course of the disease in *Macacus rhesus* monkeys is one with a primary attack of great intensity invariably fatal if not treated, followed in those treated, by relapse-like attacks which may also prove fatal, a state of chronic infection, and a period when parasites are still present in the blood, as well as a further period in which although clinically recovered the animal can still be shown to be infected.

Parasites appear in the blood from 2-10 days after subcutaneous inoculation. For 122 animals the average period was 5-6 days. Survival after the 6th day following appearance of parasites is rare. The average time of death from the date of inoculation was 10-8 days. The periodicity was determined as approximately 24 hours, segmentation almost invariably occurring at 12 noon. Different stages of development of the parasite may be seen microscopically with advancing infection, which takes place in step-like fashion and is generally accompanied by severe anaemia. In splenectomized animals the increase in numbers is more regular.

Gametocytes are seen in the later stages of the infection, females being more numerous than males. Out of 148 animals only 8 had haemoglobinuria generally seen late in the attack. Spontaneous disappearance of parasites may occur apart from the type of treatment a year or longer after inoculation, but evidence of infection after 533 days was also obtained. This type of infection is valuable in chemotherapeutic studies. Various criteria regarding the efficacy of a drug have been employed such as saving of life in the primary attack, disappearance of parasites and length of a parasitic interval following drug administration, as well as total period of infection and sterilization. Atabrin proved very effective in treatment but relapses were invariable, independent of time of administration and dosage and the total duration of infection was not influenced by the amount of drug given.

In testing the effect of 1:11 normal undecane diamidine it was found that the drug was active in *P. knowlesi* infections. Five out of eleven animals survived the primary attack and four were saved. Its action is slower and less certain than that of atebirin. The young forms of parasite were specially affected. Evidence of kidney and liver damage was seen in sections but no methaemoglobin was found. *In vitro* experiments showed marked inhibition of respiration. The same drug is ineffective against *P. relictum* infections of canaries.

MISCELLANEOUS.

BARDSWELL (Noel Dean) Tuberculosis in Cyprus. An Interim Report on its Incidence and Means of Control made under the Auspices of The National Association for the Prevention of Tuberculosis.—pp. vi+228. With 9 maps (2 folding) 3 graphs 34 figs. & 1 plan. 1937. London. National Association for the Prevention of Tuberculosis. [Summary appears also in *Bulletin of Hygiene*]

The purpose of the Mission to which this report refers was to determine by a survey the amount and distribution of tuberculosis in Cyprus and by this means to discover whether any sound basis exists for the statements which had been made as to the unusual prevalence of the disease among the people. The most significant result of the inquiry is that the tuberculosis problem is by no means so menacing as it was considered to be. The disease presents itself in much the same character intensity and distribution as in similar countries, perhaps even in a less degree. The problem is therefore of manageable proportions.

The author used the percutaneous test of Moro in his investigations on the rate of infection. The tuberculin ointment consisted of equal parts of old tuberculin and lanolin prepared and sent out fortnightly from Edinburgh. It was considered that the use of the intradermal test would have been unwise in view of the attitude of the Cypriot parents, nervous and apt to withdraw co-operation should any untoward happening occur which could be attributed to the test. The author claims that there is little or no difference between the sensitiveness of the von Pirquet and Moro methods. School-children were tested in this way. Of 8,084 children in villages, 6.5 per cent were found to be positive. Of 1,841 in towns, 8.2 per cent. were positive. In many villages evidence of infection could be definitely associated with a tuberculous person.

Patients who had previously been notified as suffering from tuberculosis were examined, so far as this was possible in certain towns and villages. In a population of 178,434 there were 386 cases on the live register. On investigation 91 were found to have died, the diagnosis was confirmed in 106 and was not confirmed in 18. The remainder were not seen. Twelve further cases, not notified, were found. A report by Dr BEVAN shows that of 173 notified cases in the Larnaca District, 98 were dead the diagnosis in 21 was confirmed and in 10 was not confirmed on examination and the rest were not seen. It is estimated that in this district there are about 0.8 cases of tuberculosis per 1,000 and in Larnaca town about 1.5 per 1,000.

Many of the patients presented signs of chronic pulmonary tuberculosis of the fibroid type and cases of acute disease were not common.

The living conditions of the Cypriots are poor their houses dark and ill-ventilated, but the brilliant sunshine which is experienced for the greater part of the year must play a considerable part in killing the tubercle bacilli exposed to it. Tuberculosis is therefore largely spread among intimate house contacts.

Malaria was not found to influence the incidence of tuberculosis.

The report is well illustrated with photographs. An index would be a useful addition to facilitate reference to the points made.

[It is impossible in an abstract to do justice to this report Dr Bardswell wrote in a fascinating manner and in the short time at his disposal collected a mass of information which is given in detail. The survey of primitive or semi-primitive people is not an easy matter and the arguments against using the Mantoux test are very strong but it would be unwise to compare too closely the results of the Moro test carried out with tuberculin not freshly prepared with those obtained elsewhere by the use of freshly diluted tuberculin administered by the Mantoux technique X-ray diagnosis was apparently not attempted to any extent in the investigation and physical examination was the standard test with or without sputum examination An error is made (p 75) in the reference to the work of the reviewer (*Bull of Hygiene* 1938 Vol 13 p 628) who found a morbidity rate (which he did not claim to be an exact picture of the actual position) of 11.55 per 1,000 in 9,866 Natives of Tanganyika Territory This figure is wrongly given by Bardswell as the mortality rate] C W

CUMMINS (S. L.) WILCOCKS (Charles) COCHRANE (E.) BRADFIELD (E. W. C.) BARDSWELL (N. D.) DAVIES (H. N.) COOPER (Mrs Martin) *The Control of Tuberculosis in Tropical and Sub-tropical Regions.—Trans 25th Ann Conference Nat Assoc for Prevention of Tuberculosis* 1938. pp 129-166 With 2 maps (1 folding) & 3 figs. [Summary appears also in *Bulletin of Hygiene*]

This volume gives the papers read by many speakers covering the subjects of the employment of ex-patients the boarding-out of children from tuberculous households anti tuberculosis activities in rural areas the family and tuberculosis and the mental aspects of tuberculosis The section which will most interest readers of this *Bulletin* however is that devoted to the control of tuberculosis in tropical and subtropical regions

In opening the session the Marquess of DUFFERIN and AVA remarked that an increase in tuberculosis has recently been reported in many British Colonies and that in some it is already one of the chief causes of death. Professor S. Lyle Cummins gave an account of the early investigations into the tuberculosis of native races [of which he himself is one of the pioneers] and quoted the findings of BORREL in the Senegalese troops and those made by the British in the South African Native Labour Corps in France during the war In the circumstances these Natives showed an enormous mortality 221.9 per 10,000 in the case of the South African Native Corps. In Africa the Natives appear to show a resistance to the onset of tuberculosis far more effective than the immunity they develop to the disease when once started which is of a low order Under natural conditions of village life infection very often leads to no more than a positive tuberculin reaction

Wilcocks outlined proposals similar to those detailed in this *Bulletin* 1938 Vol. 35 p 629 Cochrane gave an account of the work done in British Guiana [see also *Bull of Hygiene* 1937 Vol 12 p 739] Important measures instituted were the examination of contacts and the introduction of collapse therapy which has been applied to 42 patients with considerable success. Bradfield described the position in India where 2,000,000 persons are estimated to be suffering from tuberculosis. It is intended to allot 75 per cent of available funds to organizations primarily of a preventive character and the dispensary

is to be the pivot of the whole scheme which is now thanks to the King Emperor's Anti Tuberculosis Fund, being actively inaugurated.

Bardswell described the conditions encountered during his investigations in Cyprus. A summary of his report on that country is given above.

Davies has been actively engaged in tuberculosis work in Tanganyika Territory for 11 years. Infection and disease spread primarily in the homes of sputum positive patients. He considers that natives showing a strongly positive tuberculin test have acute foci in a lymphatic node only waiting to spread after further stimulus. It has been found that contacts showing strong reactions have gradually lost the intensity of response to tuberculin and gained in health after the removal or death of the sputum positive persons responsible for their infections.

The capacity to resist infection—that is to prevent infection from progressing to disease—depends upon the dose received, the general immunity and the removal from further massive reinfection.

Patients with advanced disease rarely live more than two years after first being diagnosed. Since 1933 pneumothorax treatment with supplementary surgical measures has been applied to 261 patients under conditions of great difficulty in hospital and dispensaries on the slopes of Kilimanjaro. A village settlement has been constructed and is now occupied. In general, Davies corroborates the findings of Wilcocks in the same Territory [*Bull. of Hygiene* 1938 Vol. 13 p. 628].

[From his knowledge of Davies's work the reviewer can confirm the success of his methods and the arduous nature of the task. The importance of this demonstration of the success of modern methods in the treatment of native tuberculosis cannot be over-emphasized. It is the largest undertaking of its kind in East Africa. See also below.]

Mrs. Martin Cooper described the anti-tuberculosis work being done in Jamaica. C IV

DAVIES (H. N.) The Work of a Tuberculosis Unit in East Africa.—*Tubercle* 1938, Nov. Vol. 20 No. 2 pp. 76-88. With 6 figs. 1 map & 1 graph. [Summary appears also in *Bulletin of Hygiene*.]

This is an account of the work done by the tuberculosis unit which includes a hospital and 10 outlying dispensaries at Kibongoto on the slopes of Kilimanjaro Tanganyika Territory and a branch hospital in the Pare mountains, under the direction of the author from 1927 onwards. Considerable numbers of patients suffering from tuberculosis had previously been reported from this part of Tanganyika Territory and it was decided that the disease was prevalent enough to warrant special measures.

Investigation was conducted by means of the Mantoux test using a dilution of 1 in 10 000, and by the examination of natives presenting themselves at the dispensaries which were gradually instituted. Special attention was paid to those with chest complaints, and a feature of the work was the examination of the family contacts of cases of tuberculosis. Thus 1 103 contacts of 81 sputum positive persons were examined in one village and 82 further cases of disease and 626 infected persons were found among them. In the same village among 680 positive tuberculin reactors 22 per cent. developed clinical disease within five years. A large percentage of bone and joint cases were found to be contacts of sputum-positive persons. Reports

from the Veterinary Department show that tuberculosis in cattle is negligible

The author repeatedly emphasizes that marked infection and tuberculous disease were found in the members of families where sputum-positive cases existed. He found that persons showing strongly positive tuberculin reactions were comparatively easily precipitated into manifest disease especially if contact was maintained but records investigations which showed that the intensity of these reactions decreased if contact was broken with a corresponding improvement in general health

At the end of 1936 almost 3 000 cases of tuberculosis had been seen by the unit and of these 2,122 were local natives [the population of the whole district was 164 119 according to the 1931 census] Pulmonary tuberculosis was present in 1 441 of which 940 were known to be sputum positive Glandular disease including bronchial adenitis was present in 498 In the classification of 1 000 pulmonary cases (according to the method of Lyle CUMINGS) 51 per cent were acute initial and 53 per cent were in an advanced state [presumably on first diagnosis]

At first only simple sanatorium treatment was given but from 1933 onwards collapse therapy was used and was aided by X-ray facilities which became available then. The X ray apparatus used was that introduced into Tanganyika by the reviewer

Artificial pneumothorax with or without additional measures was given to 219 patients, of whom 200 were followed up Phrenectomy alone was used in 31 cases and in a few others various operative measures were undertaken. In all collapse treatment was given to 261 patients, of whom 238 were traced at the end of 1937 Of these 142 were alive and 96 were working and of these 96 the periods since the commencement of treatment were as follows —

Years	-1	1	2	3	4	Total
Numbers	9	27	12	24	24	96

Comparing advanced cases treated by collapse with similar cases treated by purely medical measures the following table may be constructed of those dying within one year —

Classification	Collapse treatment		Medical treatment	
	Number	Percentage dead	Number	Percentage dead
A.3	87	34	153	92
C.3	100	27	137	73

Recently a village settlement has been started near the hospital, and five or six families live on small farms pursuing suitable handicrafts under close medical supervision. It is hoped to extend this after-care establishment

[The reviewer has some first-hand knowledge of the work of Dr Davies and the difficulties he has experienced and overcome. This work has demonstrated that collapse therapy can be used with success even in native peoples provided that those administering it are patient and enthusiastic. It should stimulate others throughout the tropics to take in hand the treatment of tuberculosis, which is too often regarded as impossible. See also COCHRANE *Bull of Hygiene* Vol. 13 p 874 and WILCOCKS *Ibid* p. 628.] C IV

SMITH (W. Harden) Pulmonary Tuberculosis in Africans.—*East African Med J* 1939 Jan. Vol. 15 No 10 pp. 318-328. [15 refs.] [Summary appears also in *Bulletin of Hygiene*]

This paper is an adequate summary of the work published on tuberculosis in African natives and American Negroes in recent years, with the author's views on method of control. Only two factors are capable of control, namely the open case and the economic conditions. Of the latter housing is the most important, and in rural communities much can be done if the intelligent co-operation of native chiefs is enlisted. In the control of sputum positive cases treatment and segregation are available and it is important that patients who develop the disease away from their own districts should be repatriated and that supervision should be attempted where they feel no sense of strangeness. The work of the tuberculosis hospital at Kibongoto Tanganyika Territory is quoted as an example of what can be done for patients near their homes.

Tuberculosis is a major problem in Africa and though no dramatic measures are possible, there are many indirect ways in which it may be reduced C IV

CARMICHAEL (J) Tuberculosis. Investigations in Uganda.—*East African Med J* 1938. Oct. Vol. 15 No 7 pp. 220-231 [15 refs.] [Summary appears also in *Bulletin of Hygiene*]

This is a report of valuable work on the typing of strains of *Mycobacterium tuberculosis* recovered from animals and man in Uganda. Tuberculosis is rare in the humped Zebu cattle so common in East Africa, and a post-mortem incidence of only 0.8 per cent was found in 33 627 carcasses inspected. Double intradermal tests on 178 gave one positive result or 0.6 per cent. On the other hand an incidence of 17 per cent was found in the carcasses of 5,908 Ankole cattle inspected. Tuberculin tests on 360 in one district showed 68 per cent. positive. Half of the lesions found are confined to the thoracic cavity. Of 31 strains of tubercle bacilli isolated from cattle all were of the typical dysgonic bovine type.

Three healthy Zebu calves were inoculated with 50 mgm (? subcutaneously) of a standard British bovine strain which normally kills in this dosage, in six weeks. The lesions found in these Zebu calves, however, were local and retrogressive with only slight tendency to generalization. This finding supports other observations on the apparent resistance of the Zebu cattle to tuberculosis.

Tuberculosis was found in 12 sheep in one of which the first recorded instance the human type was the cause of the lesions. Twelve tuberculous goats were seen all infected by the bovine type. No signs of tuberculosis were seen in the human occupants of the huts

in which three tuberculous goats were found. [But it would have been interesting to have tested their reactions to tuberculin.]

In a community in which it is the custom for man and animals to inhabit the same houses it is obviously important to know to what extent disease is transmitted. The bovine type of tubercle bacillus is fully pathogenic for man

The author has typed the organisms recovered from 247 cases of pulmonary tuberculosis in various tribes in Uganda. Four were of the bovine type and were found in tribes which live in close contact with cattle. This proportion corresponds roughly with European figures and the findings serve to demonstrate that the bovine organism plays a part in the epidemiology of tuberculosis in Uganda

[It would be instructive to know if the high rate in the Ankole cattle were reflected in a higher tuberculin rate or morbidity rate from tuberculosis among the natives owning such cattle than is found in the tribes owning Zebu cattle.] C II

KETTELKAMP (G D) MURPHY (Paul) & TRUMPE (Darrell) Results of Treatment of Tuberculosis in the Negro—*Amer Rev Tuberculosis* 1938 Oct. Vol 38 No 4 pp 458-465 [Summary appears also in *Bulletin of Hygiene*]

In recent years more and more evidence is coming to light to show that tuberculosis in the Negro is not the hopeless condition it was formerly thought to be.

The authors have compared the whites and the negroes who constituted two groups of 1 000 consecutive discharges from the Robert Koch Hospital St Louis in 1922-1926 and 1933-1937. No definite manifestations of tuberculosis peculiar to the negro were noticed, and the negroes are very amenable to sanatorium treatment. As a group the whites leave hospital in better condition than do the negroes but the disparity is not so great in the later as in the earlier group. The results in the earlier group varied with race in the later group with sex. Thus in the later 1 000 discharges the (descending) order of desirability of end results was White female negro female white male negro male. On the whole the negroes had more severe symptoms on admission than the whites.

The negroes are now exhibiting a widespread appreciation of the modern methods of combating tuberculosis and a willingness to avail themselves of all the opportunities afforded them.

[These results are of particular interest and value to workers who are introducing the modern methods of treatment into Africa. See also DAVIES above.] C IV

GIOSEFFI (M.) Malaria e tubercolosi. [Malaria and Tuberculosis.]—*Riforma Med* 1938 Oct 8 Vol 54 No 40 pp 1548-1550 [Summary appears also in *Bulletin of Hygiene*]

Three views are held regarding the interaction of malaria and tuberculosis. The first is that there is an antagonism between the two and that malaria confers immunity and aids fibrosis. The second is that malaria predisposes to and aggravates tuberculosis. The third is that malaria has no influence on tuberculosis.

During an epidemic of malaria in Istria the author had the opportunity of studying the question. He examined 1 129 persons from 170 family groups and compared his findings with those made by

LOY in 1,898 autopsies. LOY holds that malaria has a deleterious influence on tuberculosis, and the author's findings making allowance for the fact that they were in living people while LOY's were in autopsies, were not unlike the latter's.

The author finds that well treated malaria has no injurious action on chronic fibrous lesions, but that in active pulmonary tuberculosis malaria exerts a harmful effect by reducing general and local resistance. Attempts to treat tuberculosis by inducing malaria are unjustified, and energetic treatment of malaria in tuberculous persons is essential. It should not be overlooked that loss of weight, oscillations of temperature, chills and sweats are symptoms of tuberculosis, and attention should be paid to the respiratory system in the examination of patients in malarious regions especially if symptoms do not yield to anti-malarial drugs. In such areas also the blood of tuberculous persons should be watched for parasites. C IV

SAX (P. N.) The Problem of Tuberculosis in India.—*Jl Indian Med Assoc* 1938, Dec Vol. 8, No. 3 pp 160-163.

FERRER (Isabel) Treatment of Chronic Ulcers with Formalin.—*Monthly Bull Bureau of Health Manila*, 1938 Apr Vol 18, No 4 pp. 155-158.

Although many chronic ulcers respond to the classical and well tested local treatments commonly used, there are ulcers which resist. Fourteen children with chronic ulcers of one month to two years duration were treated by washing the ulcer with 10 per cent. formalin solution and scraping the necrotic tissues with a cotton ball. Excess of formalin was washed out with sterile water the wound was dried very well with plain cotton and was then liberally painted with saturated gentian violet solution. This was allowed to dry in the sun for 10 minutes and no dressing was applied but the children were prevented from playing in dusty places. In one case this treatment was repeated every other day (presumably though it is not definitely stated, it is preferable to apply it daily).

Of the 14 children four refused to continue the treatment on account of the (little) pain caused by the formalin. These were not yet cured after six months of the usual antiseptic dressings. The remaining 10 children were cured in two or three weeks under the formalin gentian violet treatment. Cost is very small and no dressings are needed. C IV

STROCCHI (Ottaviano) *Lukera tropicale. Curata con applicazioni locali di Neojodo I.C.I. in soluzione.* (*Tropical Ulcer—Local Treatment by Neojodo I.C.I.*)—*Arch. Ital. Sci Med Colon e Parasit.* 1938, Aug Vol 19 No 8 pp. 499-507

The author treats tropical phagedenic ulcer by first cleansing with hydrogen peroxide and then applying gauze saturated with a preparation of arsenobenzol and iodine, which he names "Neojodo I.C.I." This is applied in 3 per cent. solution on alternate days and skin growth is assisted by adhesive plaster (presumably covering the whole). In the later stages, when healing is evident the Neojodo I.C.I. may be used in 1 per cent. solution.

Three cases are described and healing took place in from three to four weeks the ulcers having been extensive and foul at the beginning of treatment. C IV

GOODMAN (M H) Chronic Streptococcal Ulcer of the Skin Unresponsive to Local Therapy but cured by Sulfanilamide Report of Two Cases.—*Jl Amer Med Assoc* 1938 Oct 15 Vol 111 No. 16 pp 1427-1431 With 7 figs

Though the case here described did not occur in the tropics the condition of chronic ulcer is so common there that any treatment found successful is worth noting in order that it may be given a more extensive trial

The patient gave a history of having been bitten by insects six to seven weeks before being seen by the author all the spots had healed and had caused no trouble except two one on the arm and one on the leg These became swollen red and tender and were incised in spite of the local application of antiseptics the sores did not heal but became progressively larger Among the various preparations locally applied without benefit were 3 per cent aqueous-alcoholic gentian violet 10 per cent ammoniated mercury ointment boric ointment compresses of 1:1000 bichloride of mercury solutions of potassium permanganate chloramine T and others. A β -haemolytic streptococcus was isolated. By this time the ulcer had a markedly inflamed necrosing undermined serpiginous border with an uneven glazed granular base discharging a thin yellowish serous fluid Within 48 hours of treatment by sulphanilamide being started healing set in and was uneventful. The initial doses were 60 grains daily (in three doses) reduced gradually to 15 as the healing progressed. A second case in which the chronicity and appearance led to the suspicion of the ulcers being tuberculous but from which streptococci were again isolated yielded similarly to sulphanilamide In a footnote mention is made of a third patient with five large ulcers on one leg and three on the other which had failed to respond even after several months to local treatment but cleared readily with sulphanilamide. MOVTEL (L. R.) Traitement de la dishydrose et de l'eczéma dishydrosique de Brocq (Hong Kong Foot Athletic Foot) par les dérivés sulfamidés intus et extra [Treatment of "Hongkong Foot" by Sulphamide Derivatives].—*Rev Méd Française d'Extrême Orient* 1938 Apr Vol 17 No 4 p 443

Brocq's eczema known locally in South China as Hongkong foot has been ascribed to at least found associated with *Penicillium Aspergillus* and *Trichophyton pedis* α and β [see this *Bulletin* 1931 Vol. 28 p 396] and with *Epidermophyton interdigitale* [idem 1932 Vol. 29 p 272] others maintain that it is streptococcal. The author supports this last view Lesions may extend beyond the toes and even become a generalized eczema. Preparations containing ichthyol or iodine or salicylic acid have all been reported as beneficial but their action is far from constantly so The author has found sulphonamide derivatives most successful in his cases given internally or in the form of Rubiazol injected intramuscularly or Septazine intravenously Benefit accrues also when 1 per cent. rubiazol is applied locally Apparently these are not alone sufficient for a permanent cure since the use of alcohol iodine salicylic acid is recommended to be used for a long time after cure to prevent relapse caused by the fungal or microbial parasites which infest the skin of parts previously affected. REVIEWS AND NOTICES.

FINDLAY (G. M.) (C.B.E., M.D. D.Sc. Wellcome Bureau of Scientific Research, London). *Recent Advances in Chemotherapy*. With a Foreword by C. S. Wessely C.M.G., C.B.E., M.B., B.S., F.R.S. Second Edition.—pp. x+523. With 1 chart. 1939. London J. & A. Churchill Ltd., 104 Gloucester Place Portman Square. [21s.]

The eight years which have elapsed since the appearance of the first edition of this book [this *Bulletin* 1930 Vol. 27 p. 1029] have produced such a mass of experimental work on the mode of action of drugs, and have witnessed discoveries of such practical significance that it is not surprising that the author in order to find space for these advances in knowledge, without increasing the size of the volume has found it necessary to re-write the second edition almost entirely omitting much of interest which was contained in the first edition.

The discovery that in the sulphocamide drugs we have chemotherapeutic agents of great value in the treatment of acute bacterial infections—a discovery equal to if not more important than the original introduction of arsenphenamine by Ehrlich—has proved a great stimulus to chemotherapeutic investigations throughout the world. The volume covers an enormous field dealing with the chemotherapeutics of helminthic infections, of amoebiasis, leishmaniasis, trypanosomiasis and malaria, of syphilis, and of tuberculous and leprosy, of the acute bacterial infections and of the virus infections. Curiously enough the spirochaetal infections other than syphilis, and the important infections due to the *phloplasma* group are ignored in the present edition, although an important addition to the therapy of the latter group has been made by the discovery of acapron.

The chapter relating to the chemotherapy of malaria has been extensively revised, and naturally much space is devoted to a discussion of the new synthetic compounds plasmoquine and atabrin. The great amount of experimental work which has been done during the last 10 years on the mechanism of the action of drugs and on the significance of drug-resistance has necessitated the complete re-casting of the chapter on the chemotherapy of trypanosomiasis.

As, however, might be anticipated the main change in the book is found in the chapter dealing with the chemotherapy of acute bacterial infections. How intense has been research on this subject since the discovery of the anti-streptococcal activity of prontosil by Mietzsch and Klarer in 1932 can be judged from the fact that the space devoted to the treatment of acute bacterial infections has been increased from 34 pages in the first edition to 164 pages in the present edition.

Valuable lists of references are given at the end of each section, making it easy for the reader to pursue more fully any point dealt with in the book. An important innovation in the present edition is that an author's index has been added to the subject index at the end of the book.

In the reviewer's opinion it would be difficult to write too highly of this most excellent work. Not only will it prove most useful to the laboratory investigator as a book of reference but it will also be of the greatest practical value to the physician in the tropics and to others who may have little access to current literature.

INTERNATIONAL LABOUR OFFICE Studies and Reports Ser B
(Economic Conditions) No 26 Labour Conditions in Indo-China.
1938 Geneva. pp 85-92. Medical Protection [Review appears
also in *Bulletin of Hygiene*]

Indo-China is a French colony with some 23 000 000 native population. Economic and social development is rapidly and completely transforming the country the old time family system still dominates home industries, but is being replaced by the industrial system for new mining and industrial undertakings. For this latter purpose contract labour has to be moved to the undertakings. The well being of such labour requires supervision. The workers have to be medically inspected and vaccinated when recruited and repatriated and are under medical supervision during their stay on the plantations. Returns of sickness and death must be made. Medical attention is given during sickness in hospital if serious. If there are 6 000 workers a whole-time doctor must be engaged. Otherwise one doctor may serve several neighbouring plantations. On red lands where malaria is rife 1.75 grammes of quinine must be taken every week mosquito nets are required and other anti malarial measures such as drainage must be adopted. Clearing ground on red lands is particularly unhealthy work but anti-malaria precautions under the auspices of the Pasteur Institute have done good work. In one instance a percentage of deaths of 28.3 in 1927 fell by 1931 to 0. In another the percentage of cases of unfitness for work fell from 20 or 25 to 3. These measures mean an increase of 40 per cent. in the value of labour employed. But they have to be constantly maintained. Control of drinking water has caused the almost entire disappearance of diseases due to bad water. Boots and leggings with antiseptic washes are abolishing troublesome ulcers. Fresh vegetables increase resistance to disease and Java rice is banishing beriberi. The employer is responsible for burial and for finding heirs to any property and deferred pay. The mortality of plantation workers was 5.4 per cent. in 1927 4.5 per cent. in 1928 2.83 per cent. in 1929 and 2.32 per cent. in 1930 all high rates since they apply to persons in the prime of life who were medically examined on recruitment. The whole of this report which deals with the introduction of civilized industry among native races is of great interest.

E. L. Collis

JORGE (Ricardo) *Flèvre jaune* [Yellow Fever]—*Arquivos do Instituto de Higiene* Lisbon 1938. Vol 4 No 1 pp xv+134
With 10 figs. (1 coloured)

The present interest in yellow fever one of the three great traditional pestilences—plague cholera and yellow fever—depends not so much on its ravages in the past as on the succession of recent discoveries concerning its epidemiology and control.

During the past twelve years the distinguished author as the delegate for Portugal on the Committee of the International Public Health Office has taken an active part in the study of the problem of yellow fever and in the present publication has given a graphic description of some of the more important stages in the growth of our present-day knowledge. Very appropriately in view of his official position the author reproduces certain communications and suggestions made by him at meetings of the International Committee illustrating the various points dealt with in this book.

These are considered as three acts of a dramatic film. Africa is the scene of the first act where early this century the existence of yellow fever could no longer be concealed. Then various erroneous theories as to its nature were followed by the foundation of the laboratory at Lagos and the discovery of the susceptibility of *Macacus rhesus*. The second act comprises both Africa and America. In his historical introduction to this section the author states that it is generally admitted that Columbus found yellow fever already present in the Antilles when he discovered America, a view which is opposed to recent studies by Carter and others [see this *Bulletin* 1932 Vol. 29 p. 245] supporting the African origin of the disease. The epidemic at Rio de Janeiro and also those at Dakar and Matadi again called attention to the potentialities of this disease, and each was suppressed by intense anti-mosquito campaigns. The Institute at Manguinhos became an active centre of yellow fever investigation.

In addition the long duration of yellow fever immunity (usually for life) was established by serological tests first in monkeys and then in mice and these discoveries were applied mainly through the help of the Rockefeller Foundation to a delimitation of the endemic areas of the disease by means of protection tests in mice. The surprising results of these investigations discussions on the diagnostic value of these tests and the introduction of the use of the viscerotome in Brazil complete this section.

The third act opens in Brazil with the occurrence of outbreaks of yellow fever in the absence of *Aedes aegypti* and in forest regions where any human origin of infection can be excluded. As a result, the existence of a jungle variety of the disease has been established occurring in wild monkeys and possibly other mammals, and transmitted by species of mosquitoes other than *Aedes*.

The various stages in these discoveries are presented with admirable fairness and impartiality and Dr. Jorge's book constitutes a valuable addition to the literature on the subject which should be read by all those interested in recent developments in our knowledge of yellow fever.

TROPICAL DISEASES BULLETIN.

Vol. 36]

1939

[No 5

SUMMARY OF RECENT ABSTRACTS *

IV TRYPANOSOMIASIS

Epidemiology

The extent to which trypanosomiasis is prevalent in West Africa is shown by the fact that in Nigeria the total number of cases diagnosed from 1931-36 was 284,933 (MACQUEEN p 697) and in North Dahomey during the period 1932-36 the new cases found numbered 7 702 (BEAULTS p 707)

Artiology

SCHWETZ (p 700) divides trypanosomes morphologically into three groups —

- 1 *Congolense* monomorphic with lateral blepharoplast
- 2 *Vivax* monomorphic with terminal or subterminal blepharoplast.
- 3 *Brucei* polymorphic with subterminal or lateral blepharoplast

The elaborations of these are given in the original abstract

JACOVO (p 327) proposes the generic name *Castellanella* for trypanosomes of conventional type reserving the name *Trypanosoma* for forms similar to those observed in the blood of frogs. This proposal is not accepted as valid by WENYON CASTELLANI and JACOVO (p 327) publish details of a human case in support of this proposed classification

HOARE and BROOM (p 701) found that it is possible in practically all cases to differentiate *T. uniforme* and *T. vivax* by measuring the length of only 10 trypanosomes. If the mean length is less than 18μ the infection is *T. uniforme* if more than 20μ it is *T. vivax*

Working on the respiratory metabolism of *T. rhodesiense* CHRISTOPHERS and GULTOV (p 709) found that the most striking feature was the utilization of glucose the formation of acid products and the large oxygen uptake. Deprived of glucose trypanosomes rapidly become motionless, deformed and lysed and the uptake of

* The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938 Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

oxygen ceases. *P. knowlesi* on the other hand, takes up oxygen steadily in the absence of added glucose and independently of the normal presence of this in serum or red cells. Oxygen is taken from haemoglobin which is altered if not actually split up there is no formation of acid. Certain drugs cause inhibition of the oxygen uptake by both trypanosomes and malaria parasites and this may be related to the therapeutic effect. The oxygen uptake gives a continuous record of the lethal effect of a drug, and the experimental method used by the authors is rapid and precise, and provides a ready means of telling whether a strain is arsenic-fast. VON BRAND (p. 712) shows that the carbohydrate metabolism of the pathogenic trypanosomes is very intense but the sugar is only partially oxidized in the presence of oxygen. The carbohydrate metabolism of the host is disturbed. Injury to the host may be due to loss of carbohydrate, or to the lactic acid formed by the trypanosomes or to toxins perhaps originating from protein metabolism of the parasites.

CORSON (p. 333) found no evidence of lowering of virulence of a strain of *T. rhodensis* maintained for nearly three years in ruminants and *G. morsitans*.

Sleeping sickness has become more virulent during the past 6 or 7 years in some localities in Nigeria where *G. morsitans* is not present and there is very little game (MACQUEEN p. 696).

BOURGUIGNON (p. 328) found in the south-east of the Belgian Congo a patient infected with a trypanosome having the characters of *T. rhodensis*. The strain in the guinea-pig was resistant to a dose of 1 gm. per kilo of trypanamide and cyclically transmissible in *G. palpalis*. The exaltation in virulence is probably due to the presence in that region of different species of *Glossina* able to transmit *T. gambiense*.

VAN HOOFF *et al.* (p. 693) investigating the transmissibility by *G. palpalis* of strains of *T. gambiense* from the Congo found that it varied from zero to 10.2 as calculated by the formula (q/v). Differences were found in various endemic zones and the two factors capable of lowering transmissibility appeared to be long sojourn in one host and lengthy drug treatment in refractory cases. Natural resistance of *T. gambiense* to trypanamide is more common than is believed. It can be acquired by passage through unaccustomed hosts, and inadequate treatment cannot be the only explanation.

BRUTSAERT and HENRAED (p. 704) give details of a method of cultivating trypanosomes in a medium containing Ringer solution with NaCl Tyrode solution and citrated human blood. In taking blood however it is drawn into a syringe containing 1 per cent. polymethyl sulphamate of sodium (liquide Roche) instead of sodium citrate. This method is useful in diagnosis when trypanosomes cannot be seen in the blood.

STRODER (p. 717) found that after being subjected to a pressure of 800 atmospheres for 5 minutes trypanosomes were infective but that after 1,300 atmospheres they became rounded, and after 1,400 were non-pathogenic for mice.

Transmission.

VAN HOOFF *et al.* (p. 334) found that preliminary meals on normal blood did not modify the infectibility of *G. palpalis* with *T. vivax* whereas with *T. gambiense* infectibility is decreased. From dissections made of flies fed on non transmissible feebly transmissible and easily

transmissible strains these authors (p 336) in agreement with YORKE conclude that proventricular infection does not necessarily imply ultimate invasion of the salivary glands and does not give any certain indication of cyclical transmissibility. Special long thin forms apparently destined to invade the salivary glands, however may be seen and infection of the proventriculus by these confirms the belief that the normal infection of *Glossina* by *T gambiense* is by the indirect route and dependent upon a preliminary development in the intestine.

VAN HOOFF HENRARD and PEEL (p 335) found that a meal of blood containing trypanamide or Bayer 205 does not destroy *T gambiense* infecting the intestine proventriculus and salivary glands of *Glossina* but some of the flies are no longer able to transmit the infection. Virulence is changed but evolution is not influenced unless the drug is present in very large amounts. No inhibitory action on trypanamide resistant trypanosomes was seen. Analogous results were given with *T brucei* but *T congolense* was not influenced.

Although *G morsitans* at normal indoor temperatures shows positive phototropic reaction to light JACK and WILLIAMS (p 338) found that at temperatures over 30°C. it will seek the dark regardless of the temperature there even if that temperature is rapidly fatal (49°C.) The distribution of tsetse flies in relation to vegetation and other features of their habitat may be explicable to a large extent on the basis of phototropic reactions. BAX (p 337) shows that *G swynnertoni* is attracted by the scent of oxen up to about 180 feet and by the sight of moving oxen up to 450 feet. LLOYD (p 702) points out that in Tanganyika Territory *G morsitans* can live in certain favourable types of vegetation independently of an *Isobertinia brachystegia* community and will not populate cultivated banana plantations in areas where favoured natural types of vegetation are present.

BOURGUIGNON (p 329) considers that the danger of mechanical transmission in the south-east Congo is far from negligible. In certain regions *G palpalis* *G morsitans* *G pallidipes* and *G longipalpis* were all found. Both *G palpalis* and *G morsitans* were found by TARANTINO (p 700) in the west of Abyssinia though no human trypanosomiasis has been seen.

The pupation period of one specimen of *G palpalis* was found by GUIBERT (p 702) to be 31 days.

The native pig of the Congo may be a reservoir of *T gambiense* VAN HOOFF *et al* (p 330) infected pigs both by inoculation and by bite. Parasites are scanty in the blood and there is no pathological reaction and the pig may be infective for at least a year. After cyclical transmission through three pigs in series flies infected from the third produced infection in a human volunteer.

Clinical

CORSON (p 333) found that only two of four human volunteers were infected in an experiment on the transmission of *T rhodesiense* by *G morsitans* and concludes that variations in resistance occur in man since no loss of virulence was observed in the trypanosomes. Inapparent infection in man may not be rare, and spontaneous recovery probably also takes place.

Reviewing the results obtained from the examination of a large series of fresh gland juice preparations stained thin and thick gland juice films stained thick blood films and triple centrifugation blood

preparations, RAOULT (p. 703) concludes that the thick blood film is in general the best method, and that stained gland juice is better than fresh. Stained juice preparations, however, are sometimes positive when the blood is negative. GUTBERT (p. 704) found trypanosomes in the bone marrow of 18 patients who had already been diagnosed, but failed in two in whom the diagnosis could not be made by other means, while VAN DER BRAAKEN concludes from the examination of 25 rats that bone marrow puncture is probably not of much value in diagnosis.

HORN-GILL (p. 705) tested three groups of people with the serum-formalin reaction—patients infected with *T. gambiense* apparently healthy natives from fly free country and out-patients other than detected cases of human trypanosomiasis. He concludes that the reaction (in an area where kala azar is not endemic) if positive within 60 minutes, is strong evidence in favour of trypanosomiasis and if negative at 24 hours practically excludes it. Bayer 205 in the serum retards the end point as does previous treatment with trypanocide. Interference by syphilis is negligible. For the technique the original abstract should be consulted. GUTBERT (p. 706) has devised a simple method of applying the Pandy reaction to the cerebrospinal fluid, which could be used by itinerant sleeping sickness workers. The reagent is carbolic acid crystals 10 gm. in 150 cc. distilled water and the reading made in a nepheloscope. A black ring is negative. Positive readings vary from a greyish ring (slightly positive) through a blue tinge to a white cloud, when the reaction is strongly positive and indicates a protein value of more than 0.5 gm. per litre and usually more than 50 cells per cmm.

SCHWARTZ (p. 702) reports acquired trypanosomiasis in a child less than 20 days old. The child died after remaining in good clinical condition for six months. In Tanganyika Territory (p. 309) a child was seen with *T. rhodesiense* in the blood and enormous numbers in ascitic fluid.

Chemotherapy

It has been pointed out that trypanosomes require for the metabolism a large quantity of sugar (see also CHRISTOPHERS & FULTON above). Synthalin produces hypoglycaemia, and it is thought that possibly its curative action in mice might be due to action. LOURIE and YOUNG (p. 342) however from experiments with trypanosomes *in vitro* conclude that the drug has a direct trypanocidal action, even on atoxyl- and Bayer resistant strains. The effect of insulin was negligible. This finding led KING, LOURIE and YOUNG (p. 343) to test other compounds, of entirely different chemical composition from the known trypanocidal substances, and of these n undecano-11-diamine was the most active, producing permanent cures in laboratory animals. These experiments open up a new field in chemotherapy. BROWNING (p. 716) supports the conclusions of LOURIE and YOUNG that the therapeutic effect of synthalin (which he confirms) is not due to the hypoglycaemia it produces.

A further new type of trypanocidal agent has been found by BROWNING *et al.* (p. 344) in phenanthridinum compounds. Two of these are effective in mice against *T. brucei* (including a strain resistant

to arsacetin) and one is curative in *T. congolense* (and also *Sp. minus*) infections

Testing the toxicity of the glyphenarsines (tryparsamide trypanarsyl etc.) on white rats VAN DEN BRANDEN and PORTIER (p. 349) conclude that if visual troubles or other ill effects in abnormal numbers are produced, the cause is the state of the patient or faults of technique.

MURGATROYD (p. 341) tested the therapeutic action of neocryl on patients with *T. gambiense* infection. A rapid and definite clinical improvement occurred in practically every case treated especially in the early cases with normal spinal fluids. The results resemble those to be expected from tryparsamide but cannot be assessed fully until the later fate of the patients is known. Two other arsenicals K.324 and K.352 were unsatisfactory. MACQUEEN (p. 697) also reports good initial results in the treatment of 60 cases with neocryl. Dimness of vision was a feature in two, one of whom died. The later effects of neocryl treatment were studied by ACRES (p. 341). He found the same rapid initial clinical improvement but before six months after the completion of treatment 2 of 9 first stage and 7 or 8 of 12 second stage patients had relapsed. The drug is therefore disappointing.

STRANGEWAYS (p. 345) shows that thioarsinites (containing trivalent arsenic) are toxic to trypanosomes *in vitro* in high dilution and this is due to hydrolysis and the liberation of the highly trypanocidal arsenoxide. Neoarsphenamine is probably adsorbed and oxidized within the trypanosome or on its surface to arsenoxide.

RADNA (p. 708) uses the intrathecal injection of arsebenyl to increase the permeability of the meningeal barrier to drugs injected in the ordinary way. He reports that 7 patients with abnormal spinal fluids were cured by this means. The technique is given.

As a result of the treatment of 34 patients with anthiomaline BERTRAND (p. 708) concludes that it is of little use when the spinal fluid is changed but is a compound of the first order in producing peripheral sterilization even in cases resistant to tryparsamide. LAUNOY and PRIEUR (p. 350) found that amino-phenylstibinate of methylglucamine had good therapeutic action on mice infected with *T. brucei* and normal *T. annamense*. Naturally resistant *T. congolense* and artificially resistant *T. annamense* responded about equally.

No prophylactic or permanent therapeutic value for guineapigs with *T. gambiense* infection was found by WITTEBOLLE (p. 349) in the use of Trystibine (Dn 18).

BIOZZI (p. 716) tested colloidal zinc silver and copper on *T. brucei* *in vitro* and in guineapigs. All exerted definitely lytic action but the copper preparation Zimocuprolo was the most successful curing the animals on intravenous injection. It causes abscesses if injected subcutaneously.

The chemical composition of Surfen and Surfen C is given by IEWSCH (p. 343) together with references to the successful treatment of *T. congolense* and *T. brucei* infections. A related substance is stated to possess activity against *T. cruzi* which has not been affected hitherto by any chemotherapeutic agent. Surfen C is contraindicated in human trypanosomiasis by the production of acute nephritis. The use of Surfen C in Northern Rhodesia in the treatment of animals led to disastrous results some dying within 15 minutes and showing extensive haemorrhages throughout the lungs though others tolerated the drug fairly well (LE ROUX p. 329). Similarly experiments in the Gold Coast were unsuccessful in cattle though good results were

[May 1939]

obtained in dogs (STEWART p. 330). The most effective drug is still tartar emetic though horses with *T. brucei* infection were cured with nugganol.

TUNG (p. 714) in studying the photodynamic action of methylene blue on *T. brucei* *in vitro* found that in the presence of light a dilution of 1 in 100 000 was sufficient to produce immobilization whereas without light 1 in 100 was required. The immobilizing effect was parallel to the lethal activity and immobilized trypanosomes failed to infect mice. Trypanosomes treated with the photodynamic action in a dilution insufficient to immobilize have a longer incubation period and survival than controls.

STRANGEWAYS (p. 346) states that in neutral or slightly alkaline solutions of glutathione and ascorbic acid exposed to air a substance is rapidly formed which is very toxic for trypanosomes *in vitro*. This is probably hydrogen peroxide.

RADWA (p. 347) concludes that arsenic-resistant trypanosomes are just as chemo-sensitive *in vitro* as normal parasites, but his work is criticised by YORKE. He also observed that agglutinins were present in the sera of treated patients. He therefore used blood transfusion from convalescent patients in addition to chemotherapy. In the treatment of resistant patients Though they did not respond to either method alone the combination produced sterilization.

MEYER and BOCK (p. 335) show that in a patient with trypanosomiasis, diabetes, filariasis, tertian malaria and ankylostomiasis, insulin treatment was not interfered with by germanin and atehrin. germanin appeared to provoke the latent malaria. *M. diurnus* was uninfluenced by the treatments, and germanin was effective in spite of the complications.

Prevention.

DANGERFIELD GAUNT and WORMALL (p. 714) have described a method of determining Bayer 205 in plasma, but difficulties are present in applying it to urine. After intravenous injection the amount in the plasma (of rabbits and dogs) falls rapidly for the first few days, but it can still be found after 6 months, especially if administered in several small doses. This persistence may account for the marked prophylactic action of the drug. The prophylactic action of moranyl on a community of 621 individuals in the Congo was studied by OXLOVITCH (p. 340). Twenty new cases of disease were found in 1934 and this was repeated twice at 3-monthly intervals. Examinations made regularly on considerable numbers up to 3 months after the last injection, failed to reveal any cases, but 4 persons who had not received the drug were found to be diseased.

MACQUEEN (p. 697) states that it has become increasingly evident that in Nigeria treatment alone cannot control trypanosomiasis, and protective measures such as communal clearing and concentration, consider that therapeutic warfare against human trypanosomiasis is the best method in the Belgian Congo.

NASH (p. 332) distinguishes between aggressive and defensive clearings against *Glossina*. The former aim at the eradication of season sanctuaries, the latter at the protection of the populace during the course of normal work or travel by driving back the fly to a distance. LE ROUX (p. 329) considers that an essential measure is

eradication of trypanosomiasis of cattle in a district of Northern Rhodesia is that an attempt to reduce the food supply of *G morsitans* should be made, for instance by shooting buffalo

Trypanosomiasis in Animals and Experimental Work

VAN SACEGHEM (p 716) inoculated calves of less than one month old with *T congolense* passaged through guineapigs or rabbits (to eliminate infections such as piroplasma peculiar to the ox) and found that a benign infection lasting several months and ending in spontaneous cure resulted leaving real immunity. MACQUEEN (p 698) records an experiment from which it is concluded that certain cattle which had recovered from *T vivax* infection and resisted subsequent injections of *T vivax* and *T congolense* possessed a natural rather than acquired resistance. PERLA (p 350) failed to find consistent results in raising the natural resistance of mice against *T equiperdum* and *T brucei* by the administration of vitamin C prior to and throughout the course of infection.

CASTELLANI and JACOZO (p 328) report success in increasing the natural resistance of guineapigs to *T gambiense* by the use of an antigen consisting of blood rich in trypanosomes treated with small quantities of bile or defibrinated homologous blood rich in the dead bodies and products of autolysis of trypanosomes.

TARANTINO (p 700) shows that *T brucei* and *T congolense* infections of cattle are found in Abyssinia.

GUIDETTI (p 328) produced various involution forms by exposing *T brucei* from the blood of guineapigs to the action of certain dyes.

FRENCH (p 712) working on *T brucei* and *T congolense* infections in animals, found that an increased excretion of nitrogen body bases chlorides and phosphates takes place. The relative proportion of albumin in plasma decreases and that of euglobulin increases progressively to death or crisis. There is no alteration of the blood urea. Increase in the sedimentation rate of red cells was found by the same author (p 347) in cattle sheep and donkeys infected with *T congolense* and *T brucei*. It was most marked in donkeys but the rate of sedimentation of normal blood of these animals also shows differences.

In rabbits the fatty constituents of the plasma other than cholesterol are markedly increased in *T brucei* infection (TUNG and MA, p 713). PACKCHIANIAN (p 348) found that the electrical conductivity of defibrinated rat blood infected with *T brucei* was higher than that of normal blood.

HOARE (p 331) discusses the polymorphic trypanosome causing disease in African pigs and concludes that its correct name is *T simiae* Bruce et al 1912. *T simiae* has been found to occur in pigs in the forest in the Gold Coast. Great and sudden mortality is experienced. The usual infection is by *T brucei*. *T theileri* was found in large numbers in the blood of cattle (p 330). In French West Africa CURASSON (p 331) observed epidemics of *T brucei* infection of pigs. It may be benign or severe depending possibly on successive reinfections and numerous passages through the pig or on avitaminosis.

SHARROCKS (p 348) found that a serum prepared by an antigen of living *T hippicum* was antagonistic to more strains than one prepared by injecting trypanosomes killed by 0.5 per cent. phenol. The survival time in rats was in direct proportion to the amount of serum

administered. It appeared that trypanosomes resistant to one injection were not completely so to a second. There is a slight *in vitro* action of human serum on the organisms, but this is not responsible for the complete protection afforded to rats by the administration of normal human serum.

Oxo (p 713) found that the serum of rabbits immunized against turtle serum inhibited the trypanolytic action, but not the haem-agglutinating action, of sera of the turtle and other cold blooded animals. Trypanosomes failed to resist fresh cold-blooded serum but resisted inactivated serum, after long continued addition of the fresh serum to cultures.

TALLAFERRO (p 717) contrasts the action of trypanocidal antibody and ablastin (reproduction-inhibiting antibody) in *T. lewisi* infections. Passive transfer of ablastin takes place as effectively in splenectomized and blockaded rats as in normal rats, but that of trypanocidal antibody is slightly impaired. Passive immunity with ablastin lasts only a few days. In normal rats it is replaced by active ablastic immunity but in splenectomized and blockaded rats this does not occur. Passive immunity with the trypanocidal antibody lasts only a few days. Surviving trypanosomes in splenectomized and blockaded rats actively multiply owing to the failure of development of ablastic immunity. An epidemic in rats due to *T. lewisi* is described by SLATSEAST & al. (p 332). The symptoms are given.

CHAGAS DISEASE

LYOFF (p 722) shows that growth of *T. cruzi* is abundant in serum to which is added both haematin and ascorbic acid.

LIND SOEL DROEG (p 718) showed that *Trypanosoma infans* could transmit *L. icterohaemorrhagiae* and that when infected with paratyphoid organisms there was reason to believe that infection could be transmitted by *Past. pestis*. For the complement fixation reaction this author uses a dry culture antigen prepared from condensation fluid of 14 day cultures of *T. cruzi* on Bonacci's medium.

MAZZA & al. (p 718) found 33 per cent of 1722 specimens of *Trypanosoma infans* infected with *T. cruzi*. *Trypanosoma* captured in the sleeping rooms of dwellings in La Rioja. *Trypanosoma* captured in poultry yards and dove-cotes were not so heavily infected. Wood and Wood (p 719) failed to find infection in the faeces of 287 cone-nose bugs and the blood of 80 rodents in the United States.

JOHNSON (p 722) examined the cardiac changes in infected dogs. There is parenchymatous myocarditis with interstitial reaction. These may be acute or chronic and the focal lesions only occur on rupture of the cardiac fibres and liberation of the parasites, and are probably not due to toxins. Scarring and focal lesions are found in chronic cases when parasites cannot be seen. Wood (p 354) describes the cytological variations in white-footed mice infected with *T. cruzi*. Increase in large lymphocytes and decrease in eosinophil leucocytes were observed. The spleen is enlarged with hyperplasia of lymphoblasts and lymphocytes and hyperplasia of the reticulo-endothelial cells were produced. The bronchial, lumbar and inguinal glands were enlarged.

LACORTE (p 721) uses an antigen prepared from the spleen of a well-infected puppy for the Machado reaction. Positive results were obtained in 68.5 per cent. of 35 cases.

MAZZA (p 718) shows a fatality rate of 5.8 per cent. in 240 cases reported in the Argentine. In most of the dwellings occupied by patients puppies and kittens were found naturally infected by *T. cruzi*. Descriptions of cases are given by TALICE *et al* (p 352) MAZZA *et al* (pp 353-721) and LUNDEBERG (p 720). Typical lesions are recorded but in one meningo-choroiditis was present with encephalitis a condition constantly present in animals but not hitherto reported in man. Dacryoadenitis and facial oedema are emphasized. TALICE (p 351) found four cases of disease in Payandó where *T. infestans* is very prevalent.

IENSCHE (p 344) states that a substance related to Surfen and Surfen C possesses activity against *T. cruzi* which has not been affected hitherto by any chemotherapeutic agent. KOFORD *et al* (p 353) working with tissue cultures of *T. cruzi* in embryonic rat heart tested three arsenicals. Arsenious trithiosalicylic acid was the most toxic for *T. cruzi* but was toxic also to tissue *in vitro* and to mammals.

C II

CHOLERA.

PRECIS OF ABSTRACTS IN THIS SECTION

OLISCH (p. 364) describes a method of recording epidemics of cholera in Russia by means of "isodates," analogous with isobars, designating on a map places attacked by the disease at approximately the same time.

RAJA (p. 365) mentions two pilgrim events in the propagation of cholera in India in 1938. GRATTAN (p. 365) incriminates infected butter as originating an outbreak in British troops. HASSETT (p. 365) shows that a water-borne epidemic started in Swat State, far from the original focus, and was conveyed by pilgrims. Two carriers originated the outbreak in a jail reported by MAITRA *et al.* (p. 366). KUNDO and PA HOW (p. 366) recovered *V. cholera* from prawns in Burma.

NGUYEN VIEM HAI (p. 366) mentions cholera in French Indo-China. The King Institute of Preventive Medicine, Gundy (p. 366) recognizes special zones of predominance of the Inaba and Ogawa types, and reports experiments on house flies which indicate that they are not efficient as carriers.

HISHIMURA (p. 367) found that the types of *V. cholera* isolated over 15 years previously by NOSECHI still retain their specific characters.

PASIRICHA *et al.* (p. 367) isolated *V. cholera* from the stools of three of 2,000 patients (suffering from other diseases) in Calcutta. All had abdominal conditions, but not such as to suggest cholera. The characters of the vibrios are given.

The Prevention Bureau, Ministry of Health, Japan (p. 367) differentiates between the presumptive diagnosis of cholera based on morphology and a rapid result of the agglutination test on a slide, and the absolute diagnosis based on a more elaborate serum test and Pfeiffer's bacterolytic test. TAYLOR (p. 368) reiterates the opinion that, for India, *V. cholera* belongs to the special group "O" No. 1.

(Gardner and Venkatraman) is non-haemolytic and gives characteristic biochemical reactions. Vibrios of other antigenic types exist abundantly in nature and it is not therefore surprising that they are found in the intestinal contents both of normal people and patients with cholera. RUSSELL (pp. 368-369) has tested many differential serum methods. He states that monovalent antiserum "O" Inaba is specific and preferable to "O" Ogawa and Napoli. Details of the essentials in the diagnosis of the true cholera vibrio are given. Inaba "O" anti-serum prepared with lithium chloride antigen agglutinates at a higher titre than that prepared by other methods and Inaba "O" antisera are more efficient than Ogawa "O". In the study of the specific polysaccharides of *V. cholera* LIXTON *et al.* (p. 370) emphasize that only strains freshly isolated in the early part of an epidemic should be used, as these contain a lipoid-polysaccharide complex which is absent from strains isolated later in an epidemic, or maintained for a long time in the laboratory.

LAIGRET and AUBERTIN (p. 370) succeeded in reviving *V. cholera* which had been desiccated over calcium chloride for 24 hours and preserved at room temperature for five weeks. The epidemiologic importance of this observation is noted. Working on an electrophoretic reaction, LIXTON *et al.* (p. 371) conclude that a shift in surfs

potential is the cause of serological distinction of the R derivatives from their S homologues. LODENKÄMPER and KALLINICH (p 371) claim that pleomorphic spheres, later growing out into vibrios were obtained in the filtrate (through membrane) of a suspension of *V. metchnikovi*.

MERTENS *et al* (p 371) show that the El Tor vibrio is haemolytic to goat erythrocytes belongs usually to the Ogawa type serologically and is usually Voges-Proskauer positive. BAARS (p 372) studied the katabolic products formed from glucose in a special medium containing chalk. The ratio of CO₂ and fermented sugar was 0.88 for the V P positive El Tor and 0.52 for the V P negative *V. cholerae*. MARRAS (p 373) notes that the El Tor vibrio cannot be distinguished from *V. cholerae* by serological methods alone.

BERNARD *et al* (p 373) describe the technique for the extraction of the potent exohaemolysin of the El Tor vibrio from agar or bouillon. By the same technique a feeble endohaemolysin may be obtained from *V. cholerae* under certain conditions and they (p 373) consider that the same haemolysin may be common to the El Tor and the true cholera vibrio. They describe colour phenomena produced on suspensions of erythrocytes by the El Tor haemolysin. DEL FAVERO (p 374) showed that laboratory strains of *V. cholerae* subjected to 15 passages and incubated at 20°C. became strongly haemolytic to sheep erythrocytes.

DE MOOR (p 374) describes an outbreak of cholera like disease near Macassar which was not explosive and which he considers to be endemic and not imported. About 400 strains of vibrios showing the characters of the El Tor type were isolated they were distinctly haemolytic. VAN LOGHEM (p 375) examined two of these strains and confirmed that they were of the El Tor type. He suggests the name El Tor enteritis for the disease. OMAR (p 375) isolated an El Tor vibrio from the stool of a woman who had never left Egypt. She gave no history of significant intestinal disturbance.

SOLIMAN (p 375) shows that saprophytic vibrios are not serologically identical with *V. cholerae*.

TAYLOR and AHUJA (p 376) here amplify the contention that vibrios found in water may be found in the stools of cholera patients and normal people without possessing any aetiological relationship. Such vibrios (which do not agglutinate with pure O cholera serum) are almost universally found in water in North India, where cholera is not endemic. PANDIT and MAITRA (p 376) isolated 33 strains from open surface waters in Assam. PASRICHA *et al* (p 377) found that vibrios isolated from water flies and cockroaches were all inagglutinable with Inaba O serum and most belonged to Heiberg's types I and II. LAHIRI and DAS (p 377) examined 75 strains of vibrios isolated from animals. None agglutinated with Inaba O serum. They suggest that the vibrios are present in the stools as contaminants.

VARDON and DATTA ROY (p 377) describe a cheap papain-casein medium for the preparation of bacteriophage especially cholera phage. GENEVRAY and BRUNEAU (p 378) use a medium of 20 gm. peptone and 30 gm. salt to 1 000 cc. distilled water at pH 8.5 for the rapid passages of culture from cholera stools and for the elimination of contaminants such as *Ps. pyocyanea* and *Proteus vulgaris*. BANERJEE (p 378) uses Ramon's glucose bouillon for the anaerobic culture of *V. cholerae* as the pH does not change.

DEMONTE and GUPTA (p. 379) failed to isolate *V. cholerae* from the blood of 26 cholera patients, and CHATTERJEE and MALIK (p. 379) failed in attempts with urine, but *V. cholerae* was isolated from material obtained by liver puncture as well as from the stools of a boy reported by PASRICHA *et al.* (p. 379). GHOSH (p. 379) records five patients with typical symptoms of cholera from whose stools *Ps. pyocyanea* but no *V. cholerae* was isolated.

On the assumption that hypochloreaemia is one of the dangerous features of cholera MASSIAS (p. 380) injects 20 cc. of a 20 per cent. sodium chloride solution intravenously. Mortality has been lowered to 22 per cent. THOMAS and TING (p. 380) show that pyrogenic substances in the distilled water used for intravenous salines are responsible for untoward effects and advise rigid precautions (q.v.) in the distillation and preparation of the solution. BANERJEE (p. 381) avoids the rigors common after intravenous saline by regulating the temperature of the solution to as much above 36.7°C. as the rectal temperature is below this.

CHATTERJEE and DEO (p. 381) regard the A phage as that mainly concerned in cure but all available types should be used in massive doses at the earliest opportunity.

SMITH (p. 382) shows how quarantine measures have reduced the incidence of cholera in the Philippines. The discovery of the cholera vibrio in stools whether agglutinable or not, is sufficient to justify isolation and treatment. WAHBI (p. 382) notes that a quarantine station for pilgrims has been established at Rabba near the Irak frontier.

The vaccine used in the Federated Malay States (p. 382) is prepared from four strains and contains Inaba and Ogawa sub-types in equal proportions. YU (p. 383) shows that smooth strains vary in virulence and protecting capacity—strains with high animal virulence should be used for vaccines. PASRICHA *et al.* (p. 383) notes the inefficiency of certain vaccines prepared by commercial firms and the good quality of those supplied by recognized laboratories in India. CARO (p. 383) shows that 94 per cent. of 548 patients in a Haiphong epidemic had not been vaccinated and that this epidemic, in which vaccination was performed on a large scale, was extinguished, though it continued to prevail in the Tonking delta long afterwards. But QUENARDEL (p. 384) states that in Tonking reports on the efficiency of the large scale vaccination procedure were by no means all favourable.

C. H.

OLTSCHA (Reimer) with a Foreword by H. ZEISS. *Die Epidemiologie und Epidemiographie der Cholera in Russland. Ein Beitrag zur Geomedizin. [Epidemiology and Epidemiography of Cholera in Russia.]—Ztschr. f. Hyg. u. Infektionskr.* 1938. Sept. 5. Vol. 121. No. 1. pp. 1-26. With 1 fig.

Russia, in somewhat the same way as Bengal is regarded as one of the homes of cholera from which widespread epidemics may take their origin. The chief interest of the present article lies in the method of representing cholera incidence by maps, in which the separate "governments" of European Russia are variously shaded for the degree of mortality which they experienced in different cholera years and by a series of lines like isobars which are named "isodates." These lines in red, enclose territories which have been involved in cholera epidemics at approximately equal times. The more closely the isodates are set

the slower obviously has been the spread of cholera in that region. Remarks made in the introduction may be quoted — 'The errors of all previous maps are avoided by Olzscha with the introduction of the Isodates

With this method it will be possible not only to represent the course of epidemics, such as cholera plague influenza, small pox but perhaps also to probe more deeply the secrets of their progression in every country and part of the earth They may serve graphically to depict the original endemic area of an epidemic

Russia has experienced 55 cholera years since the epidemic of 1823 but only 13 of these can be regarded as major epidemics while about half are graded as evanescent It might have been expected that in those epidemics which repeated themselves in succeeding years the second-year epidemic would tend to be of less degree than the first but the reverse is frequently the case A series of cholera years 1830 1831 1847 1849 1853 1855 1870 and 1871 are dealt with seriatim in the text and shaded maps with isodate lines are given of these years in a special folding plate.

RAJA (K. C. K. E.) Note épidémiologique sur le choléra dans l'Inde en 1938 [Cholera in India in 1938.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Nov. Vol. 30 No. 11 pp. 2552-2561

The period of cholera prevalence covered is not the whole year but only that up to the end of August. Figures are given for the several provinces of India which admit of direct comparison of incidence and mortality. Two pilgrim events are selected for special mention in connexion with the propagation of cholera from well defined centres. These were the Kumbh Mela of Hardwar and Bndraban.

W F H

GRATTAN (H. W.) An Outbreak of Twenty-Eight Cases of Cholera among British Troops in Benares during September-October, 1912. —*Jl. Roy. Army Med. Corps* 1939 Jan. Vol. 72 No. 1 pp. 21-25

The author describes an epidemic of cholera among British troops which occurred many years ago. His verdict was that the infection had originated in contaminated butter.

W F H

HASSETT (C. J.) A Cholera Epidemic in Swat State, N.W.F., 1937 — *Indian Med. Gaz.* 1938. Oct. Vol. 73 No. 10 pp. 602-605. With 1 map & 1 graph.

The Swat State of the Malakand Agency in the North West Frontier Province of India is not an endemic focus of cholera which when it does occur is always imported from outside. The present epidemic started suddenly. It was obviously water-borne and, with some difficulty the human element by which the water had been infected was traced. It proved to be a party of Hindu pilgrims. The importance of the outbreak from the public health point of view lies in that the disease must have been carried a long distance before making itself apparent in an explosive outbreak.

MAITRA (G. C.) SEN GUPTA (P. N.) & THANT (U) *Cholera Epidemics in Burma and the Type of Vibrio associated with them.*—*Indian Med Gaz.* 1938. July Vol. 73 No. 7 pp. 406-408. [10 refs.]

The interesting point recorded in this article is of three cases of cholera occurring in a jail set apart for habitual offenders, having no association with outsiders. A search was instituted and all prisoners employed in the jail kitchen and all contacts with actual cases came under examination. Two carriers of true cholera vibrios were in this way discovered and they were isolated until bacteriological reports declared them to be free of infective cholera organisms. *W F H*

KUMDU (K. P.) & PA HOW (U) *Prawns as a Possible Vector of V. cholerae.*—*Indian Med Gaz.* 1938. Oct. Vol. 73. No. 10. pp. 603-606.

Prawns caught in the delta districts of Burma are brought to Rangoon for sale. Various consignments were examined and two prawns yielded typical cholera vibrios the agglutination and cultural reactions of which would have led to the diagnosis of cholera had they been isolated from the excreta of a suspected case of cholera. *W F H*

NGUYEN VIEK HAI. *Rapport sur l'épidémie de choléra de 1937 dans la province de Kien-An.* [The Epidemic of Cholera in Kien-An in 1937].—*Rev Méd Française d'Extrême-Orient* 1938. Apr Vol. 17 No. 4 pp. 428-432.

A complete account is given of the ravages of cholera in a special northern province of French Indo-China during 1937 the details of which are of official interest. *W F H*

GUINDY. *REPORT OF THE KING INSTITUTE OF PREVENTIVE MEDICINE FOR YEAR ENDING 30TH SEPTEMBER 1937* [SHORTT (H. E.) Director]. pp. 23-28.—*Cholera Enquiry*

Some suggestion has been made that the Ogawa strain of the cholera vibrio might only be a laboratory phase of culture and not a vibrio occurring in nature. This possibility seems to have been definitely negatived, as "several hundred Ogawa strains have been met with in the course of investigation." A topographical distribution of the two main cholera types, Inaba and Ogawa, has been met with sufficiently distinct apparently to justify recognition of special zones or areas of predominance. No difference in the severity of Inaba or Ogawa epidemics could be demonstrated.

A special research into the rôle of the common house-fly in the spread of cholera showed that ingested vibrios are either rapidly excreted or are destroyed in the gut of the fly. Further experiments were designed to test the vibriocidal action of extracts of the crop and intestine with the result that "while the control plates showed growth of cholera the plates inoculated with a mixture of cholera suspension and the extract after one hour's contact remained sterile."

NISHIMURA (Haruo) On the Types of Cholera of Shanghai Epidemic of 1937—Reprinted from *Jl Shanghai Sci Inst* 1938. July Section 4 Vol 3 pp 251-263

The 16 strains of cholera isolated in the Shanghai epidemic of 1937 were compared with standard type strains Inaba (original type) Hikojima (middle type) and Ogawa (variant type) Although it is over 15 years since these types were isolated by NOBECU they still retain their specific character All the 16 strains now tested proved to be of the original Inaba type W F H

PARRICHA (C L.) LAITRI (M N) & DAS (P C) The Isolation of *Vibrio cholerae* from Non-Cholera Individuals.—*Indian Med Ga.* 1938 Nov Vol 73 No 11 pp 669-670

It is now very generally maintained that the 'true' cholera vibrio must be agglutinated by a pure O serum and that agglutination by an H+O serum is not specific. Examination for vibrios has been made in the Carmichael Hospital Calcutta during the past five years of stools of 2 000 patients suffering from diseases other than cholera with varying results. Recently the investigation has become more specific with appropriate sera. The examination of the stools for vibrios was carried out after a two-stage enhancement in peptone water and isolation on Aronson's medium. The 1 *cholerae* was isolated from three individuals—(1) with ill-defined abdominal symptoms for 2½ months before admission (2) with chronic diarrhoea on admission and (3) with a history of dysentery 6 months prior to admission. The vibrios isolated were monoflagellate of Heiberg's group I agglutinable to full titre with cholera (Inaba) O and H+O serums, inagglutinable with pure Ogawa serum, non-haemolytic to goat erythrocytes not phage-contaminated and they were acted on by the different types of cholera phage. W F H

JOURNAL OF THE PUBLIC HEALTH ASSOCIATION OF JAPAN 1938 Sept. Vol 14 No 9 pp 1-6—Guide for the Identification of Cholera Vibrios in Stools. By the Prevention Bureau Ministry of Health and Social Affairs.

Clear instructions are given in this guide to the identification of cholera vibrios which should be very useful to all laboratory workers faced with the necessity of furnishing a verdict on the early cases of a possible cholera epidemic. The headings indicate the general course of the procedure—collection and handling of the materials microscopic examination of smears cultures and immunological tests. Diagnosis is divided into the two headings of (a) presumptive and (b) absolute. The presumptive judgment of cholera is accorded when the morphological structure and motility of the bacteria correspond to those of cholera vibrios and a distinct positive result is observed within 2 or 3 minutes in the agglutination test on a glass slide. An absolute judgment is dependent on a more elaborate serum test with agglutination to titre and inclusion of Pfeiffer's bacteriolytic test. The Pfeiffer reaction is very often omitted W F H

altered with further subculture and thus phenol agar is not suitable for the isolation and preservation of O somatic antigen. (5) The non-specific ciliary H antigen is eliminated by the addition in suitable proportion of 96 per cent alcohol to a cholera suspension and alcohol agar can also inhibit the culture. (6) Inaba O antiserum prepared with lithium chloride antigen has been shown capable of agglutinating at 1-6000 this is a higher titre than is given by a somatic serum obtained with O antigen heated for two hours at 100°C or with phenol or with alcohol antigens which give agglutinations of 1-3000 1-2000 and 1-1000 respectively. (7) Inaba O antisera of all these antigens have higher titres than Ogawa O antisera and Napoli O antisera. (8) The anti-O serum produced with lithium somatic Inaba O antigen should help to bring about concordant results in different laboratories in the essential diagnosis of the typical cholera vibrio.

LINTON (Richard W.) SHRIVASTAVA (D. L.) SEAL (S. C.) & MOOKERJI (S. P.) Studies on the Specific Polysaccharides of the Vibrios. Part II. Chemistry and Serology.—*Indian J. Med. Res.* 1938, July Vol 26 No 1 pp 41-54 [10 refs.]

The authors continue their studies on the chemical architecture of the vibrios of their six groups by endeavouring to correlate specific precipitin serological reactions with polysaccharide composition. It had already been shown that such polysaccharides could be used in precipitin test to distinguish easily between El Tor vibrios and vibrios isolated from cholera cases. The present work is in continuation of that finding. The antisera used were obtained by injection of 18-hour agar cultures intravenously in rabbits, for it had not been found possible to obtain antisera to the polysaccharides themselves. In the present chemical and serological research previous findings were confirmed that cholera strains are quite distinct from strains from other sources. Particular emphasis is laid on the discovery of two types of cholera strains, one which is the freshly isolated strain of the early part of an epidemic and the other the strain of the later part of an epidemic. The fresh strain contained a lipod-polysaccharide complex which was absent in the second type and also absent in strains maintained for a long time in the laboratory and in water and carrier strains. It would appear desirable therefore that only freshly isolated strains should be used "in studies of antigenic structure".

W. F. H.

LAURET (J.) & AUBERTIN (Alme P.) Sur la reviviscence du vibron cholérique après sa desiccation et sa conservation à l'état frais. [Revival of the Cholera Vibrio after Desiccation and its Preservation in Nature].—*Bull. Acad. Méd.* 1938, July 5, 102nd Year 3rd Ser. Vol 120 No 28 pp 50-54.

Desiccation has usually been considered fatal to cholera vibrios, which were classified in this respect as very fragile organisms. The present experiments have shown that it is possible to revive the cholera vibrio even after it has been dried for 5 weeks. The technique of drying is to centrifuge down a cholera suspension, mix the deposit with equal parts of a mixture disodium phosphate 10 parts and monopotassium phosphate 1 part. desiccate this mixture over chloride of calcium for not more than 24 hours and preserve at room temperature. In restoring the vibrio to life from its presumably dormant condition the first

culture set up must be in bouillon. Desiccation for longer than 24 hours or by other methods such as over sulphuric acid kills the vibrios. They remain during their period of preservation strictly aerobic.

The author speculates on the importance of this finding in its epidemiological aspect. Is it possible that in nature cholera vibrios may become dried and serve at a later time as the cause of a new outbreak or again is it possible that dry vibrios may be transported as dust and give rise to infection at a distance? W F H

LINTON (R. W.), MITRA (B. N.) & SEAL (S. C.) *Electrophoresis and Metabolism of Some Vibrio Strains in Relation to Variability and Chemical Classification.*—*Indian J Med Res* 1938 Oct Vol 26 No 2 pp 329-334

Much work has been done by Linton and his collaborators on the chemical structure and metabolism of cholera vibrios by which they have been separated into a number of groups. To the methods previously adopted they now add an electrophoretic reaction combining it with the other features for the determination of possible differences between S and R vibrio homologues. It is the surface electric charge of the organisms which is studied by subjecting them to electrophoresis. The conclusion is reached that — The serological changes brought about by treatment with antiserum or by other processes follow changes in chemical structure, metabolism and surface potential. A shift in the latter is the cause of serological distinction of the R-derivatives from their S-homologues and partly accounts for the uniformity of serological behaviour of the rough vibrio strains in general. W F H

LODENKÄMPER (H.) & KALLINICH (W.) *Entwicklungstudien an Vibrionen. I Mitteilung [Developmental Cycle in Vibrios.]*—*Zent f Bakt I Abt Orig* 1938 Oct. 17 Vol. 142, No 7/8. pp 376-388 With 4 figs. [11 refs.]

This communication raises once more a subject which has been for some time in abeyance, that of the existence of a cycle of development in bacteria. The organism chosen for the purpose of experimentation in the production of bacterial polymorphism was *Vibrio metchnikovii*. A filtrate of this organism through a Berkefeld candle gave no indication of the presence of filtrable forms but membrane filtration furnished a product which showed after remaining clear for 3 weeks some pleomorphic spheres. These spheres could be made to grow out into vibrios on nutrient agar. W F H

MERTENS (W. K.), MOCHTAR (A.), BAARS (J. K.) *Vergelykend onderzoek van *V. cholerae* en *V. El Tor* Mededeeling I [I. Comparison of *V. cholerae* and *V. El Tor*]* [MERTENS & MOCHTAR]—*Geneesk Tijdschr v Nederl Indië* 1938 Oct. 25 Vol. 78, No 43 pp 2642-2664 [Refs. in footnotes.] Mededeeling II *De reactie van Voges-Proskauer in de cholera-diagnostiek. [II Voges-Proskauer Test in Cholera Diagnosis.]* [MOCHTAR & BAARS]—*Ibid* pp 2665-2671 [10 refs.] English summary

[So many laboratories now preserve their own and the type strains of *V. cholerae* and *V. El Tor* that it is possible to obtain large numbers

of these for comparative purposes. The history of the cholera-El Tor controversy is well known. It is however of the utmost importance to distinguish between these two main types as decisions at frontier and other quarantine stations turn on the diagnosis made. The bacteriological procedure for making the decision is already almost stereotyped]. A summary of the conclusions arrived at by the authors may be given —

I (1) Cholera and El Tor strains belong to HERSKOV's type I. They form acid in glucose mannite maltose, saccharose and mannose but not in arabinose. (2) El Tor vibrios haemolyse goat erythrocytes in bouillon in 24 hours and develop a rose halo around their colonies on blood agar while cholera is non-haemolytic. (3) Cholera strains belong serologically to either the IKEDA or the OGAWA type. El Tor strains belong to the OGAWA type and only a few to the IKEDA type.

II All of the 178 strains of vibrios studied possessed certain common characters — (a) production of acid in glucose mannitol maltose, dextrose and mannose no acid in lactose and arabinose positive indole and cholera-red reactions (b) agreement with the "O" sub-group of GARDNER and VEKKATRAMAN

Out of the 178 strains 105 were non-haemolytic and are to be regarded as true cholera strains. They were all, except two, Voges-Proskauer negative. Seventy-one strains, being haemolytic, are of El Tor type and of these 62 were Voges-Proskauer positive and the remaining 9 negative.

BAARS (J. H.) Glucose-dissimilation door *Vibrio cholerae* en *Vibrio El Tor*. [Dissimilation of Glucose by *V. cholerae* and *V. El Tor*] — *Antonie van Leeuwenhoek Nederl. Tijdschr. v. Hyg. Microbiol. en Serol.* 1938. Vol. 5. No. 1. pp. 43-63. (Refs. in footnotes.) English summary. Also in *Geneesk. Tijdschr. v. Nederl. Indis* 1938. Nov. 15. Vol. 78. No. 48. pp. 2881-2890.

It is generally contended that cholera vibrios ferment glucose without production of gas and it has been shown that the formation of acid from carbohydrates is such that a culture is rendered sterile in 2 to 3 days. This last finding suggested that a research into the catabolic products formed from glucose necessitated the development of culture conditions which should, at least, be as favourable as possible to continued vibrio growth. The first medium used had the composition — glucose 5, difco peptone 5, di-pot. phosphate 5, sod. chloride 5, tap water 1,000 with pH 7.4. In the matter of continued growth and activity improvement was obtained by adding chalk to the medium to neutralize the acid formed and increasing the amount of glucose present. The medium now had the composition — glucose 20, difco peptone 5, sod. chloride 5, calc. carbonate 15, distilled water 1,000 with pH 7.2. In this medium, which was daily shaken and incubated at 27.5°C. abundant gas developed. The purity of the culture was checked at the end of the test. Analysis of the products of growth showed that both *V. cholerae* and *V. El Tor* gave as products — carbon dioxide, formic acid, acetic acid, lactic acid, succinic acid and ethyl alcohol. As one of the distinguishing characters of the two vibrios is that the cholera vibrio is Voges-Proskauer negative while the El Tor vibrio is V.P. positive, it was natural that the latter should be found to produce acetyl-methyl-carbinol with sometimes, traces of 2-3 butylene glycol or diacetyl. "The ratio of produced carbon dioxide

and fermented sugar was found to be for the V.P. positive *El Tor* strains 0 88 and for the V.P. negative *cholerae* strains 0 52.

MARRAS (F Maria) L'agglutination nell' identificazione del vibrione del colera non è specifica ed in molti casi non ha valore. [Agglutination not Specific in the Identification of the Cholera Vibrio]—*Ann d'Igiene* 1938 Nov Vol. 48. No 11 pp 649-663

Five vibrios isolated at El Tor during the pilgrimage of 1936 were from individuals without any sign of cholera. They produced indole were strongly haemolytic to sheep erythrocytes and agglutinated at dilution of 1 1000 with testing cholera sera for both O and O+H antigens. Similar results were obtained by absorption and cross agglutination tests. Again the same result was obtained with 27 vibrios isolated at El Tor during 1937 and with vibrios isolated in 1938. The conclusion is drawn that the cholera vibrio cannot be differentiated serologically from the vibrio El Tor

W F H

BERNARD (P Noël) GUILLERM (J) & GALLUT (J) Extraction de l'hémolysine du vibron d'El Tor. [Extraction of El Tor Haemolysin.]—*C R Soc Biol* 1939 Vol. 130 No 1 pp 23-24

It had been shown that it was possible to extract a haemodigestive ferment from the agar on which the cholera vibrio had been grown for 3 days [this *Bulletin* 1938 Vol. 35 p 308]. In the same way the El Tor vibrio impregnates the substance of the nutrient agar with its characteristic haemolysin which can be extracted. The method of extraction is to soak the agar in 0.9 per cent toluene-covered saline water of pH 8.2. This fluid is freed from particulate matter and residual organisms by frequent centrifuging but must on no account be filtered through a filter candle. It is saturated with ammonium sulphate and still the pH 8.2 must be preserved. A similar technique is employed to obtain haemolysin from a bouillon culture and the product may be 200 times more haemolytic than the original bouillon culture. It is not possible to extract by this technique a haemolysin from the cholera vibrio culture even when the organism exhibits a temporary haemolytic power on first isolation. If a suspension of cholera vibrios however is kept for 5 days at incubation temperature or a bouillon culture for 9 days it becomes possible then to extract a feeble haemolysin. The two substances thus extracted from El Tor and cholera vibrios respectively correspond, evidently from the conditions for their production to exohaemolysin and endohaemolysin

W F H

BERNARD (P Noël) GUILLERM (J) & GALLUT (J) Sur quelques caractères des hémolysines des vibriens cholériques. [Haemolysins of Cholera Vibrios.]—*C R Soc Biol* 1939 Vol. 130 No 3 pp 228-230

The hypothesis is presented here that one and the same haemolysin is common to the El Tor and the true cholera vibrios. In the former it is free and in the latter it is combined with a neutralizing substance. Would not, then, a certain variability in the amount of the two constituents of the complex suffice to explain what are certainly anomalous features of the cholera vibrio haemolysin?

W F H

[May 1939]

BERNARD (P Noël) GUILLEMIN (J) & GALLUT (J) L'hémolyse par le vibron d'El Tor et par son hémolytine. [Haemolysis by the El Tor Vibrio and by its Haemolysin.]—*C R Soc Biol* 1939 Vol 130 No 2 PP 147-148.

The haemolysin of the El Tor vibrio obtained by extraction (see above) produces a limpid red ruby colouration in the suspension of erythrocytes on which it acts, whereas the addition of a suspension of living vibrios from an agar culture brings about after some minutes at 37°C a violet turbidity. It seems probable that the violet colouration of the erythrocytes is a phenomenon of reduction. It does not occur if the vibrios are killed. This same violet tinting of a suspension of erythrocytes is also caused by glutathion or even yellow of egg. It disappears when haemolysis occurs.

W F H

DEL FAVERO (E) Influenza del fattore termico sul vibrione colerigeno e sue proprietà di fronte alla emolisi [Effect of Heat on the Cholera Vibrio and its Haemolytic Power]—*Arch. Ital. Sci. Med. Colon. e Perissit* 1938. July Vol. 19 No 7 pp. 430-431

Laboratory strains of the cholera vibrio which were agglutinable to high serum-titre and were non-haemolytic have been subjected to 15 passages and incubation at 20°C. There was no appreciable alteration in their agglutinability but the vibrios became strongly haemolytic in sheep erythrocytes, which were also agglutinated.

DE MOON (C E) Un vibron du type El Tor responsable dans la partie sud de l'île de Célèbes (Indes Néerlandaises) d'une épidémie présentant les apparences complètes du choléra. [An El Tor Vibrio as Cause of a Cholera Epidemic in Celebes.]—*Bull. Office Internat. d'Hyg. Publique* 1938 July Vol 30 No 7 pp 1510-1519

A description is given here of an epidemic of cholera or cholera-like disease in villages near Macassar the capital of the island of Celebes. The importance of the occurrence rests on whether the vibrio isolated can be truly designated as an El Tor type. Cases varied in their gravity from a cholera *sufferens* type where death supervened in a few hours to a cholerae or choleraic diarrhoea and even symptomless type. Rice water stools dehydration and development of oligæmia sicca. The outbreak occurred as one or two cases a day often at several days interval, without explosive development. The first epidemic of 1837 was not accompanied by bacillary dysentery but that of 1838, which raged during the rainy season, was accompanied by a serious epidemic of Shiga confirmed the cholera like characters morphological, biochemical and serological. The agglutination tests applied were those of the non-specific H agglutinin and that of the specific O agglutinin (Inaba and Ogawa type). These were positive as also was the Pfeif test. Haemolytic activity was shown for goat erythrocytes. About 400 strains were examined and they were all practically identical in particular they were distinctly haemolytic.

The author considers the disease here in question is endemic and not an accidental importation. Further examination of the vibrios and commentary on their position is provided by Professor van Loghem.

II F H

VAN LOGHEM (J J) Un vibrión El Tor pathogène isolé aux Indes Néerlandaises [A Pathogenic "El Tor" Vibrio from the Netherlands Indies].—*Bull Office Internat d'Hyg Publique* 1933 July Vol. 30 No 7 pp 1520-1523

Two of the vibrio strains 757 and 794 isolated by Dr de Moor in the Macassar epidemic described by him were sent to Professor van Loghem at Amsterdam for examination. This examination confirmed the diagnosis already made of a pathogenic El Tor vibrio in all respects. The most important characters of the vibrio were —(1) It gave the reactions of Heiberg's group I (2) The modified Voges-Proskauer reaction was positive (3) Marked haemolysis occurred in goat blood bouillon in 24 hours (4) Positive agglutination was manifested with anticholera serums HO and O (Gardner group I) and there was no loss of agglutinability of suspensions heated for 3 hours at 56-57°C. (5) Marked toxicity was shown for the white rat of 5-day bouillon cultures killed with phenol or as Seitz filtrates. These are the characters of an El Tor vibrio. Van Loghem as a result of his examination, says — On the assumption that the vibrio of Koch and the vibrio El Tor represent two different bacterial species I conclude that the Celebes outbreak is not identical with true cholera. With this dualistic view as basis I propose to distinguish the diseases caused by the two vibrios and to name that caused by the El Tor vibrio *enteritis cholerae formis* or more simply El Tor enteritis.

OMAR (Wasfy) Vibrio El-Tor Isolated from the Stools of an Egyptian who has never been to Hedjaz.—*Jl Egyptian Med Assoc* 1933 July Vol. 21 No 7 pp 415-428

At the Tor camp laboratory during the years 1930-1933 the number of stool examinations of returning pilgrims was 61,339 with isolation of 583 vibrios of which 77 were agglutinable El Tor vibrios. It is to be noted however that during the first 6 years only an HO serum was used whereas latterly a standard O serum has been used. The presumption is that the pilgrims pick up an El Tor vibrio while on pilgrimage and this seems to be substantiated by the examination of 1,532 Egyptians some years ago before they started no El Tor vibrios were discovered. Now the author has made examination of 1199 specimens of stools during the off-pilgrimage season. He has isolated 16 vibrios of which one was of El Tor type agglutinable with the H+O and O standard sera. The carrier of this vibrio is a woman who has never left Egypt. Although she suffers from cystitis she is in good general health and gives no history of any present or remote signs of any significant intestinal disturbance. The medium which has been found most satisfactory for isolation of vibrios is the glyco-coll haemoglobin medium of Vedder and Van Dam.

TAYLOR (J) & ARUJA (M. L.) Incidence and Characters of Vibrios in Waters in Northern India. —*Indian J Med Res.* 1938. July Vol 26 No. 1 pp 1-32. [12 refs] [Summary appears also in *Bulletin of Hygiene*]

The examination of water supplies for the type of vibrio present has a special bearing on the occurrence of vibrios in cholera stools other than typical *V. cholerae*. The authors practically insist that the typical *V. cholerae* is the vibrio which agglutinates with pure "O" serum of O group I (Gardner and Venkatraman). On the other hand "H" antigen may be possessed by many vibrios in common with *V. cholerae* so that agglutinability with Inaba "HO" serum may be due to this antigen and indicates that an "HO" serum is not satisfactory for the detection of the cholera vibrio. The investigation here reported was conducted to discover which were the vibrios found in water in parts of India not at the time visited by cholera. It takes into account like wise the cholera season by dividing the investigation into two parts: (1) Observations during the hot-weather and monsoon periods, and (2) Observations during the cold weather period. All types of vibrio of the Heiberg six groups were found although in very varying numbers. During the hot weather or monsoon the majority of the types belonged to Heiberg's groups I and II while in the cold weather vibrios from the same area belonged mainly to groups V and VI. Vibrios it has been found are almost universally present in unprotected wells, tanks and rivers in areas of Northern India where cholera is not endemic and their presence is in no way related to contamination from cholera sources. No isolated strain was agglutinable with pure "O" cholera serum, although "many of the strains showed O serological relationship with vibrios other than typical *V. cholerae* isolated from cases of clinical cholera and from carriers in Bengal and other parts of India." All these findings lead up to the deduction that vibrios other than typical *V. cholerae* isolated from cholera stools are probably water vibrios. "It is obvious say the authors, that with this almost universal distribution of vibrios in water including waters which may be used for drinking purposes, vibrios must frequently obtain entrance to the intestinal tract of those using the water and the appearance of such vibrios in stools of healthy individuals or in cholera cases is to be expected."

W F H

PANDIT (S R) & MAITRA (N M) Vibrios in Natural Water Sources in Assam. —*Indian J Med Res.* 1938. July Vol 26 No 1 pp 39-40

This short communication has reference to the vibrios isolated from open surface waters in Assam. The method used for isolation differed somewhat from other similar essays in that cultivation was carried out at a pH close upon 9.0. It was found that 33 strains isolated were monotrichate and 17 leptotrichate. A point worth noting is that *Bacillus faecalis alkaligenes* although giving the same fermentation reactions as the vibrios did not reduce nitrates or liquefy gelatin, and produced

alkalinity in milk. No material difference was noted in the incidence of vibrios or in their characters during the cold weather as compared with the hot weather period. *W F H*

PASRICHA (C L.) CHATTERJEE (D N.) & DAS (P C.) The Distribution and Characteristics of Vibrios Isolated from Certain Non-Human Sources in Calcutta.—*Indian Jl Med Res* 1938 July Vol 26 No 1 pp 33-37

This study deals with surface waters, tubed water supplies, flies and cockroaches as non human sources of vibrios. It takes its importance from a well attested fact that although the O inagglutinable vibrios are found in sewage or in polluted waters similar vibrios are occasionally found in the stools of cholera patients, carriers or contacts and their presence sometimes causes confusion in making a bacteriological diagnosis. From this finding arises the question whether such inagglutinable vibrios may not be choleric. By inagglutinability is meant non-agglutinability with pure O serum of the type group I of Gardner and Venkatraman for naturally they do agglutinate with O serum produced by their own O type of antigen. The summary of the authors' findings from an investigation of 300 samples of surface waters, 320 flies and 94 cockroaches is comprised in the statements that (1) The vibrios isolated from different samples of water from flies and cockroaches were all inagglutinable with Inaba O serum and (2) Biochemically the majority of the strains of vibrios isolated belonged to Heiberg's types I and II and very few to the other types. *W F H*

LAHIRI (M N.) & DAS (P C.) Vibrios from Certain Non-Human Sources.—*Indian Med Ga.* 1938 Nov Vol 73 No 11 pp 670-671

These non human sources were a variety of animals. The results of the examination of single specimens show that except for mules, mice and cats vibrios are found in the stools of the majority of the animals. From the number of positive isolations and the percentages which are given it is possible to calculate the number of animals of each species dealt with. A total of 195 animals of 13 different species was examined. Seventy five strains were examined in detail—all were inagglutinable with O Inaba serum, 33 were agglutinable to full titre with H + O serum, grouped according to Heiberg, 41 were of group I, 32 of group II and one each of groups III and VI. Indole production was positive in 54 and 16 were haemolytic to sheep erythrocytes. Bacteriophages active against the vibrios isolated from the animals were not found in a series of fifty stools. This with the irregular isolation of vibrios from the stools of laboratory animals suggests that vibrios are present in the stools of animals as contaminants. *W F H*

VARDON (A C.) & DATTA ROY (B K.) A Papain-Caseln Culture Medium for the Preparation of Bacteriophage and for General Laboratory Use.—*Indian Jl Med Res* 1938 Oct. Vol. 26 No 2 pp 379-392. [Summary appears also in *Bulletin of Hygiene*.]

Experiments were undertaken by the authors to find a cheap, unobjectionable, and satisfactory nutrient medium for general laboratory

use and for preparation of therapeutic bacteriophage. The papain mutton routine medium was not altogether satisfactory for the purpose. They have prepared a papain-casein medium which answers all requirements. It is a medium in which the nitrogen content is represented mainly by proteose and peptone. Full details are given of the technique of preparation. The relative cost of Witte's peptone medium, papain-mutton broth and papain-casein broth is given as 39 13.5 4.6 respectively and the new medium is described as suitable for the growth of ordinary bacteria, delicate bacteria and bacteriophage. Much of the work was done with *V. cholerae* and cholera-dysentery bacteriophage but *Bact. coli*, *Bact. typhosum*, *Bact. paratyphosum A* and *B. streptococci*, pneumococci and *N. gonorrhoeae* were also used.

GENEVRAY (J.) & BRUXEAU (J.) Utilisation de l'eau peptonée hypersalée comme milieu d'isolement du vibron cholérique [Hypersalted Peptone Water as Cholera Isolation Medium].—C. R. Soc. Biol. 1933, Vol. 129, No. 25, pp. 163-167.

It had been found that rapid and successive passages of culture from cholera stools were successful in the isolation of *V. cholerae*. Some disadvantages attached to the method because of the overgrowth of organisms like *Ps. pyocyaneus* and *Proteus vulgaris* especially when the stool sample arrived late in the day and the first culture obtained could not be dealt with till next morning. As an excess of salt such as 30-40 parts per 1,000 of peptone water did not inhibit the growth of the cholera vibrio the method now adopted—and with success—is to make up the peptone water with 20 gm. peptone and 30 gm. salt to the 1,000 cc. distilled water and adjust to pH 8.5. Ordinarily the procedure adopted is after sowing and an incubation of 8 hours at 37°C. to make a fresh sowing of one loop from the surface to nutrient agar and another to a tube of hypersalted peptone water. The next morning the agar tube is examined and fresh sowing made from an isolated colony. It may sometimes be necessary to sow again from the second peptone water tube to agar.

W F H

BANERJEE (D. N.) Culture du vibron cholérique anaérobie les variations de son pH et son pouvoir toxique. [Anaerobic Culture of the Cholera Vibrio].—C. R. Soc. Biol. 1939, Vol. 130, No. 1, pp. 32-34.

It was found that the cholera vibrio grew luxuriantly under anaerobic conditions in glucose media. Changes in pH of the medium are well known and these occur for both aerobic and anaerobic cultures whether ordinary or glucose media. In RAMON'S glucose medium, however the pH does not change whatever the oxygen conditions and therefore this medium, with the addition of glucose is the one to be preferred.

W F H

[No reference to RAMON'S medium is given in this paper but the following (RAMON, G. C. R. Soc. Biol., 1933, Vol. 112, p. 8) is probably the medium used—10 cc. HCl and 225 gm. fresh hog's stomach are digested at 45°C. for 2 hours. To this is then added 325 gm. veal finely minced, and the whole is well mixed. After 20-22 hours digestion is stopped by heating to 80-100°C., and the mixture is strained. The liquid is brought to pH 8 by means of soda lye and subsequently heated to 100°C. for 20 minutes, filtered and autoclaved. Glucose (1.5 to 2 gm. per litre) and sodium acetate (5 to 10 gm. per litre) are added after sterilisation.]

DEMONTE (A J H) & GUPTA (S K) Blood Culture in Cholera.—
Indian Med Ga 1938 Nov Vol 73 No 11 p 670

Blood cultures were made on 26 cholera patients and in 20 of these within 9 hours of the onset of symptoms. In no case was the cholera vibrio isolated. W F H

PASRICHA (C L) DEMONTE (A J H) & CHATTERJEE (B C) Vibrio cholerae from Material obtained by Liver Puncture during Life.—
Indian Med Ga 1938 July Vol 73 No 7 pp 405-406

In life cholera vibrios are capable of isolation from stools vomit or urine but no record exists of recovery from the liver. This has been done by the authors. A boy of 7 years developed cholera and on the third day complained of pain on the right side of the abdomen. An icteroid tinge was present in the conjunctivae which deepened into jaundice. By the seventh day he had become worse and liver dulness extended to below the umbilicus. Liver puncture was done and the few drops of blood obtained were inoculated into peptone water. The patient improved after the puncture and was well in about 14 days. Typical O-agglutinable smooth cholera vibrios had been isolated from the stools but not from the blood or urine. The liver puncture material gave a positive culture and again O-agglutinable cholera vibrios were obtained with all the same characteristics biochemical serological and bacteriophagic as vibrios obtained from the stools. W F H

CHATTERJEE (D N) & MALIK (K S) The Bacteriological Examination and the Hydrogen-Ion Concentration of the Urine of a Series of 122 Cholera Patients.—*Indian Med Ga* 1938 Oct Vol 73 No. 10 pp 612-613

No cholera vibrios were isolated from the urine of patients. The urine of 50 bacteriologically-proven cholera patients was found to be of pH 4.4 to 5.4 during the acute stage of the disease and to become normal with the subsidence of acute symptoms. W F H

CHATTERJEE (B C) Cholera its Diagnosis and Treatment.—*Calcutta Med Jl* 1938 Dec Vol 34 No 6 pp 508-528

OTSUO (G) Réaction d'agglutination des sérums immunisés par l'antigène O de vibron cholérique, au point de vue du diagnostic [Immune Sera from Antigen O in the Diagnosis of Cholera].—*Bull Office Internat d'Hyg Publique* 1938 July Vol 30 No 7 pp 1506-1509

GHOSH (H.) *B. pyocyaneus* Infection simulating Cholera and Acute Dysentery.—*Jl Indian Med Assoc* 1938 Sept. Vol 7 No 12 pp 655-656

Several patients were admitted to hospital with typical symptoms of cholera and blood in the stools. In the cultures of the stools made from 7 patients *Ps. pyocyanea* was found in five and no cholera vibrios

The organism too was highly virulent for the rabbit in a dose of 0.25 cc. of 22-hour broth culture. The author recollects a number of cases in the past with dysenteric symptoms in which *Ps. pyocyaneus* was isolated.

W F H

MASSIAS (Charles) A propos du traitement du choléra. Les injections intraveineuses de solution chlorurée hypertonique à 20%. [Intravenous Injection of 20 Per Cent. Hypertonic Saline in Cholera.]—*Rev Méd Française d'Extrême-Orient* 1933. Feb. Vol 16. No 2. pp 131-134 [26 refs.]

Many of the grave features of cholera are due to hypochloraemia. Chloropenia, in fact, is a more important symptom than dehydration. With this foundation to go on the author has made a practice of injecting as a matter of urgency 20 per cent sodium chloride intravenously in cholera. The dose has been 20 cc. and is repeated 12 hours later if necessary. In this way the loss of salt, which has taken place through vomiting and diarrhoea, is restored and so is diuresis. Mortality has been lowered to 22 per cent. It is possible that a 10 per cent. solution of salt may be a better concentration than 20 per cent. and, certainly a 30 per cent. concentration is harmful by producing tachypnoea and arterial hypertension.

W F H

THOMAS (Harold) & TENG (Lih-cheng) Innocuous Intravenous Infusion with an Appeal for the Establishment of Central Solution Laboratories for Cholera Relief.—*Chinese Med J.* 1933. Oct. Vol 54 No 4 pp. 358-368. With 1 fig [13 refs.]

Although dramatic results follow the administration intravenously of saline solution to cholera patients and to dehydrated patients suffering from dysentery and typhoid these are apt to be temporary and to be followed by dangerous symptoms. In fact the mortality among those receiving a saline injection might be higher than among those who do not. Experimental work has shown that these symptoms are due to pyrogenic substances in the distilled water used. The distilled water must be pure and must be maintained pure and ready for use. Four principles are to be followed in distillation — (a) Discard the first run of the distillate for a period of 15 minutes. (b) Distill slowly to avoid foaming. (c) Deconcentrate rapidly. (d) Cleanse still every six months." Other instructions are that no delay must occur over sterilization of the distillate which should be collected directly into glass- or enamel-ware containers. Sterilization of the distillate must take place as quickly as possible and not later than three hours. All tubing needles and glassware which are used for the operation of injection are cleansed with green soap solution and distilled water. Here also sterilization must be carried out within three hours. Only chemically pure salt and glucose are used in making up injection solutions. These precautions, while simple enough cannot be too carefully carried out.

It is stated that, with the technique adopted, 570 intravenous infusions of saline and glucose have been given "with not a single untoward reaction." An important and reasonable recommendation is made that — "Hospitals and Municipalities during cholera epidemics should cooperate for the preparation and wholesale distribution from

a central laboratory of fresh distilled water freshly distilled and sterilized water or better the saline or glucose solutions ready for infusion
W F H

BANERJEE (D N) Reaktion nach Salzlösunginfusionen bei Cholera. [Reaction after Saline Injection in Cholera.]—*Arch f Schiffs u Trop Hyg* 1938 Dec. Vol 42. No 12. pp 543-547

As a consequence of the intravenous injection of salt solution in cholera patients a rigor is a very common (81 per cent) result and it may be slight moderate or severe. The experience of the author was gained from 1 714 injections in 1 000 cholera patients and the principle followed was to regulate the injection so that its temperature should be as much above 36.7°C (98°F) as the rectal temperature was below it. Usually 1 pint of alkaline isotonic solution (sod chloride 90 grs sod. bicarbonate 160 grs. freshly sterilized tap water 1 pint) was given first followed by 1 to 6 pints of ordinary normal or hypertonic salt solution (sod chloride 120 grs. calc chloride 4 grs. freshly sterilized tap water 1 pint) according to the indication given by the specific gravity of the blood. A considerable number of the patients also received 25 to 50 cc of a 25 per cent glucose solution. It was found advisable before beginning the saline injection to reduce the high rectal temperature by an enema of 15 to 20 ounces of ice-cooled normal salt solution as in this way the reaction appeared to be diminished in intensity

OMAR (Wassif) The Bacteriophage in the Treatment and Prophylaxis of Cholera.—*Jl Egyptian Med Assoc* 1938 Aug Vol 21 No 8 pp 491-501 [21 refs.]

CHATTERJEE (S K.) & DEO (L. R S) Some Factors controlling the Activity of Bacteriophage and the Method of filling Medicinal Phials with Bacteriophage Suspension as practised in the Bacteriophage Laboratory Government of Bihar.—*Jl Indian Med Assoc* 1938 Dec Vol 8 No 3 pp 141-144

Treatment to be effective in a disease like cholera must be rapid and consequently the bacteriophage to be used in cholera therapy must be of quick acting type. It is on this account that the dominant phage used is of the A type which has a generation period of under one hour. Freshly isolated A phages are very unstable and have to be adapted to laboratory conditions and to as many strains of smooth vibrios as possible. It is this phage which can be separated in a large proportion of convalescents and this is held to be an indication that it is the phage mainly concerned in bringing about the cure of the patients. An endeavour should be made however to combine other cholera phages with the A phage and indeed the phage mixture issued for therapeutic purposes should contain all available types of phage. A very essential point in cholera phage therapy is also its administration in massive doses at the earliest opportunity. It may be used up to 9 months after preparation.

A filling process is described in which filtration of phage suspension and filling of medicinal phials are all done in one operation instead of two
W F H

SMITH (H F) *Revue des mesures adoptées pour empêcher l'introduction du choléra dans les îles Philippines en 1937* [Prevention of Cholera in the Philippines in 1937]—*Bull Office Internat d'Hyg Publique* 1938 July Vol. 30 No 7 pp 1524-1545. With 6 figs. on 1 plate

Cholera has ravaged the Philippines in the past and the stringent regulations now adopted can claim to have eliminated practically all danger of entry of the disease by sea. In 1902 there were notified 13 755 deaths from cholera and in 1903 there were 82,843. This state of affairs continued up to 1909 with variations from 472 to 28,868 deaths yearly. Since 1910 there have been accidental epidemics but none has attained the proportions of the earlier years. With the exception of one case in 1935 and one in 1937 the Philippines have had no cholera since the beginning of 1934. There is very direct and constant communication between Manila and Hong Kong which are distant only 36 to 48 hours by sea, so that the result attained is obviously due to the measures adopted for prevention of cholera entry by passengers or crew. Great attention is paid to avoidance of undue or indeed any delay to ships in taking or discharging cargo and such delay as is suffered by passengers who are suspect is made as pleasant as possible. The article consists of a description in most minute detail of how passengers and sailors are examined, how stools are obtained for examination and how the individuals concerned are identified with certainty. A study of this detail will be of great use to those engaged in the same practice or who propose to put similar procedure into operation. It is well to note that "in the Philippines the needs of quarantine demand that the discovery of the cholera vibrio in the stools whether agglutinable or not, suffices to label the person who has furnished the stool a carrier and to justify his isolation and his treatment." W F H

WAHBI (Subhi) *Rapport bactériolo-parasitologique sur l'examen des pèlerins au laboratoire de la quarantaine à Najaf (février-mars 1938)* [Examination of Pilgrims at Najaf.]—*Bull Office Internat d'Hyg Publique* 1938 Nov Vol. 30 No 11 pp. 2531-2533

The route across the desert from Irak to Mecca is important because it is the shortest for pilgrims from Afghanistan, Iran and Irak, and, moreover, gives the pilgrim an opportunity of visiting the holy places of Najaf and Karbala. Arrangements have been made for quarantine of returning pilgrims at Rabha near the Irak frontier and laboratory examination directed from Najaf. An *El Tor vibrio* has already been isolated and a considerable infection with pathogenic *Intest. All.* protozoa and helminths demonstrated among pilgrims. *Intest. All.* and water here

FEDERATED MALAY STATES. *ANNUAL REPORT* free hours. Only chemical research for the year 1938. Using up injection solutions. Director] [Cholera pp. 14-19. Such cannot be too carefully

A striking testimony to the technique adopted, "570 intravenous quarantine service is the technique adopted, "570 intravenous occurred in the territory. The preparation and wholesale distribution from

Malay States are four. This vaccine contains Inaba and Ogawa sub-types in approximately equal proportions with the idea of providing the various antigens required to produce a satisfactory immunization response. W F H

YU (H) The Virulence and Immunogenic Activities of *V. cholerae* in the Preparation of Cholera Vaccine.—*Chinese Med J* 1938 Sept Vol. 54 No 3 pp 255-258

The strains of *V. cholerae* used in this investigation were 37 isolated in Shanghai in 1932-36 and the Lister Institute strain. A conclusion is reached from experiments on mice that the smooth strains of *V. cholerae* vary in virulence and protecting capacity. Cultures used in the preparation of cholera vaccine should be selected because of their high virulence in animal test. W F H

PASRICHA (C L), CHATTERJEE (D N) & PAUL (B M) Studies on the Potency of Prophylactic Vaccines. I. Cholera Vaccine.—*Indian Med Gaz* 1938, Aug Vol. 73 No 8 pp 463-465

Cholera vaccines as used in India are of three main sources: recognized laboratories, local commercial firms and foreign. Fourteen examples of vaccines were examined for (1) sterility, (2) freedom from abnormal toxicity, (3) antigenic response in rabbits, (4) antigenic response in man and (5) protective value in guineapigs. It was found that—(a) All the vaccines were sterile and free from abnormal toxicity. (b) All the six cholera vaccines from recognized laboratories gave satisfactory antigenic response and protected guineapigs against 2 M.L.D. of *V. cholerae*. (c) Four of the eight commercial preparations of cholera vaccines produced cholera agglutinins and possessed protective properties and four vaccines gave uniformly negative results. W F H

CARO L'épidémie de choléra de 1937 à Haiphong. Les enseignements de la campagne de vaccination. [Vaccination at Haiphong in the Cholera Epidemic of 1937].—*Ann de Méd et de Pharm Colon* 1938, July-Aug-Sept. Vol. 36 No 3 pp 726-731

Recorded deaths and cases seem to show that the cholera epidemic of 1937 which visited Haiphong was one of the most severe of recent years. Some of its severity may be traced to the incursion of refugees. A remarkable effort was made by the authorities to apply anti-cholera vaccination on a large scale in record time to counter the menace. Vaccination began on 23rd September and had been carried out on 41,000 individuals by 3rd October. A total of 158,000 mainly concerned was reached. The dose administered was single and should be millions of organisms being designed to bring about with the A phage and indeed the number of persons. Ten days after the purpose should contain all available cases steadily decreased by lysis. An point in cholera phage therapy is also shown by hospital showed that 94 per doses at the earliest opportunity. It may be testimony to the value of preparation. the fact that in Haiphong
A filling process is described in which filtration on a large scale. It was and filling of medicinal phials are all done in one throughout the Tonking two

delta for long after. No evidence of any influence exerted by vaccination to mitigate the severity of the attack in the individual could be obtained. *W F H*

QUEMARD. Vaccination anticholérique. [Anti-cholera Vaccination.]
—*Rev Méd Française d'Extrême-Orient*. 1938. Apr Vol. 17
No 4 pp 416-425

There is abundant evidence that in Tonking a very active campaign of vaccination against cholera was undertaken for 6,500 000 inoculations were performed in the short space of 4 months.

Many reports were received of the efficiency of the vaccination procedure but these reports were by no means all favourable. *W F H*

MALARIA

PRÉCIS OF ABSTRACTS IN THIS SECTION

MACKAY (p 387) shows that in Dar-es-Salaam *A. gambiae* flourishes in the rainy season and *A. funestus* in the dry and that both are important in transmission which is therefore continuous. Carriers on the outskirts of the town form a permanent reservoir of infection.

BUSCH (p 388) gives information on malaria in the German navy during the war.

PARROT and CATANEI (p 388) show that premunition is established in Algiers about the tenth year of age. It is more ephemeral in *P. falciparum* infections than in the others and excessive prevalence of vectors causes violent *P. falciparum* epidemics from time to time partly because of the disappearance of premunition to that species. LEFEBVRE (p 389) reports that malaria in Laos is endemic and shows little variation from season to season. Epidemics are practically unknown. *P. falciparum* is the commonest parasite and *A. minimus* the most important vector.

CHRISTOPHERS and SINTON (p 390) enquiring into the history of the nomenclature of malaria parasites show that the common names *P. vivax*, *P. malariae* and *P. falciparum* are justified.

CIUCA *et al* (p 390) from studies of 3 strains of *P. vivax* conclude that individuals in Rumania are more susceptible to an imported strain than to one of local origin and if infected with a local strain possess a relative immunity towards an imported strain. Maintenance of a local strain in a non-endemic country did not bring about any change in it.

MISSIROLI (p 391) recounts the effect of the different races of *A. maculipennis* on the epidemiology of malaria. TOUMANOFF (p 391) found that the interval between feeding and egg laying of *A. hyrcanus* var. *sincensis* varies between 12 and 100 days in winter and is about 9 days in the hot weather. He has (p 391) succeeded in carrying this mosquito through two generations in the laboratory.

CICCHITTO (p 392) found a high degree of reticulocytosis in malaria especially in malarial anaemias. CARROT and FABIANT (p 392) describe a patient who died with an acute jaundice syndrome. Subperitoneal haemorrhages were found in the upper abdomen and the syndrome was ascribed to malaria. GREEN (p 392) describes malaria in 3 infants diagnosed by blood examination within two days of birth and MEASHAM (p 393) one in whom the blood was positive 17 days after birth in the non-transmission season.

SHUTE and BADENSKI (p 393) stress the importance of the diagnosis of the species of infecting Plasmodium and of aborting induced primary attacks of *P. falciparum* malaria at about the tenth day. A single negative blood film is not enough to exclude the diagnosis of malaria.

TRENSZ (p 394) describes Henry's reaction and CHORINE (p 394) shows that flocculation in distilled water closely resembles melanoflocculation. Melanin is merely an indicator and can be replaced by other substances. The reaction only becomes positive when the euglobulins form 32 per cent. of total serum proteins. The degree of dilution or concentration of hydrogen ions is the determining factor. The reaction has undeniable clinical value. SICAVLT and MESSERLIN (p 395) describe a method to determine the maximum dilution which gives a positive reaction. AZZI and DEL FRADK (p 395) found that serum from

non-syphilitic infants suffering from malaria may give positive serological tests for syphilis.

SIXTON (p 396) records the action of atabrin upon gametocytes of *P. falciparum*. DE MELLO (p 396) and also CHOPRA (p 396) review the drugs used in malaria. GÖRZ (p 396) considers cinchona febrifuge more effective than quinine, and GURST (p 397) found Malarene to be less so.

LUCHERINI (p 397) describes a patient suffering from chronic malaria who developed haemoglobinuria after taking atabrin but further treatment with atabrin produced no ill effects. LIVADAS *et al* (p 397) compared quinine, atabrin and plasmoquine in treatment of quinine and plasmoquine have special advantages. CHOREMIS and SPILIOPOULOS (p 398) record cases of temporary laryngeal and peripheral paralysis in children after the administration of atabrin and plasmoquine which are therefore neurotropic and should be given in courses not exceeding five days.

After testing mapharsen in the treatment of induced *P. vivax* malaria GOLDMAN (p 398) concludes that it is the drug of choice, being as effective as atabrin, easy to administer and safe. It has not been tested in *P. falciparum* infections.

NIYEN (p 399) tested sulphathiazole in the three malarial infections but found it to be much less efficient than quinine and much more costly but SORLEY and CURRIE (p 400) found it useful in *P. vivax* infections especially if followed by atabrin.

PIZZELLO (p 400) draws attention to the substantial identity of the mechanism of Ascoli's treatment and of natural climatic therapy and (p 400) describes these activations which occur after the completion of the Ascoli method of treatment. The late febrile manifestations differ from relapses in that recovery is spontaneous and the interval between the end of treatment and the onset of the reactivation attack varies inversely with the duration of infection.

SIXTON *et al* (p 401) found that Certuna failed to prevent infection with *P. falciparum* in experiments on five patients.

The Malaria Commission of the Council of Public Health of Holland (p 401) conclude that a therapeutic campaign is not at present practical. The killing of all *Anopheles* in summer and autumn should reduce malaria in the following year to one-fifth of its ordinary frequency but spraying with Shelltox should be performed every 14 days. This method is costly. As *A. maculipennis atroparvus* prefers water containing 1500 mgm. chlorine per litre to lower concentrations, the change of the IJsselmeer from salt water to sweet water will eliminate breeding places of this vector.

STROTHER SMITH (p 403) reports that the emptying of all water receptacles including tanks and irrigation ditches, from 6 a.m. to 9 a.m. on one day each week and the cleaning of the edges of larger collections of water has markedly diminished the prevalence of mosquitoes in certain cantonments in Northern India. MICHELSON (p 403) describes a method, depending upon a gunny screen supplied with oil by means of a wick for the continuous oiling of streams. KING (p 403) found phenothiazine in sulphonated petroleum oil and acetone to be an efficient *Culex* larvicide in the laboratory.

BRUMPT (p 404) considers that foreign bodies in the tissues of mosquitoes are liable to undergo chitination, and oocysts and sporozoites are no exception to this rule and chitin may be deposited

round groups of the latter. The presence of black spores of the type associated with malarial infection is an indication that infection has occurred.

COGGESHALL and EATON (p. 404) have prepared antigens from blood and spleen of infected monkeys which give complement fixation reactions with the serum of infected animals. Protective antibodies and complement fixing antibodies are probably distinct. EATON (p. 405) shows that in monkeys infected with *P. knowlesi* agglutinins appear between the 15th and 45th day which are specific for that species and act only on mature parasites. COGGESHALL and EATON (p. 405) show that in monkeys the interval between infection and appearance of parasites varies with the number of parasites injected but the severity of the disease does not. Serum from chronically infected monkeys will protect against death if suitably administered and the optimum protection is obtained with serum from monkeys superinfected seven times during the course of two months (COGGESHALL and KUMAR p. 406). C IV

COLONIAL DEVELOPMENT FUND (MALARIAL RESEARCH SCHEME)
Second (Final) Report of the Malaria Unit, Dar-es-Salaam for the Period November 1934 to December 1936 [MACKAY (R.) Malaria Research Officer Tanganyika Territory]—61 pp. With 10 charts 2 maps 4 plans 1 histogram & 22 figs. on 6 plates 1938 Dar-es-Salaam Govt. Printer [5s.]

The first report of the Dar-es-Salaam Malaria Unit was abstracted in this *Bulletin* 1936 Vol. 33 p. 225. This final report completes the narrative.

The local species of *Anopheles* are *gambiae funestus maculipalpis squamosus mauritanus* (and var. *lencobrosus*) *marshalli gambiae* var. *melas* and *nisi*. Only the first two are important vectors; some of the others have been caught in houses but none has been found infected. There is a retarding of the parasite development rate in *Anopheles* and a decrease in the number infected during the dry season. The average infection rates for three years 1934-36 were: *A. gambiae* oöcysts 2.15 sporozoites 3.46 per cent. *A. funestus* oöcysts 0.83 sporozoites 2.76 per cent. The numbers of *Anopheles* dissected were, *gambiae* 18,511 and *funestus* 19,055. *A. funestus* is as important as *A. gambiae* in the local transmission of malaria. The *gambiae* infection rate curve follows the rainfall curve; *funestus* flourishes best in the dry season. Thus malaria transmission goes on almost without remission. *A. gambiae* breeds in road puddles, hoof marks, gravel pits, and in similar small collections of water. It is a more urban species than *funestus* which breeds in grass-protected still water with varying degrees of shade. Examination of the pH of water of breeding places of the two species showed that pH 7.6-8.0 was most common. *A. gambiae* var. *melas* was found breeding in water with a saline content as high as 3,267 parts NaCl per hundred thousand; it has not been found infected.

Mean spleen rates for ages 0 to 5 were 88.2 and for ages 6 to 10 79.4 per cent. which are indicative of very early infestation. The infection rate is fairly constant throughout the year. The trend of the graph showing the number of parasites per cubic millimetre of blood follows closely that of the infection rate of *Anopheles*.

The anti-malarial measures that have been or are being taken, are fully described. Human carriers living on the outskirts of the

town are a permanent reservoir of infection for *Anopheles* breeding in the vicinity and thus intensify the infection of those living on the periphery of the controlled area. A protective zone free from uncontrolled dwellings is advocated. Attention is given to man-made *Anopheles* breeding-places and to how these should be avoided. Appendices reproduce the text of local legislation for the control of malaria and specimen copies of propaganda pamphlets.

This report together with its predecessor forms a very informing record of an unusually complete malaria survey Norman White

BRUCH (Hans-Gerhard) *Die Malaria in der Geschichte der Völker* [Malaria in the History of Populations].—Reprinted from *Veröffentlichungen d. Gebiets des Marins Sanitätsdienstes* 1938. No. 30 pp. 93-146. [89 refs.]

This is a thesis submitted for the degree of doctor of medicine by the author who qualified in 1937 and is now in the German navy. It is an interesting study of the literature of the subject. Some of the statistical data which he gives regarding malaria in the great war are taken from the official reports and are of considerable interest. Thus in the five years of war 1,068,848 men were mobilized in the German navy. Of this number 1,872, 1.77 per mille were attacked by malaria, including blackwater fever. Of the 1,872, 1,844 were returned fit for service 9 died, 1 was partially unfit for service. He considers that the small number of cases in the navy can be attributed to the special skill of German naval medical officers. He gives the following comparative table of malarial morbidity and mortality in Macedonia quoted from Ziemann —

	In the British Army			In the German Army		
	Attacked		Died	Attacked		Died
	Number	0/00	0'00	Number	0'00	0'00
1916	32,019	256.5	2.3	5,004	53.6	0.61
1917	71,412	391.1	1.3	16,672	141.2	0.92
1918	59,087	458.9	2.1	—	—	—

E. D. W. Greig

PARROT (Louis) & CATANET (Antoine) *Sur les facteurs d'apparition des épidémies de paludisme en Algérie.* [The Factors determining Epidemic Malaria in Algeria].—*C. R. Acad. Sci.* 1938 Nov 2. Vol. 207 No. 18 pp. 809-811

Exceptional circumstances enabled the authors to study the natural evolution of *falciparum* malar and *malariae* infections in a population of 1,878 Berbers very highly infected, without medical assistance, and temporarily protected from reinfection. Abnormally frequent and violent rainstorms prevented the formation of anopheline breeding places throughout the transmission season. Blood examinations of the entire population were made monthly or bi-monthly for 14 months.

Malarial infections were twice as frequent below the age of 15 as above that age. At all ages *P. falciparum* was most in evidence.

Between the ages of 11 and 15 the frequency of *falciparum* decreased about a third of *vivax* about a half and of *malariae* about four fifths. Above the age of 15 up to 50 the index of infection for all three species remained fairly constant. In all infected persons parasites were scanty in the peripheral blood especially in adolescents and adults. Gametocyte carriers were 5 per cent. of *falciparum* infected 42.8 per cent of *vivax* and 63.6 per cent of *malariae*.

These observations tend to confirm the observations of Edm. SERGEANT that premunition is established among the infected population of Algeria about the 10th year. It is less complete less early and more ephemeral in the case of *falciparum* infections than in those of *malariae* and *vivax*. The proportion of gametocyte carriers among the infected by the three species indicates that old cases of *vivax* and *malariae* constitute in Algeria more important reservoirs of endemic malaria infection than do old cases of *falciparum*. It is but rarely that *vivax* and *malariae* occasion violent epidemics. premunition against these species is more lasting. Excessive prevalence of anopheline vectors causes from time to time violent *falciparum* epidemics partly because the premunition acquired in the previous epidemic has in large part disappeared.

N IV

LEFEBVRE Recherches sur le paludisme au Laos (Investigation of Malaria in Laos).—*Rev Méd Française d'Extrême-Orient* 1938. Apr Vol 17 No 4 pp 336-354 With 3 graphs.

Reports have appeared from time to time regarding the prevalence of malaria in different parts of Laos but this is the first comprehensive report dealing with malaria conditions in Laos as a whole. Laos is a territory about half the size of France it forms a strip in parts a narrow strip of country running north-south between Annam the frontier with which is formed by a high mountain chain and the river Mekong which bounds it on the west. The widest northern part of the country is very mountainous. The only low lying area is found in the valley of the Mekong this narrow strip of flat land consists of rice fields and cleared forest. It is the most densely populated area. The rainy season is from mid-April to the beginning of October. The total annual rainfall varies from 1.70 to 3.70 metres according to locality.

With the exception of certain centres on the banks of the Mekong where malaria is little if at all endemic the rest of the country is severely infected. Very severe forms of the disease are encountered but these affect for the most part new arrivals. Judging from hospital returns the disease is most prevalent in the rains but the disease among the indigenous population is characterized by chronicity prevailing everywhere without intermission and with but little variation from season to season or from year to year. Epidemics of malaria are practically unknown. The spleen index of children from 2 to 12 years of age is 59 per cent and the parasite index 43 per cent. These are average rates for children from all parts. In some of the mountainous regions spleen and parasite rates from 60 to 90 per cent have been recorded. Excluding hospital cases parasites found were *falciparum* 63.9 *vivax* 20.4 and *malariae* 15.7 per cent. Splenic enlargement is less pronounced among *vivax* carriers than among *falciparum* and *malariae* carriers. Eighteen species of anophelines were found. *A. minimus* is the most important vector. Thanks to the

adaptability of its larval form this species persists throughout the year. In some localities and at certain seasons *A. maculatus*, *A. jeyporiensis* and *A. leucosplyrus* are effective vectors. Malaria is the most important cause of sickness and death in Laos. N IV

CHRISTOPHERS (Rickard) & SIXTON (J. A.) The Correct Name of the Malignant Tertian Malaria Parasite.—*Brit. Med. J.* 1938. Dec 3 pp 1130-1134 [32 refs.]

The authors of this informing contribution explain the causes and origins of the confusion attendant upon the multiplicity of names that have been bestowed upon the parasite of malignant tertian malaria. *Plasmodium falciparum* is now more generally adopted than it was a few years ago but there are authors who persist in calling the parasite *P. praecox* and some *P. immaculatum*. Uniformity is greatly to be desired. The account given of the earliest published descriptions of the three malaria parasites is of great interest. It explains why the *de jure* nomenclature of the parasites of benign tertian, quartan and malignant tertian malaria, viz. *Oscillaria vivax* (Grassi and Feletti), *O. quateriana* (Celli and Sanfelice) and *O. malarialis* (Laveran) was never generally adopted and how an opinion of the International Commission of Zoological Nomenclature justifies the adoption of the names now most commonly used, viz. *Plasmodium vivax* (Grassi and Feletti), *P. malarialis* (Grassi and Feletti) and *P. falciparum* (Wied.) N IV

CITCA (M.), BALLIF (L.), CHELARISCO (M.) & LAURENTE (N.) Contributions à l'étude de l'infection expérimentale au *Plasmodium vivax* (Etude comparée de trois souches du parasite.) [Experimental Infection with *P. vivax*. Comparative Study of Three Strains of the Parasite.]—*Arch. Roumaines Path. Expériment. et Microbiol.* 1937. Sept. Vol 10. No 3. pp 217-265. With 18 graphs.

Working in Rumania the author has investigated during a number of years three strains of *Plasmodium vivax* in their passage through series of paralytics. Two of these strains were of local origin while one was an imported one the "Madagascar" strain from Horton in England, where it had been maintained for some years. In these studies one of the local strains was sent to Horton, where it was maintained in paralytics for two years. It was then sent back to Rumania. Similarly, the "Madagascar" Horton strain yielded another line after it had been kept for some time in Holland, again at Horton and finally in Rumania. The object of these transfers was to discover if there was any difference between the influence of a malarial and a non-malarial country. The various passages amounting to many hundreds, were effected mostly by blood inoculations but from time to time mosquito transmissions were effected.

The studies involved a careful morphological investigation of the strains at different stages and a detailed analysis of the case records of each patient from the point of view of incubation period, duration and height of fever, tendency to spontaneous recovery, response to drug treatment and the many other characters which may be grouped under the heading of biological features. The paper is a long one and contains numerous protocols which will have to be studied in detail by those who wish to weigh the evidence on which the conclusions

are based. They are these: The individuals inoculated are more susceptible to an imported strain than to one of local origin. The maintenance of a local strain in a non-endemic country did not bring about any change in the strain. Individuals who have been infected with a local strain have a relative immunity towards an imported strain. As regards their response to drug treatment it was not possible to distinguish between imported and local strains. C. V. Henry

MISSIROLI (A.) Varieties of *Anopheles maculipennis* and the Malaria Problem in Italy—Internat. Congress of Entomology, Berlin 15th-20th Aug. 1938. With 6 figs on 1 plate 2 maps & 1 graph.

The author retells the story of the observations and investigations that led to the identification of the different races or varieties of *A. maculipennis* and shows how the geographical distribution of these varieties with their differing biological characteristics explains the vagaries of malaria distribution in Italy. The author's own contributions to these observations have been important. The paper is interesting but contains nothing that has not been previously published and duly noted in this *Bulletin*. N. H.

TOUMANOFF (C.) Au sujet de l'asthénie observée chez les femelles de *A. hyrcanus* var *sinensis* du Tonkin pendant la période hivernale et de ses conséquences probables dans la transmission du paludisme [On the Retarded Winter Development ("Asthenia") in Female *A. hyrcanus* in Tonking, and on the Relation of this to the Transmission of Malaria by this Insect.]—*Bull. Soc. Path. Exot.* 1938 Oct. 12. Vol. 31 No. 8 pp. 733-736.

In Tonking *Anopheles hyrcanus* var *sinensis* does not actually hibernate but the interval between feeding and egg laying becomes greatly extended in winter. It may apparently range from about 12 days to over 100, the period in the hot weather being about 9 days. At the cold time of the year the females which are to some extent domestic feed readily which may give the species considerable importance locally as a vector of malaria. The author develops the parallel between this species and *A. maculipennis atroparvus* of Holland. In certain other species of mosquitoes which have been studied in Tonking the effect of winter in retarding the development of ovaries is not so great as it is in *hyrcanus*. P. A. Buxton

TOUMANOFF (C.) Les résultats de l'essai d'élevage au laboratoire de *A. hyrcanus* var *sinensis* Wied. [Rearing *A. hyrcanus* var *sinensis* in the Laboratory]—*Rev. Méd. Française d'Extrême-Orient* 1938 Apr. Vol. 17 No. 4 pp. 355-364. With 4 figs. [19 refs.]

Anopheles hyrcanus var *sinensis* has been carried through two generations in the laboratory. Some difficulty was encountered for a large proportion of the females which emerged failed to become fertilized. The total number of species of *Anopheles* which have been bred successfully in the laboratory is still few. [See also this *Bulletin* 1938 Vol. 35 p. 194.]

The author also discusses what is known at present about the structure of the surface of the egg of this species. It is already known that this species produces eggs of several different types but whether the differences are genetic or due to environment is not known.

The paper contains a discourse on the views of ROUBAUD about stenogamy which is consistently mis-spelt sibengamy

P A Buxton

CIOCHITTO (Angelo M.) Reticolociti e infezione malarica. [Reticulocytosis and Malarial Infections.]—*Riv di Malarologia* Ser I 1938 Vol 17 No. 4 pp 282-287 French summary

A study of eighteen cases of malaria in the tropics, with special reference to reticulocytes led to the following conclusions. A moderate or high degree of reticulocytosis is observed in malarial infections, and is most marked in malarial anaemias. There appears to be no relationship between the degree of reticulocytosis and the species of malaria parasite, but the former does vary directly with the degree of malarial anaemia and also with the splenic index in primary infections. In cases of malarial haemolytic jaundice reticulocytosis is well marked and persists until recovery is complete. Specific treatment brings the number of reticulocytes within normal limits *pari passu* with the return of the blood to normal

CARROT & FARIANI (G.) Syndrome douloureux abdominal palustre. [Painful Abdominal Syndrome in Malaria.]—*Bull Soc Path. Exot.* 1938 Nov 9 Vol 31 No 9 pp 841-843

An Algerian aged 21 suffered from chronic malaria of long standing. He was admitted to hospital with the symptoms of acute appendicitis and was submitted to operation. The appendix appeared to be practically normal. Three months later he was once more admitted to hospital suffering from abdominal pain, diarrhoea, vomiting and fever. *Schizonts of falciparum* were found in the blood. He was treated with quinine the temperature fell and the symptoms improved. A week after the beginning of the attack fever returned, bilious vomiting and jaundice appeared. The abdomen was very painful and there was marked rigidity in the epigastric region. scanty urine albuminuria, blood urea 0.95 and very numerous parasites in the blood. Quinine was given intramuscularly and intravenously. The patient died. Post-mortem examination showed enlarged liver and spleen. There were small sub-peritoneal haemorrhages, either discrete or in patches more or less circular and measuring several centimetres across. These haemorrhages were confined to the upper part of the abdomen. Most were in the submesocolon chiefly in the cavity behind the omentum, or near the base of the omentum along the course of the great mesenteric artery. The mesenteric glands were slightly enlarged. There was no perivisceritis.

The patient thus died with an acute jaundice syndrome. The pain and the lesions were both confined to the upper part of the abdomen. It would seem then that an acute malarial abdominal syndrome can be caused by sub-peritoneal haemorrhages. The authors are tempted to postulate an involvement of the sympathetic nervous system in this case.

GREEN (J G.) Three Cases of Subtertian Malaria in the Newborn.—*West African Med J* 1938, Oct Vol. 10 No 1 p. 42.

A woman at full term was admitted to hospital suffering from severe malaria. a child was born after an easy labour 24 hours later. The placenta appeared normal and no parasites were seen in the baby's

blood. The following day the infant died in coma with hyperpyrexia. On post mortem examination the brain was found to be congested and four parasites per field were seen in smears of blood from the cerebral veins.

The second case was that of a primipara who had two rigors during labour. malaria parasites were found in the blood. The child was born cyanosed and comatose. No parasites were found in blood from the cord and the placenta appeared normal. The infant's blood contained parasites, however four to the field. Both infant and mother made good recoveries under quinine treatment.

In the third case an infant two days after a normal labour had an attack of malaria. parasites were found in the blood. Quinine effected a cure. The mother showed no clinical signs of malaria, but four days after delivery her blood contained malaria parasites.

MEASHAM (J. E.) A Case of Congenital Malaria.—*Trans. Roy. Soc. Trop. Med. & Hyg.* 1938 Nov. 28 Vol. 32 No. 3 pp. 423-425. With 3 charts.

A primipara suffered during the 16th week of pregnancy from an acute attack of *vivax* malaria which was treated with atabrin. A relapse in the 38th week also treated with atabrin caused the onset of labour. At the time of delivery no parasites were found in the peripheral blood of the mother nor in the blood of the infant which was examined daily for 10 days. Placental smears showed numerous *vivax* rings, schizonts and gametocytes. When 17 days old the infant had a temperature of 102°F. Its blood then contained *vivax* rings, schizonts and gametocytes. This occurred in the non transmission season when careful search failed to find a single specimen of *A. fluviatilis* the only proved local carrier. The author considers this to be a definite case of congenital malaria.

SHUTE (P. G.) & BADENSKI (G.) A Study of the Numerical Prevalence of Asexual Parasites in Primary Malaria.—*Arch. Roumaines Path. Experim. & Microbiol.* Paris. 1937 Dec. Vol. 10 No. 4 pp. 453-459. With 7 charts on 2 folding plates.

Seven cases of primary induced malaria, three *falciparum*, two *vivax* and two *malariae* were studied. Blood films were made and parasites counted by Sinton's method, twice daily. The authors found that during the first few days it is often impossible to find parasites. This is markedly so in *malariae* infections, frequent in *vivax* infections but less frequent in *falciparum* infections. The primary fever in all three infections is in most cases intermittent (remittent?). Fever of this type persists longer in *falciparum* than in other infections, often 7 to 10 days. The necessity for aborting *falciparum* attacks is urgent on or about the tenth day. It is generally advisable in *vivax* infections but *malariae* infections may generally be allowed to continue unchecked. In *vivax* infections the number of parasites in the blood is of less importance than the number of generations of parasites. The lowest parasite counts are found in *malariae* infections. In the interest of the patient it is not of first importance to find out how many parasites he has in the blood. It is important to diagnose the species and to determine whether it is a primary attack. Greater care is needed in the treatment of primary cases than of relapses and *falciparum* cases.

call for more careful treatment than do *typhus* and *malaria* infections. When fever is intermittent (remittent?) a single blood film is not sufficient to exclude the diagnosis of malaria. If necessary blood films should be examined three or four days in succession before deciding that the case is not malaria.

TREKSZ (F) *Technique de la mélanoflocculation de Henry modifiée.* [Modified Technique of Henry's Reaction.]—*Arch Inst Prophylactique* 1938 July-Sept. Vol. 10 No. 3. pp. 217-221

A detailed account of the technique of Henry's reaction including the preparation and standardization of the reagent.

N IV

CHORINE (V) *La réaction de Henry.* [Henry's Reaction.]—*Arch. Inst. Prophylactique* 1938. July-Sept. Vol. 10 No. 3 pp. 202-216. With 1 fig.

This is an excellent account of Henry's reaction and sets forth the author's views of the nature of the reaction which are founded on prolonged research and are well known. The reaction is not due to the presence of antibodies in the serum. Melanin has neither the properties of an antigen nor of a toxophore group except for organisms normally deprived of this pigment. Positive reactions are met with in diseases in which there is no production of pigment, and in fowl malaria the feebly positive reaction normally found in fowls decreases during the course of the disease. The intensity of the reaction may vary from day to day in the same serum kept on ice. The reaction only occurs in distilled water or in hypotonic solutions: this is unlike the behaviour of antibodies. Flocculation in distilled water closely corresponds to melano-flocculation. The action of melanin is that of an indicator in which rôle it can be replaced by numerous other substances. The chemical mechanism of the reaction is complex: the chief rôle is played by euglobulins. The precipitation of euglobulins is only evident in a dilution of 1 in 10 without an indicator or of 1 in 4 or 5 with an indicator. A positive reaction only occurs when euglobulins form 32 per cent. of the total proteins of the serum: above this amount the intensity of the reaction is proportional to the quantity of euglobulin present. Malarial euglobulins have no special affinity for melanin: they differ in no way from the euglobulins of normal serum. Heating the serum to 55°C. for half an hour abolishes the melanin reaction: this is due to the alkalization of the serum consequent on the loss of CO₂. From the clinical point of view the measurement of flocculation of the serum in a dilution of 1 in 10 distilled water gives similar results to its measurement in a 1 in 5 dilution with an indicator added. In therapeutic malaria Henry's reaction becomes positive from the 3rd to the 5th day after injection of malarial blood. The reaction has undeniable clinical value. A negative reaction during a period of apyrexia excludes a diagnosis of malaria: a positive reaction is a sign of probability.

N IV

CHORINE (V) *La réaction de Henry n'est due qu'à des modifications quantitatives dans le sérum.* [Henry's Reaction only due to Quantitative Changes in Serum.]—*Bull. Soc. Path. Evol.* 1938 Nov 9 Vol. 31 No. 9 pp. 838-840

The author restates his view that flocculation produced by distilled water and the flocculation of Henry's reaction are essentially the same.

They are exactly parallel phenomena. Dilution of the serum with hypotonic solutions of ammonium chloride renders the euglobulins unstable. The greater the proportion of insoluble proteids to total proteids the more rapidly is this instability brought about. Another very simple method of rendering the euglobulins unstable is to lower the pH of the serum to near the isoelectric point of globulins. No matter what serum is acidified with hydrochloric acid it flocculates with melanin in certain limits. The addition of more acid prohibits flocculation. The degree of dilution or concentration of hydrogen ions in the serum is the determining factor. Malarial euglobulins have no special affinity for melanin. The author describes experiments proving his contentions.

SICAULT (G.) & MESSERLIN (A.) Note sur une technique nouvelle de mélanoflocculation en échelle. [New Technique for Graduated Melanoflocculation Test.]—*Bull Soc Path Exot* 1938, Nov 9 Vol. 31 No 9 pp 834-837

In the absence of a photometer which not every laboratory possesses it is not possible to measure the intensity of flocculation either with the technique of Henry Villain or Trenszt. It is the same with the distilled water reaction of Chorine. For this reason the authors of this paper have designed a method to determine the maximum dilution which gives a positive reaction. The test is carried out as follows —

Three rows of haemolysis tubes or preferably 7 mm tubes which the authors use for their micro-reaction are set up seven tubes in each row. In the first row are put dilutions of serum in NH_4Cl 9/1000 pH 7. The dilutions are 1/3 1/10 1/20 1/50 1/100 1/200 1/400. In each tube of the second row are put 9 drops of diluted antigen 1 in 5 (soluble melanin diluted with NH_4Cl 4 5/1000 pH 7). The third row are control tubes containing similar dilutions of serum to those in the tubes of the first row but in this case the diluent is NH_4Cl 4 5/1000 pH 6. Two drops from each tube of the first row are then put into the corresponding tube of the second row and shaken. The results are read at the end of three hours. In positive cases there will be a thick brown deposit in dilutions 1/3 to 1/10 and flocculation will be observed in higher dilutions, to a degree varying in different cases.

In the discussion of this paper V CHORINE said that it is more important to determine the maximum quantity of serum which will produce flocculation. This indicates the degree of instability of the serum. The minimum dose of serum capable of producing flocculation has a less precise significance.

AZZI (Antonio Sellek) & DEL FRATE (Alejandro) Reacciones serológicas de la sífilis y paludismo en la infancia. Revisión de la literatura y experiencia personal. [Serological Tests for Syphilis in Infants with Malaria Infection.]—*Archivos Med Infantil* 1938 July-Aug-Sept Vol. 7 No 3 pp 388-393 [17 refs] English summary

Diametrically opposite opinions have been expressed regarding the results of serological tests for syphilis in malarious subjects some maintaining that positive reactions may be given by the sera of malaria patients in whom there is no indication of syphilis others that such results are due to concomitant syphilis or the residue of former infection.

The authors have tested sera from twenty children 15 of whom were infected with *P. falciparum* and five with *P. vivax* but in none were there any signs of syphilis. By the Kahn technique two with *falciparum* infection gave positives (one plus, and three plus) and one with *vivax* gave a two plus, i.e. 3 of the 20 gave some degree of positive. By the Meinicke (K.R. II) three gave a one plus, also two *falciparum* and one *vivax* (but the two *falciparum* patients were not the same as those giving the reaction by the Kahn method) by a third method—a modification of M.K.R.II—five positives were obtained, the *vivax* as above and four *falciparum* patients, two of the latter (four plus) being patients whose sera had reacted negatively to the other two tests. The authors conclude that malaria may give positive reactions during an attack of fever. [These small figures are given as percentages 15 15 and 25 to the respective techniques if weak and strong be taken together] H H S

SINTOX (J. A.) The Action of Atabrin upon the Gametocytes of *Plasmodium falciparum*.—*Riv. di Malarologia* Sez. I 1938. Vol. 17. No. 5. pp. 305-330. With 1 chart 2 text figs. & 23 coloured figs. on 1 plate. [48 refs.] English summary

A summary of the observations recorded at length in this paper was presented by the author to the Royal Society of Tropical Medicine and Hygiene and was reproduced in this *Bulletin* 1938 Vol. 35 pp. 894-5.

DE MELLO (I. Frolano) Chemoprophylaxis of Malaria in Portuguese India.—*South African Med. J.* 1938. Oct. 8. Vol. 12. No. 19 pp. 710-724. [46 refs.]

The title of this paper inadequately describes its contents. Therapeutics of malaria more nearly describes its scope for the vast majority of remedies that have been used in the treatment and clinical prophylaxis of malaria are passed in review and compared. No original observations are recorded. N II

CHOPRA (R. N.) Anti-Malarial Remedies. Natural and Synthetic.—*Calcutta Med. J.* 1938. Sept. Vol. 34. No. 3. pp. 183-193. [14 refs.]

This is an adequate description of the relative value of cinchona derivatives and synthetic drugs in the treatment of malaria for the guidance of the medical practitioner. It contains nothing original. V IV

GOMZ (Ramkrishna N.) Cinchona Febrifuge in the Treatment of Malaria.—*Indian Med. Gaz.* 1938. Oct. Vol. 73. No. 10 pp. 608-609.

Clinical experience has led the author to the conclusion that cinchona febrifuge is more effective than quinine in the treatment of malaria more effective in the reduction of splenomegaly and in the prevention of relapse. He appears to have used both drugs in smaller doses than those usually employed. The laxative effect of cinchona

febrifuge is referred to Cinchona febrifuge is of special value in rural communities honey which is available in villages is a good vehicle for making pills for adults or paste for children. N IV

GUEST (Columba) The Treatment of Malaria with Malarene.—*Bull Inst Med Res Federated Malay States* 1937 No 1 8 pp With 4 graphs.

Malarene is a proprietary preparation The manufacturers state that it contains the amorphous alkaloids of cinchona an alkaline nitrophenate and other valuable ingredients of strong antimalarial properties Fifty cases of acute malaria were treated in alternating sequence with malarene and quinine Malarene was inferior to quinine in controlling fever and in causing the disappearance of parasites from the peripheral blood Malarene gave rise to no toxic effects but some patients treated with it complained of headache and giddiness. N IV

LICHERINI (Tommaso) Primo caso in Italia di emoglobinuria da atebirin [First Case reported in Italy of Haemoglobinuria associated with Atebrin Treatment of Malaria]—*Polidimico Sez. Prat* 1938, Oct. 10 Vol 45 No 41 pp 1849-54 1857-9 With 1 chart

This is a long and detailed description of a case of haemoglobinuria in a patient who had been suffering from malaria of long duration During the three days previous to the onset of symptoms of haemoglobinuria the patient had been taking three tablets of atebirin a day and no other drugs It is interesting to note that after her recovery the patient was again treated with atebirin without any ill effects. A very high degree of leucocytosis up to 44 000 was noted during the attack of haemoglobinuria Some preliminary work on the haemolytic properties of atebirin *in vitro* is reported. A short discussion of the literature of malarial haemoglobinuria is also included N IV

LIVADAS (G) CANELLAKIS (A P) & VALAORAS (V G) Observations on Action of the Antimalaria Drugs in Greece.—*Riv di Malarologia Sez. I* 1938, Vol 17 No 4 pp 268-290 With 3 figs.

This is a careful record of the treatment of 112 cases of malaria in a mountainous village (population 900) in the north of the Peloponnesus The number of cases is small but the fact that the patients were kept under continuous observation for a long period of time gives value to the report The patients were divided into seven groups of about equal size the first three were treated with quinine the course of treatment lasting 7 10 and 20 days respectively One group was treated with atebirin one with plasmoquine one with atebirin followed by plasmoquine and one with quinoplasmin The doses given were those now generally recommended Atebrin displayed the quickest effect upon fever plasmoquine alone was the least efficient as a febrifuge Quinoplasmin was the most active in the reduction of splenomegaly Atebrin caused the disappearance of schizonts from the blood rather more rapidly than any other treatment The gametocytes

of *malarias* were more resistant to treatment than were those of *ruox*. Plasmoquine alone among the remedies used destroyed *falciparum* gametocytes. Quinine was more effective than the synthetic remedies in causing an increase in red cells and in their haemoglobin content. Quinoplasmin was most effective in preventing relapse. The conclusion is reached that the combination of atebirin and plasmoquine and more especially the combination of quinine and plasmoquine have special advantages in the general treatment of malaria. N W

CHOREMIS (H.) & SPILIOPOULOS (G.) Paralytische Erscheinungen nach Gebrauch von synthetischen Antimalaria Mitteln. [Paralytic Manifestations following Administration of Antimalarial Synthetic Drugs].—*Deut Med Woch* 1938 Nov 18. Vol. 64 No 47 pp 1680-1682.

The author first describes the case of a child aged 3 years who suffered from benign tertian malaria for which he was given four intramuscular injections of quinine this was followed by two intramuscular injections of atebirin 0.1 gm daily after an interval of a day he received on the first day 2 tablets of plasmoquine simplex, 0.01 gm. in each on the second day half a tablet was given.

Two days after the taking of plasmoquine there occurred obstinate vomiting with aphonia and difficulty of swallowing marked exhaustion and atony of muscles, especially of the lower extremities. The aphonia and difficulty of swallowing disappeared in 2 days but the muscular atony lasted for 14 days. Later as he had still enlargement of the spleen and fever atebirin was again administered with the result that the same symptoms again developed aphonia difficulty of swallowing and general muscular atony the symptoms appeared to be due to paralysis of the laryngeal musculature.

In another case of a child of 1½ years paralytic symptoms followed a 5-day course of atebirin 0.1 gm. daily *per os* the larynx was affected and there was aphonia and difficulty in swallowing. In three other children there developed symptoms of peripheral neuritis following administration of atebirin *per os*. In two others paralysis of the lower extremities followed administration of atebirin *per os* 0.1 gm twice daily in one 8 days after taking the atebirin and in the other 10 days. In two other children following administration of plasmoquine simplex, 0.01 gm. daily for 8 days in one case and 7 days in the other symptoms of paralysis of the laryngeal muscles and the muscles of the lower extremities occurred in the respective cases.

The author concludes from a consideration of these cases that the valuable antimalarial synthetic drugs, atebirin and plasmoquine are neurotropic. Hence it is very important that a course should not exceed 5 days. Further persons suffering from malarial cachexia should receive smaller doses than those usually prescribed, and, if possible a course of one of the vitamin B preparations should be combined with them. E D W Gray

GOLDMAN (Douglas) The Use of Mapharsen in the Treatment of Malaria.—*Amer J Med Sci* 1938. Oct Vol. 196. No 4 pp 502-509 With 3 figs.

Mapharsen is a recently introduced arsenated benzene compound for the treatment of syphilis. It is thought to be the effective breakdown

product of the arsphenamines in the body. Its composition is meta-amino parahydroxy phenyl arsine oxide —

It is administered intravenously, the dose being from 0.04 to 0.06 gm according to the patient's weight. Injections may be repeated at intervals of from 5 to 7 days. The patient should be fasting. Information is given concerning 24 patients who had been treated with malaria therapy and who subsequently received mapharsen injections: eight temperature charts are produced. One case of naturally acquired malaria was also treated with the drug. All were cases of *vivax* infection. The results were strikingly good. Parasites disappear almost immediately after an injection: after 24 hours it is only rarely that a disintegrating parasite can be found in blood smears. Splenomegaly begins to disappear almost as rapidly. The timing of the injection determines the occurrence or non-occurrence of a further febrile attack after treatment. If a chill be due in less than 24 hours after injection it usually occurs; if not or if the injection be given at the height of a chill subsequent febrile attacks are eliminated. The author considers mapharsen to be the drug of choice in the treatment of malaria: it is immeasurably more effective than quinine, certainly as effective as atabrin; it is easy to administer and safe to use. It is much less toxic to debilitated patients than is neoarsphenamine or even quinine. A case of malaria associated with severe leucopenia responded favourably and with an increase of leucocytes. Recurrences after mapharsen treatment are stated to be rare. No opportunity occurred for testing the value of the drug in the treatment of *falciparum* infections.

N IV

NIYEN (J. C.) Sulphanilamide in the Treatment of Malaria.—*Trans Roy Soc Trop Med & Hyg* 1938 Nov 26 Vol. 32, No 3 pp 413-418 With 6 graphs

Eighty unselected cases of acute malaria were treated in Kuala Lumpur with sulphanilamide. Of these cases 34 were *falciparum* infections, 38 *vivax* and 8 *malariae*. As a control 68 cases (30 *falciparum* and 38 *vivax*) were treated with quinine. All patients were kept under observation for at least 7 days; parasite counts were made daily by Sinton's method. A red and white blood cell count, differential count, and Arneth index estimation were done at the beginning and end of the course of treatment. All patients were Chinese or Indians of the labouring class. The sulphanilamide used was prontosil album (Bayer) 3 grams a day in two doses for 7 days. To the controls quinine bihydrochloride in solution was given daily for 7 days, the dose being 2 gm. per 100 lb. body weight.

It was found that prontosil abolishes fever and parasites in the majority of cases of *falciparum* malaria but is not so efficient as quinine: in 5 cases parasites were still present at the end of the course. In *vivax* cases prontosil is still less efficient: parasites were present in the blood of 15 patients at the end of treatment and two still had fever. Prontosil

was not an efficient remedy for the 8 cases of *malariae* infection. Mosquitoes fed on four crescent carriers at the end of treatment were readily infected. The author concludes that prontosil is much less efficient than quinine is more dangerous (no toxic effects were observed, however in this series of cases) and is much more costly [See also this Bulletin 1938 Vol 35 pp 561 562, 566.] N IV

SORLEY (E. R.) & CURRIE (J. G.) Notes on the Experimental Use of Prontosil Album in the Treatment of Malaria.—*Jl Roy Nav Med Serv* 1938. Oct. Vol. 24 No 4 pp 322-325

Ten cases of *vivax* malaria in Asiatic labourers were treated with prontosil album, ten grams three times a day for four days. The drug caused rapid alleviation of the patients' symptoms, more marked than is obtained with other anti-malaria drugs. In some cases parasites persisted in the peripheral blood. Three of the cases relapsed soon after the prontosil treatment. The authors recommend that the prontosil treatment be followed by a five days course of treatment with atabrin N IV

PIZZILLO (Giuseppe) Riattivazioni da rimpatrio in malarici reduci dall'A O I. (Reactivation of Malaria among the Repatriated from Italian East Africa.)—*Riforma Med* 1938. Oct. 8 Vol 54 No 40 pp 1523-1525 [13 refs]

The author discusses the time necessary for the spontaneous, or climatic cure of malaria, in patients who have removed to a non-malarial locality and quotes the opinions of several authorities. A study was made of 200 case cards of malaria patients who were repatriated from Italian East Africa. Reactivation of the malaria parasite in such persons may be either early normal or late. In this and in other respects the reactivation is similar to that produced by intravenous adrenalin therapy. Much stress is laid upon the substantial identity of the mechanism of action of Ascoli's treatment and of natural climatic therapy. Ascoli's treatment offers certain advantages: it can be carried out anywhere and by it the patient can be more rapidly restored to health than he can by nature unaided. N IV

PIZZILLO (Giuseppe) Sulla cura di Maurizio Ascoli nelle infezioni malariche. Nota 4. I. Ulteriori ricerche sulle riattivazioni. (Reactivation of Malaria during and after Ascoli's Treatment.)—*Riv di Malarologia* Ser I 1938 Vol 17 No 4 pp 281-294 German summary

The author discusses the reactivation of the malaria parasite that is associated with Ascoli's treatment with special reference to the febrile attacks that are occasionally experienced after the conclusion of treatment. In 5 per cent of the chronic cases of malaria which have undergone the complete course of treatment without febrile manifestations signs of reactivation of the malaria parasite are met with during the first week following the completion of treatment. In chronic or recent infections with a greater tendency to relapse such post-treatment reactivations are encountered in 20 per cent of cases in the first week after treatment in 12 per cent in the two successive weeks. In recent infections reactivation occurs in the fourth, fifth or sixth week.

or even later in 7 to 9 per cent of cases. These late post treatment febrile manifestations differ from malarial relapses inasmuch as recovery is spontaneous without the administration of quinine or other specific remedy there is at the worst only slight and transitory splenic enlargement and they have little or no ill effect on the general condition of the patient or on the blood. The interval that elapses between the end of treatment and these attacks varies inversely with the duration of infection. N IV

SINTON (J. A.) HUTTON (E. L.) & SHUTE (P. G.) Unsuccessful Attempts at Causal Prophylaxis with Certuna in Malignant Tertian Malaria.—*Trans Roy Soc Trop Med & Hyg* 1938 Nov 26 Vol. 32. No 3 pp 419-422.

Certuna, originally called Cilonal [see also this *Bulletin* 1938 Vol. 35 pp 562 563 564] is a product of Bayer's Elberfeld laboratories it is a dialkylamino-oxyquinolylaminobutane. It has been shown to have a destructive action on *falciparum* gametocytes. The experiments described in this paper were designed to test the potentialities of Certuna as a true causal prophylactic of *falciparum* malaria.

A batch of *A. maculipennis* var *atroparvus* was infected with a Rumanian strain of *P. falciparum*.

One patient was bitten by five infected mosquitoes 25 minutes after receiving a dose of 0.06 gm. of Certuna. He received 0.02 gm. thrice daily for the next 6 days. Fever started on the 12th day following the bites and parasites were detected the following day.

The second patient received similar treatment except that the initial dose of Certuna was given 45 minutes before 160 000 sporozoites in Locke's fluid were injected. Fever started on the 7th day and parasites were found in a thin film, on the 10th day.

In a third case three doses of 0.02 gm. were given the day before and 0.06 gm. 25 minutes before the patient was bitten by 7 mosquitoes. The drug was given for the succeeding 5 days 0.06 gm. a day. Fever appeared on the 10th day and parasites on the 11th day.

In two further cases doses of 0.04 gm. and 0.06 gm. thrice daily for 7 days were unable to prevent the development of infection.

The drug was well tolerated but it failed in all five cases to prevent infection. The dosage of sporozoites was greater than is usually acquired in nature. N IV

VERSLAGEN EN MEDEDEELINGEN BETREFFENDE DE VOLKSGEZONDHEID 1938 July 26 pp.—Verslag over de jaren 1936 en 1937 van de malaria-commissie uit den Gezondheidsraad [SCHÜFFNER (W. A. P.) Chairman] [Report of the Malaria Commission of the Council of Public Health for 1936 and 1937]

There is much close discussion in this report on questions of importance in the field campaign against malaria. Some of it has been presented in various publications. The most instructive of the headings in the report are (1) Therapeutic measures. (2) Destruction of adult mosquitoes as an antimalarial measure. (3) Abolition of the breeding places of *Anopheles maculipennis atroparvus*.

(1) *Therapeutic measures*—Most of the observations here recorded relate to the prevention of relapses and the development of the so-called healthy parasite carrier. In this respect atabrin does not seem

to have been particularly satisfactory. Plasmoquine on the other hand, used as a 14-day cure, was efficacious in preventing relapses. A 14-day treatment however of all malaria sufferers did not make much impression on the infection rate of Anopheles. As a really satisfactory method of relapse prevention the Commission commended heartily the 3-week plasmoquine cure of SRETOW. Their final conclusion on this subject is a negative one. A therapeutic malarial campaign in Holland while not exactly impossible is under present conditions not practical.

(2) *Destruction of Adult Mosquitoes* — Theoretical considerations form the basis of this antimalarial measure. KORTEWEG maintained that a portion of the sufferers from malaria in a given year have received their infection in the previous autumn on the grounds that — (1) infected Anopheles are only found in late summer and autumn and almost exclusively in dwellings. (2) individuals infected as a test in autumn developed malaria in the following spring and summer. It is not all species of *maculipennis* however which participate, in Holland, in this autumn infection. Only *A. maculipennis atroparvus* in spite of beginning sexual inactivity continues to suck human blood in late summer. *A. maculipennis merrisi* whose egg-laying ceases during August, ceases also to suck blood. If then it is asked, all infected anopheles in human dwellings are killed off in late summer and autumn will all malaria be prevented and if not what malaria is to be expected in the following year? KORTEWEG would answer the question — Those cases of primary malaria which manifest themselves before the 1st May would be prevented. The house-spraying which was the method to be adopted for killing off infected Anopheles did not require to be applied altogether indiscriminately. Certain facts were taken into account — (1) Anopheles infection in late summer and autumn is restricted to a comparatively small number of houses which become centres of infection. (2) From these centres anopheles spread infection up to the end of October to neighbouring houses within a radius of not more than 100 metres. (3) About 4/5 of the persons who in a given year suffer from malaria live at most 100 metres distant from a centre of infection, which had existed in the previous summer and autumn. It was therefore the expectation of the Commission that killing of all Anopheles in late summer and autumn, in the village of Uitgeest for example should reduce its malaria of the following year to one-fifth of its ordinary frequency. A spraying campaign took place in 1936 and it was found that — (1) In a house that had been sprayed with the insecticide Shelltox not only were all Anopheles killed, but the house remained for 14 days thereafter less attractive for Anopheles. The quantity used was abundant amounting to 0.4–0.5 litres per house per treatment this is 5 to 6 times as much as is reckoned (0.08 litre) necessary for killing the Anopheles in a house. (2) After the spraying at the end of August the Anopheles were again numerous 3 weeks later in the treated house. Even after the 2nd and 3rd treatment in the middle of September and beginning of October mosquitoes returned, although now in small numbers. Strict avoidance of the possibility of infection required that sprayings succeeded each other every 14 days. The facts regarding malaria in Uitgeest are given as — (1) There were 343 primary cases in 1936 and 71 relapses from 1935. (2) In 1937 however there were only 31 primary cases and 25 relapses. The result may be regarded as satisfactory but although *Anopheles maculipennis atroparvus* is to be accepted as the most important vector of malaria in

North Holland the method of killing off this mosquito by spraying in autumn is considered somewhat costly for general adoption.

(3) *Abolition of breeding-places of A. maculipennis atroparvus*—It has been demonstrated that the density of the larvae of *A. maculipennis atroparvus* in water with salt content of 1500 mgm Cl per litre or higher is as much as twelve times that in water of 500 mgm. Cl per litre. The suggestion is made that as the IJsselmeer changes from salt water to sweet water the consequence will be the disappearance there of the breeding places of the malaria carrying mosquito.

STROTHER SMITH (F F) Anti-Mosquito Measures in Cantonments with Special Reference to "Dry Day" instituted in 1927—*Indian Med Gaz* 1938, Oct. Vol. 73 No 10 pp 606-608.

On one day a week in certain cantonments in Northern India all water receptacles must be empty from 8 a.m. to 9 a.m. Such receptacles include animal water troughs garden tanks and irrigation ditches in gardens small pits and bullock runs from wells etc. Fire buckets are emptied and immediately refilled. The edges of larger collections of water which cannot be emptied are kept free from grass and undergrowth. Such measures if rigidly enforced and carried out throughout the mosquito breeding season result in a markedly diminished prevalence of mosquitoes. Details of the special inspection staff employed are given. The author is experimenting with success with a spraying machine called the phantomyst for the destruction of adult mosquitoes. The cubicide used is a 3 per cent. solution of Lethane in kerosene oil. The machine produces a fine mist which penetrates well and is very economical. Five minutes spraying with a large model only consumes one ounce of fluid.

MICHELSON (E G) An Apparatus for Continuous Oiling of Streams.—*Indian Med Ga.* 1938, Oct. Vol. 73 No. 10 p 612. With 1 fig.

Oil screens are commonly used on small slow running streams in Assam. These are effective but sudden storms may sweep away all the oil. To obviate this the author describes a simple device. Two quart tins are securely wired one to each supporting upright of the screen just above high water level. Two pieces of wick $2\frac{1}{4}$ inches wide of double thickness have one end immersed in the tin where it is kept in place by a weight and the other stitched to the gunny or canvas of the screen. The gunny of the screen is wide enough to allow for rising water. The tins are filled with oil. A piece of wire prevents the wick resting against the outside of the tin and thus wasting oil. One quart of oil will give a continuous coating to the stream for eight days. Screens should be spaced about 130 yards apart but this distance varies with the configuration of the stream. The even flow of oil is unaffected by spates.

KING (W V) Experiments with Phenothiazine and Mosquito Larvae.—*Jl Econom. Entom* 1938 Oct. Vol. 31 No 5 pp 610-611

A solution consisting of 1 gm. phenothiazine in 20 cc. of sulphonated petroleum oil and 5 cc. of acetone was found to be an efficient *Culex* larvicide in laboratory conditions. The solution is mixed with water

before evaporation of the acetone occurs. The phenothiazine was fatally toxic to *Culex* larvae in dilutions of one in two million. Much more experimental work is required to determine whether this larvicide has a field of usefulness in practical anti-mosquito work. N IV

BRUMPT (E.) Fréquence et origine des Black Spores de Ross au cours de l'infection des stégomyies par le *Plasmodium gallinaceum*. [Frequency and Origin of Ross's "Black Spores" in *Stegomyia* infected with *Plasmodium gallinaceum*.—Ann. Parasit. Humains et Comparés 1938, May 1 Vol 16, No. 3 pp 220-241 With 2 figs. & 4 plates [34 refs]

In this article the author discusses the various theories which have been advanced as to the nature of the black spores which were first described by Ronald Ross in 1898 on the stomachs of mosquitoes infected with the bird malarial parasite. More recently REICHENOW (1932) found them in all of twelve *Theobaldia annulata* infected with the bird parasite *Plasmodium circumflexum*. In his work on the development of the fowl parasite *P. gallinaceum* in *Stegomyia fasciata* and *S. albopicta* the author has encountered black spores in 6 to 7.5 per cent of a large number of these mosquitoes fed once or twice on infected fowls. He does not agree that they represent resistant spores, or that they are instances of hyperparasitism or as maintained by Bruce MAYNE that they are derived from the smallest branches of the tracheal system. It is clear that foreign bodies either parasitic or not in the tissues of mosquitoes are liable to undergo chitinization and malarial oocysts in various stages of development and sporozoites are no exception to this rule. When the groups of black spores, rounded bodies or the more typical banana-shaped structures are of the size of malarial oocysts it may be concluded that they have been formed by the chitinization of oocyst contents. A similar chitinization of sporozoites which have been scattered through the body after rupture of mature oocysts may take place. In either case the banana-shaped black spores are considerably larger than individual sporozoites, so that it would appear that the deposit of chitin has occurred around a group of sporozoites rather than on a single one. Chitinous masses which are larger than malarial oocysts have probably been derived from other extraneous bodies. As an illustration of this FULLERON'S observation of a chitinized microfilaria (*F. repens*) in a Malpighian tube of *Anopheles maculipennis* is quoted.

In this study the author has never found black spores in mosquitoes which had been fed on uninfected fowls or on birds infected with the parasites which do not develop in the mosquitoes used. It can be accepted therefore that the presence of black spores of the type so frequently associated with malarial infections is an indication that malarial infection of the mosquito has occurred.

The paper is illustrated by text figures and four excellent plates depicting the various types of black spores encountered. C M W

COGGERHALL (Lowell T.) & EATON (Monroe D.) The Complement Fixation Reaction in Monkey Malaria.—Jl. Experim. Med. 1938, June 1 Vol. 67 No. 6 pp. 671-682. With 6 figs. [13 refs]

From the blood of infected monkeys or from the spleens in cases of intense infections antigens can be prepared which give a positive

complement fixation reaction with the serum of infected animals. The antigen must be liberated from the parasites either by freezing drying and grinding or by prolonged autolysis after which it is extractable by normal saline solution. Complement fixation substances appear in the blood of infected monkeys early in the infection. After the acute phase has been passed over by the use of quinine or immune serum there is a rise in titre followed by a fall. During the chronic phases there is a rise in titre after relapses. As regards the production of antibodies there is a marked variation amongst different animals some producing very little, others a considerable amount. It was noted sometimes that animals which produced large amounts of the protective antibodies previously described were bad producers of complement fixing antibodies. From this it would appear that the two antibodies differ from one another. In view of its failure to be extracted by lipid solvents and its destruction by tryptic digestion it would seem that the complement fixing antibody is of a protein nature. C M IV

EATON (Monroe D) The Agglutination of *Plasmodium knowlesi* by Immune Serum.—*Jl Experim Med* 1938 June 1 Vol 67 No 6 pp 857-870 With 4 figs on 2 plates [15 refs.]

The author has tested the serum of monkeys infected with *Plasmodium knowlesi* for the presence of agglutinins against these parasites. He has shown that such agglutinins appear in the serum of monkeys between the 15th and 45th days of an infection and that the titre rises as the infection subsides. The agglutination brought about by acting on infected red cells or on parasites liberated from haemolysed infected red cells can be recognized both macroscopically and microscopically. It is only the mature parasites which are involved in this agglutination. The sera of animals which have been superinfected a number of times may give agglutination at a dilution of 1:1000. The reaction is specific as the sera of normal monkeys or monkeys infected with other species of malarial parasite are quite inactive. C M IV

COGGESHALL (Lowell T) & EATON (Monroe D) The Quantitative Relationship between Immune Serum and Infective Dose of Parasites as demonstrated by the Protection Test in Monkey Malaria.—*Jl Experim Med* 1938 July 1 Vol 68 No 1 Pt 1 pp 29-38

It is shown that the minimal number of parasites required to produce *Plasmodium knowlesi* infections in *rhesus* monkeys is 1 to 10. The interval between the injection of parasites and their appearance in the peripheral blood varies with the number of parasites injected but the interval between the appearance of parasites and the death of the animal is unaffected by the dose. The severity of the infection is the same whether the infecting dose is small or large (1 or 100 000 parasites). Protective serum from chronically infected monkeys will protect against death if administered at the time of the injection of parasites and daily afterwards. There is moreover a definite relationship between the quantity of serum required to effect the protection and the dose of parasites injected. If before the parasites are injected they are incubated with immune serum for half an hour at 37°C. In some cases when the number of injected parasites was small the half hour's

incubation with immune serum, if relatively large in amount, resulted in the death of all the parasites, for their injection failed to produce infection
C M IV

COGGESHALL (Lowell T) & KUMAR (Henry W) Effect of Repeated Superinfection upon the Potency of Immune Serum of Monkeys harboring Chronic Infections of *Plasmodium knowlesi* — II
Experim Med 1939 July 1 Vol 68 No. 1 Pt 1 pp. 17-27
With 2 charts

The authors have already shown that the pooled blood from a group of monkeys in the chronic stage of a *Plasmodium knowlesi* infection contains antibodies which are able to diminish the effect of this parasite on newly inoculated monkeys to the extent that they are saved from death. The antibody content of the pooled bloods must be low as large amounts of the serum are required to bring about the protection referred to. In the present paper it is shown that if the chronically infected monkeys are superinfected seven times during the course of two months the antibody content of the pooled blood is considerably higher less serum being required to effect protection. If on the other hand, further superinfections are carried out, the antibody content diminishes owing it is assumed to the absorption of antibody by the large number of parasites injected

NYASALAND PROTECTORATE ANNUAL MEDICAL & SANITARY REPORT
FOR YEAR ENDING 31ST DECEMBER 1937 Appendix IV 27 pp —
Nutritional Review of the Natives of Nyasaland. Preface by A D
J B WILLIAMS, O.B.E. Chairman Native Welfare Committee
[Summary appears also in *Bulletin of Hygiene*]

This review contains a mass of clearly displayed information and is of special importance in that it appears to be the first nutritional study made of the natives of Nyasaland. The main part of the survey reviews the present conditions of nutrition in Nyasaland and deals with prison hospital and school dietaries labour conditions and dietaries cost of food nature of diet and dietary habits of the general population related agricultural conditions and problems deficiency diseases etc. This is followed by a review of further studies and researches which appear desirable with an analysis of foodstuffs an anthropological and nutritional survey and an investigation of the fishing resources of Lake Nyasa. Then follow reviews of practical measures which have been taken in the past to apply scientific knowledge to the improvement of nutrition and of further measures which it appears desirable to take in the future and of the consequences which improvements in nutrition may have on the economy of the Dependency. Other sections give the various questionnaires which were sent out for preparing the Report and a list of edible wild plants in Nyasaland. [So much material is contained in this short appendix that it is impossible to condense and summarize it adequately and the review should be read in full by all who are interested in the nutritional problems of native peoples.]

TEICHLER (G) Einige Besonderheiten bei ostafrikanischen Eingeborenen [Medical Observations among East African Natives].—*Arch f Schiffs u Trop Hyg* 1938. Sept. Vol. 42. No. 9 pp 421-427 With 5 figs

The author who writes from Mnyusi in Tanganyika Territory is in medical charge of sisal plantations. The labourers about 1,500 come from a variety of tribes as far away as Rhodesia and Mozambique. Malaria is severe in those from the highlands and may simulate epidemic meningitis. On Lake Victoria he saw several cases of anal stricture in women. All gave a positive Frei reaction. In other cases there was enlargement and induration of the labia and stricture of the vagina and in men hard swellings in the groin-glands region.

A case of firm growths in the nostrils regarded as yaws was shown microscopically to be one of rhinoscleroma. The vitamin question is acute and under careful study by the Administration. Prescurvatic symptoms—feebleness pallor palpitation, fatigue vulnerability (in the literal sense)—are not rare but the author has not seen true scurvy. Patients from Lake Tanganyika with anaemia and swollen feet are common. Hookworm is suspected but is rarely found and these patients bear drugs badly especially carbon tetrachloride. Salvarsan also is ill borne and a case of salvarsan rash is figured. A frequent symptom in these natives is night blindness coming on 2-3 months after they have left the interior. It is attributed to a lack of vitamin C. The author finds that the native diet at home and in the plantations varies little

and in the plantations includes more meat. The single difference seems to be the beer which they drink freely at home but in the plantations only on Saturday and Sunday. However he seems to doubt the adequacy of this as a cause of avitaminosis. [Do the plantation labourers cook their food themselves or is it overcooked for them?] He advises the regular administration of palm oil as a furnisher of vitamins A and C.

The rest of the paper is given to a discussion of Gillian's oedema with details of cases. The conclusion is that this is not a disease *suu generis* but has various causes among which malaria is prominent.

A. G. Baghurst

CONGO BELGE. Fonds Reine Elisabeth pour l'Assistance Médicale aux Indigènes du Congo Belge. Rapport annuel 1937. [The Foréami Service in the Belgian Congo. Report for 1937].—104 pp. With 2 figs. & 2 maps (1 folding). Bruxelles. 112 Rue du Commerce.

The 1937 annual report of the Foréami institution shows that the activities have been extended to cover two-thirds of the Kwango area. The organization is briefly described and it is again explained that the object is the repeated examination of the natives in their natural surroundings and the treatment of all individuals requiring it. The medical and sanitary staff have contributed 652 working months during the year [which corresponds to about 46 persons working for the whole time. More than half of these are doctors]. The native staff numbers 521 persons, and the number of persons medically assisted has now passed 900 000. Almost the whole of the population of Kwango have been provided with medical certificates. These figures give an idea of the magnitude of the undertaking.

Brief details are given of the various diseases treated, of which the chief were—10,258 cases of trypanosomiasis with 5101 cures [this section of the report will be abstracted elsewhere in this *Bulletin*], 3,628 of yaws, 2,045 of leprosy, 3,943 of ulcer and 52,542 of helminthiasis. Surgical operations numbered 376.

The social services include maternity and child welfare and village sanitation. A section on the demography of Kwango is included, and a list of the publications of the members of the staff is given. [See also this *Bulletin* 1935 Vol. 32, p. 501.] C IV

LEDENT (G.) & PILTIER (M.) Les maladies transmissibles observées dans les colonies françaises et territoires sous mandat pendant l'année 1935. [Transmissible Diseases in the French Colonies and Mandated Territories in 1935].—*Ann. de Méd. et de Pharm. Colon.* 1937. July-Aug.-Sept. & Oct.-Nov.-Dec. Vol. 35. Nos 3 & 4. pp. 748-928. 1207-1335. With 3 maps.

This Report covers a very wide field and it is only possible to indicate some of its contents. Its interest is lessened too owing to its late appearance.

It is arranged under Disease headings, each disease being considered in turn, as it occurs in the French colonies all round the world. First come the "pestilences"—plague, cholera, yellow fever, smallpox, typhus, then the endemo-epidemic diseases—malaria and blackwater trypano- zoon, dysentery, relapsing fever, intestinal parasitism, schistosomiasis, filariasis, dengue, beriberi, yaws, tropical ulcer. [We should exclude beriberi from this category.]

A few points of general interest or unfamiliar to the reviewer will be noted. Under plague in Senegal—among defensive measures against rats it is recommended to keep a zone round each village clear of cultivation but mamoc may be tolerated because the soil remains clean and easy of surveillance burrows can be promptly detected and fumigated and the rat never attacks the roots below ground.

Under yellow fever—of 14 cases in Africa (2 suspected) one was labelled acute ascending myelitis and there was no suspicion of yellow fever in life its nature was revealed by liver examination post mortem. Two of the subjects contracted infection in the bush which raises the question of jungle yellow fever. The evidence of malaria in Madagascar was noteworthy. Of 787 000 consultations in 646 000 or 80 per cent. this was the diagnosis and 10 000 were admitted to hospital. In Réunion Is. which was malaria free before 1869 half the consultations were for malaria. The D M S reports that the major cause is deforestation on high ground with consequent erosion of soil and obstruction of the beds of the rivers.

Under bilharziasis in Cameroon it is noted that 74 per cent. of infections were in boys between 5 and 15 years and 45 per cent. in girls after the introduction in the Chad area of shower baths in several schools, as a substitute for river bathing the incidence of infection fell. The trypanosomiasis section is a full one with many tables and sketch maps.

Diseases common to France and the tropics are treated in the second fascicle and a fourth category social diseases which includes leprosy. These do not call for comment.

A G. Bagshawe

COLONIAL OFFICE Pitcairn Island. General Administrative Report and Medical Report. (Colonial No 165)—79 pp. 1938. London H.M.S.O. [1s. 3d.] [Medical Report by Duncan COOK, M.D. M.R.C.P. D.P.H. pp. 52-79. With 1 chart.]

The chief interest of this Report lies in the record that since 1858 while other Pacific populations were decreasing that of Pitcairn Island has grown from 16 to 209 and that though the diet does not include milk or butter and eggs and green leafy foods are relatively scarce apart from the early loss of teeth the people are strong and healthy.

The Report is based on enquiries made during 39 days residence in May-June, 1937. Pitcairn which lies at Lat. 25-4 S. on the route between the Panama Canal and New Zealand was colonized in 1780 by nine mutineers from the *Bounty* making with their Tahitian wives and other natives 28 souls.

In 1858 192 persons were at their own request removed to Norfolk Island but some returned. In 1864 there were 45 in Pitcairn and in 1936 209 all but nine descendants of the mutineers. The causes of this remarkable increase appear to be the isolation of the island almost complete till the opening of the Panama Canal in 1914 combined with the difficulty of landing and the consequent short stay of ships the freedom from social and economic prejudice of the half-caste islanders and the predominantly European culture which protected them from venereal disease and alcohol. For 100 years the islanders have been Seventh Day Adventists and apparently strict ones. The climate is good diseases are few and inbreeding has had no harmful effects.

Of the 200 population 110 are males and between 16 and 45 years the male preponderance is 16

It is noted that "daybiting mosquitoes breed freely in the rain-water cisterns, flies are almost unknown. Semi-wild goats roam the island and are shot for food but their milk is not used. Chickens are plentiful but are preyed on by the numerous rats. Fruits are of many kinds and are abundant. Shortage of animal food is now compensated by the importation of tinned meats. The diet seems to be both chemically and mechanically inadequate. [This mechanical inadequacy apparently refers to shortage of roughage.]

Almost the whole population was medically examined. They appeared to be of average intelligence and physically very strong. The absence in children of enlarged tonsils and adenoids was noted. The front teeth are nearly always lost and few islanders reach the age of twenty without requiring a complete or partial denture. Faeces were examined for hookworm ova without success. Schick, Dick and Mantoux tests showed 50 per cent. Schick positive, 50 per cent. Dick positive and 20 per cent. tuberculin positive. no comment is made on these results.

The author recommends that a medical officer from New Zealand should reside 10-14 days on the island every 2-3 years and that an island girl should be trained to be a Public Health Nurse. A. G. Bagshaw

JERACE (F) La colorazione alla Romanowsky con il liquido di Puntoni. ["Romanowsky" Staining with Puntoni's Fluid].—*Ann. d'Igiene*, 1938. Sept.-Oct. Vol. 48. No. 9-10. pp 606-607

The fluid is made up as follows —

Azur	5 gm
Methylene blue	2.5 gm.
Eosin A.B. extra (Gibbler)	2.5 gm.

These are ground together thoroughly in a glass mortar and added to 500 cc. of pure neutral glycerine. To this is added 500 cc. pure methyl alcohol and the mixture is shaken gently and kept at 37°C for 24 to 48 hours. It is then decanted or filtered and preserved in a yellow bottle with a ground stopper. This stain is used in the same way as Giemsa's stain, but gives better results in demonstrating basophil elements. C. H.

PAMPANA (E. J.) Colorazione dei preparati a goccia spessa demoglobulinizzazione con soluzioni isotoniche. [Haemolysis with Isotonic Solution in the staining of Thick Drop Preparations].—*Riv. di Malariologia* Sez. I 1938. Vol. 17. No. 4. pp 300-304. English summary (8 lines)

The author found that thick drop blood films could be haemolysed by solutions of NaCl in concentrations up to 10 per 1 000. Evidently dried blood in this respect differs from fresh blood. The advantage of using an isotonic solution is that distortion of cells and parasites does not occur and a colourless background is produced. It is better however to use an isotonic buffered solution, made up as follows —

Na_2HPO_4	14.824 gm
KH_2PO_4	5.33 gm
Distilled water	... 1 litre.

This maintains a pH of 7.2

The method is to dilute 1 cc of Giemsa stain with 19 cc of this solution stain for 20 minutes wash rapidly in distilled water and allow to dry. If a precipitate forms in the water after the addition of the two salts, it should be left for a few days and then filtered. It is then fit for use. C II

JACKSON (R B) The Taking of Microphotographs with the Aid of a Simple and Inexpensive Apparatus.—*Chinese Med J* 1938 Oct Vol 54 No 4 pp 367-371 With 13 figs.

A Metron Reflex Drawing outfit obtained from Messrs C Baker, 224 High Holborn London to which is fitted a microscope is enclosed in a box as shown in the figure. To the box is fitted a camera which takes plates. When the plate holder is removed an image can be projected on to a negative placed in the movable frame I J. The procedure is carried out in a dark room.

Diagram illustrating details of the box and movable glass frame used in taking microphotographs

(Reproduced from the *Chinese Medical Journal*)

The image is focussed by manipulating the microscope and camera, on to white paper in the frame by the aid of the red light of the dark room. A negative is then substituted for the paper the Metron lamp is switched on and an exposure made by means of the camera shutter.

Excellent microphotographs taken in this way are used to illustrate the article. The price of the Metron outfit (without microscope) is given as £8 2s 6d. C II

BRIESE (Reinhold R.) & COUCH (James F) Preservation of Cyanogenetic Plants for Chemical Analysis.—*J Agric Res* 1938 July 15 Vol 57 No 2 pp 81-107 With 2 figs. [31 refs]

A considerable number of tropical plants are cyanogenetic that is they contain substances which on addition of water give rise to the

formation of hydrogen cyanide. It is important if analysis of them is to be at all accurate that some method of preserving them should be found which does not materially change this property especially under circumstances where they have to be sent to a distant laboratory. It must be remembered also that the rate of formation of HCN in cyanogenetic plants is not uniform. It begins to fall in 8-10 hours and several hours (10-12) elapse before this first level is again reached.

From their investigations of a number of specimens shipped to them in the fresh state and dried, and in preservatives the authors have found that fresh plants stored at ordinary temperatures without preservatives lose in 1 to 6 days up to as much as 83 per cent. of the HCN. If they are stored at refrigerator temperature the loss on maceration is great. 67 per cent. may be lost when fresh plants are kept in water to which chloroform has been added, in other cases the loss may be but slight in four days. It is this irregularity which makes the method so uncertain. Acids cause a rapid loss, salicylic less than others. Alkalies cause a loss between 32 and 86 per cent. due to destruction of HCN rather than to inhibition of cyanogenesis. Only some 8 per cent. or less in a week is lost when alcohol is added from 10-25 per cent. but in 7-8 weeks 20 per cent. In high concentrations (50-85 per cent.) alcohol inhibited cyanogenesis.

The best preservative was aqueous solution of mercuric chloride added to the extent of 1 per cent. by weight for fresh plant. Such showed no loss after storage for as long as six months the optimum temperature for storage being 25°C. The article describes the technique for recovering HCN from samples so preserved. This is purely a chemical question and does not come within the scope of this *Bulletin*. Those interested in this aspect of the subject should consult the original.

H H S

EVANS (K. Leigh) & ARNOLD (L. E.) Experimental Studies of Poisoning with Ackee (*Blighia sapida*).—*Trans Roy Soc. Trop. Med. & Hyg.* 1938, Nov. 26. Vol. 32, No. 3, pp. 355-362. With 5 figs. on 1 plate.

This article indicates a big step towards the solution of the puzzling and fascinating problem of the toxic principle of the ackee (*Blighia sapida*). Thousands of lives have been lost by ackee poisoning in past years, as SCOTT showed in his monograph on the Vomiting Sickness of Jamaica, published in 1916. Since then deaths have been much fewer but until the actual toxic agent or constituent is known and, if possible, isolated and tests devised to prove its presence in the human subject, killing by its means will, as it has in the past, escape detection. Hence this work of Drs. Leigh Evans and Arnold has a great medico-legal as well as a clinical and academic scientific value.

After repeating and confirming the experimental work of SCOTT and of COVXAL and RALSTON carried out more than twenty years ago [see this *Bulletin* 1915 Vol. 6 p. 428, 1916, Vol. 7 p. 381, 1917 Vol. 10 p. 102, 1918, Vol. 12 p. 438] they have again demonstrated the peculiar fact that herbivorous animals require a much larger quantity of the fruit to kill them than do carnivores. Thus whereas 1 gm. per kilo will kill a kitten, guinea-pigs will survive doses under 3.5 gm. per kilo.

The details of their confirmatory work which was carried out with meticulous care and was essential to their pioneer investigations which

followed are given in this article and it is want of space only that compels us to leave this aspect of the subject. Those interested in toxicology would be well repaid by a study of it. The important advance which the authors have contributed is in separating the constituents—saponin, fat and phytosterol—from the fruit and in showing the toxicity of the first of these. That the toxic principle might very likely be a glucoside was suggested long ago by Scott but merely on the empirical and negative grounds that the poison could not be obtained from the gastric contents or tissues or excreta of fatal cases and he inferred therefore that the toxic agent was some substance rapidly decomposed or changed on absorption.

Drs. Leigh Evans and Arnold describe the method they employed for separating the saponin from the ackee extract prepared as for their preliminary animal experiments. Cases of ackee poisoning occur from November to March or even April but much more commonly from December to February or March and the authors have shown that in these the colder months of the year the saponin content is higher and the toxicity greater. They have demonstrated by carefully devised series of tests why the normal naturally opened ackee is harmless whereas the unopened fruit is highly toxic. The following tables taken from their article show these points more clearly than a long description —

TABLE II
Haemolysis Dilutions

Tube number	1	2	3	4	5	6	7	8	9	10
Blood suspension cc.	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Saline cc.	2.95	2.9	2.8	2.7	2.6	2.5	2.25	2.0	1.75	1.5
Saline ackee extract cc.	0.05	0.1	0.2	0.3	0.4	0.5	0.75	1.0	1.25	1.5

1. The arillus of the unopened ackee is lethal to kittens with a dose of 1.0 grammes per 100 grammes of kitten weight when administered intragastrically.

2. The arillus of the unopened ackee is lethal to guineapigs when a dose of 3.5 grammes per 100 grammes of guineapig weight is given subcutaneously or intragastrically.

" 3. In the partly opened ackee the arillus with embedded seed is lethal to guinea-pigs in the same dose as the arillus from the unopened ackee while the arillus with normal seed is not lethal to guinea-pigs in this dosage.

" 4. This toxic property is cumulative when repeated sublethal doses are given at daily intervals.

" 5. The arillus of the fully opened ackee is not lethal to guinea-pigs.

6. The post-mortem findings, both in kittens and guinea-pigs, indicate an acute toxæmia affecting all organs with hæmorrhages and fatty changes, chiefly in the liver and kidneys.

7. The ackee contains a saponin, which is hæmolytic in some stages of the development of the fruit, and the toxic substance is very probably this saponin.

8. The saponin is strongly hæmolytic in the arillus of the unopened ackee less so in the arillus with embedded seed of the partly opened ackee being only slightly hæmolytic in those with normal seeds while it is non-hæmolytic in the arillus of the fully opened ackee.

9. The fat content of the arillus varies with the stage of development of the ackee. There is little fat in the unopened ackee, most in the arillus of the fully opened ackee. The arillus with the embedded seed contains less fat than the arillus with the normal seed in all stages of development.

" 10. The toxicity of the arillus of the ackee varies inversely with the fat (and phytosterol) content. This is as would be expected phytosterol fixing the saponin and rendering it non-hæmolytic and, as a consequence non-toxic.

" 11. There is apparently a seasonal variation in the toxicity and fat content of the ackee. In the colder months (December to March) the fruit contains less fat and is apparently more toxic than at other times.

12. The unavailability of herbivorous animals for this particular investigation is appreciated, but, even with this handicap the findings appear to open several avenues for further investigation. In view of the age and seasonal incidences, particularly in vomiting sickness, immunological studies and experiments are being conducted to determine what part, if any is played by photochemical and photodynamic action on the fat and phytosterol content and toxicity of the fruit."

(An admirable piece of work, which, it is hoped, will be followed to its logical conclusion—the finding of a test by which proof of poisoning by ackee may be established by definite chemical means and not merely as hitherto by the pathological and histological lesions produced.)

CURASSON (G.) *Etat actuel de nos connaissances sur les plantes toxiques de l'A.O.F.* [Present-day Knowledge of Poisonous Plants of French West Africa.]—*Bull. Comité d'Etudes Hist. et Scient. de l'A.O.F.* 1938. Apr.-June. Vol. 21. No. 2. pp. 149-173.

This is little more than a list of over a hundred plants regarded as poisonous in West Africa. A few words are added to each regarding its reputed toxicity. Most of them are known in other parts of the tropics. The information when correct, is too meagre to be of much use and in the case of *Blighia sapida* with which the reviewer is best acquainted, the statements that it "causes the vomiting sickness in America, that "only the fibrous part adhering to the seeds is toxic and that "the seeds are sometimes eaten roasted by Europeans" are at variance with fact and the only other point mentioned, that the "powdered fruit is used for stupefying fish in the Gold Coast" is, to say the least, doubtful.

EARLE (H. Vigors) Toxic Effects of *Hippomane mancinella*.—*Trans Roy Soc Trop Med & Hyg* 1938 Nov 26 Vol 32. No 3 pp 363-370 With 2 plates. [20 refs.]

Hippomane mancinella the manchineel tree is found in the West Indies and along the coast of Central and South America. All parts of the plant are toxic raindrops falling on a person sheltering beneath it will cause irritation and the fruit somewhat like an apple is inadvertently eaten by new arrivals, such as sailors going ashore after a voyage. As a rule one bite is enough as it is pungent and disagreeable but even that sets up smarting salivation and soreness of the mouth if it is chewed before being ejected the buccal mucosa becomes swollen blistered and desquamates. In short on skin and mucosae the latex causes irritation and vesication and if swallowed salivation vomiting meteorism liquid stools with blood. The wood shows a handsome grain and polishes well but local carpenters will not often use it because the sawdust causes cough rhinitis laryngitis conjunctivitis and lachrymation Treatment is purely symptomatic.

The latex is sometimes used empirically as a liniment as a counter irritant and according to BODEAU as an anthelmintic [Though not included in the list of references there is a brief account of this together with a sketch of the leaves and fruit in BAX and ARCHBOLD'S *Practice of Medicine in the Tropics* Vol. 1 p 778.] H H S

VAN VEEN (A G) Kunnen peteh boonen djenkolvergiftigingen veroorzaken? [Peteh Beans and Djenkol Poisoning].—*Geneesk Tijdschr v Nederl Indië* 1938 Oct 18 Vol 78. No 42. pp 2619-2621 English summary

The djenkol bean *Pithecolobium lobatum* contains a poison djenkolic acid which causes symptoms of intense irritation of the urinary tract—renal pain dysuria perhaps anuria necrosis and fistula [see this *Bulletin* 1936 Vol 33 p 724] The notion that the peteh bean *Parkia speciosa* might also be a cause probably originated in the fact that it has a similar odour of volatile sulphuric compounds. Analysis of these beans revealed however no trace of djenkolic acid nor could any of it be found in the urine of those who had eaten them whereas it is readily found and in considerable amount after five young djenkol beans had been eaten. H H S

HAY (George Gray) Amaas.—*South African Med J* 1938 Sept. 10 Vol. 12 No 17 pp 639-642. [Summary appears also in *Bulletin of Hygiene*.]

The native settlers in the Zoutpansberg penetrated the country in two distinct groups. The northern group showed outbreaks of a disease resembling smallpox though the natives denied that it was so and called it amaas menzi Kimberley ziekte and other names, while the southern group showed cases of typical smallpox. In the author's experience amaas presents the following differences from and resemblances to classical smallpox.

1 Amaas is specially a disease of the winter months whereas smallpox occurs in hot as well as in cold climates

2. The chief characteristic of amaas is its very slight degree of infectivity

high altitude, there is no evidence of a geographical variation in erythrocyte counts if the population is carefully selected for a high health standard.

Haemoglobin determinations of 428 individuals of the same group gave a mean value of 16.73 gm. per 100 cc. blood. The Sahli acid haematm method was chosen, the instrument being calibrated by the van Slyke method. The results are compared with those of other workers and two possible explanations are suggested for the high mean obtained in Baghdad during summer: one is the very high health standard of the selected population and the other the relative anaemia due to the air density in July which is equivalent to the density in winter at 5 000-6 000 feet.

The author emphasizes the necessity for a proper appreciation of differences arising from technical or statistical sources in haematological determinations. The calibration of instruments is particularly important since as much as 20 per cent. difference may be found between instruments of the same type.

F. Murgatroyd

WAPTER (L. EVERARD) & MAJUMDAR (D. N.) *Haematological Studies in Indians. Part IX. The Analysis of the Haematological Findings in 57 Cases of Anaemia in Pregnant Tea-Garden Coolie Women with Special Reference to the Results of Treatment.*—*Indian J. Med Res.* 1938. Oct. Vol. 28. No. 2. pp. 541-595. With 37 graphs & 1 fig. [16 refs.]

The anaemias of pregnant tea-garden coolie women can be divided into two groups. One the iron deficiency group is slightly more common in primigravidae but may occur in any pregnancy or post partum. The typical blood picture is microcytic and hypochromic; the cells have a low haemoglobin concentration, anisocytosis is the rule; frequently there are normoblasts, the reticulocyte count is about 2 per cent. and there is usually a slight but distinct leucocytosis. The condition is not associated with low gastric acidity and the indirect van den Bergh reaction is usually negative. All patients had hookworm infection but there is little correlation between the degree of the infection and the anaemia, and there is no correlation between splenic enlargement and the anaemia. There is a good response to iron therapy in the early months of pregnancy and post partum, but in the latter months the response may be only slight until the uterus is empty when rapid improvement occurs. This anaemia seems to be an exaggeration of the anaemia of the normal population which, living at the lowest level of iron balance due to low intake and increased loss by hookworm disease, has on a whole a low level of haemoglobin associated with a small pale red cell. Although this is perhaps not the whole explanation the additional demand for iron during pregnancy or the extra loss of blood at parturition are determining factors in the development of the frank anaemia.

The second type, the Marmite-liver-deficiency group occurs in any but especially in the third and fourth pregnancies and becomes established at any month or post-partum but most frequently in the third trimester of pregnancy. The typical blood picture is hyper- or orthochromic and macro- or normocytic, there is some anisocytosis and polikocytosis; normoblasts and erythroblasts are seen in the peripheral blood but rarely megaloblasts, the reticulocyte count is

low and the leucocyte count is normal. There is no association with achlorhydria although there is an inconclusive association with a slightly lowered gastric acidity the van den Bergh reaction is usually positive and neurological symptoms are completely absent. There appears to be a definite correlation between the anaemia and splenic enlargement which with the positive van den Bergh reaction suggests chronic malaria as an important aetiological factor. There is a good response to Marmite by the mouth or to Campolon by intra-muscular injection but in the later stages of pregnancy the response may be counteracted or delayed particularly with Marmite until the uterus is empty.

A dietary survey of the population by Dr MITRA showed that although the total calories were not unduly low they were mainly derived from carbohydrates the total protein was low and the animal protein negligible while the total fat was also low and mostly of vegetable origin. The calcium intake was exceptionally low and the available iron was probably at the border line. The intake of vitamins A, B-complex and C were low although apparently A and B were not actually deficient as judged on most standards. Recent work suggests that calcium plays some part in the absorption and utilization of iron and the striking calcium deficiency together with the vitamin C deficiency may be of significance in the production of the hypochromic anaemias. The hyperchromic type may result from a dietary deficiency or possibly a minor toxæmia conditioned by the extra demands of a foetus in an individual on a border line diet and by chronic malaria.

BEVERIDGE (A. J.) The Blood Picture in Singapore.—*Jl Roy Army Med Corps* 1939 Jan. Vol. 72. No 1 pp 1-11

Twelve healthy soldiers aged 20-30 years newly arrived at Singapore in October 1937 were examined under standardized conditions at monthly intervals until March 1938. The mean values for all the examinations were erythrocytes 5,512,000 per cmm, leucocytes 7,551 per cmm and haemoglobin 15.135 gm. per 100 cc. the differential white count gave polymorphonuclears 56.876 per cent, lymphocytes 37.676 per cent, eosinophils 1.963 per cent, basophils 0.339 per cent, and mononuclears 3.164 per cent. Total erythrocytes and leucocytes were much in keeping with the mean averages of a number of text books but the haemoglobin was 16 per cent. below the mean average the individual variations in haemoglobin were however considerable and there was no constant or progressive loss. Compared with text-book means the differential counts showed relatively low mean values for polymorphonuclears, eosinophils, basophils and mononuclears and a relatively high mean value for lymphocytes. It is not possible to draw any conclusion regarding these differences in view of the relatively small number of observations and the wide variations in counts obtained either in the same individual or in different individuals at the same time. The author notes that the leucocyte count of any individual may fluctuate during 24 hours by as much as 100 per cent., that under ideally standardized conditions it may vary by 30 per cent., and that the fortuitous error of counting a single sample may be 30 per cent. Those remarks demand the attention of all engaged in haematological work and indicate that considerable caution is needed in interpreting haematological data.

McLEAM (John A.) Haematocrit Determinations in Normal and Abnormal Blood.—*Med Jt Australia*. 1938. Nov 5 25th Year Vol. 2. No. 19 pp 770-774 With 1 fig

Haematological determinations in a series of fifty-five normal persons were made in Melbourne Australia. Venous blood was used, 5 cc being collected in a small bottle containing 6 mgm. ammonium oxalate and 4 mgm potassium oxalate in order that changes in corpuscular volume might be minimal.

The mean values obtained are shown in the following table —

	Men	Women
Haemoglobin in gm. per 100 cc.	15.4	13.7
Erythrocytes in millions per cmm	5.1	4.7
Corpuscular volume in cc. per cent.	45.1	42.0
Corpuscular volume in cu	89	88
Corpuscular haemoglobin in $\gamma\gamma$ *	31	29
Corpuscular haemoglobin concentration as percentage	34	32

These values are compared with certain others obtained in the United States of America and in England, and the differences are seen to be relatively slight.

A number of cases of various blood diseases was then examined. Sixteen patients classified as suffering from hyperchromic macrocytic anaemia gave mean corpuscular volumes ranging from 114 cu to 170 cu, the average value being 138 cu mean corpuscular haemoglobin values ranging from 38 $\gamma\gamma$ to 58 $\gamma\gamma$ with an average value of 47 $\gamma\gamma$ and mean corpuscular haemoglobin concentrations from 29 per cent. to 45 per cent the average value being 35 per cent. Fifteen patients suffering from hypochromic anaemia gave mean corpuscular volumes ranging from 82 cu to 81 cu, the average being 73 cu mean corpuscular haemoglobin values from 13 $\gamma\gamma$ to 21 $\gamma\gamma$ with an average of 17 $\gamma\gamma$ and mean corpuscular haemoglobin concentrations varying from 17 per cent. to 27 per cent. with an average of 22 per cent. Values for a large group of secondary anaemias of various origins are given. In two cases of acholuric jaundice where the mean diameter of the red cells is less than normal, the mean corpuscular volume fell within normal limits and in a third but slightly below following the spherocytosis. The mean corpuscular volume in three cases of polycythaemia was within normal limits the mean corpuscular haemoglobin and mean corpuscular haemoglobin concentrations in two of the cases were slightly below normal.

F Margatroyd

GROSS (M) Un nouvel hémogramme. [A New Haemogram.]—*Schweiz Med Woch* 1938. Nov 19 Vol. 68. No. 47 pp 1272-1274

Nine vertical lines are used to represent respectively the total leucocytes per cmm. and the totals of the various subdivisions according to the classification of Schilling. Two parallel horizontal lines are then drawn to cut the vertical lines at points which are given values corresponding to the maximum and minimum numbers of the cells in normal blood, and the scales so determined are continued up the respective vertical lines. In any given count the values obtained are

$$1\gamma\gamma = 1 \text{ macromicrogramme} = 1 \times 10^{-12} \text{ gm}$$

joined by a curve which the author feels represents the leucocyte formula more clearly and more strikingly than mere figures. To plot this curve absolute values of the various cells are required and in order to obviate calculation of these figures from the percentage count the author has a simple nomogram. This consists of three vertical lines, scaled according to logarithmic series. The left line represents totals and the right percentages so that a straight line joining any two such values cuts the third vertical line at a point corresponding to the absolute count for such percentage and total. The author also gives a nomogram connecting total red cell count, haemoglobin value and colour index.

PELLICCIOTTA (Raffaele) *Influenza del clima tropicale sulla formula leucocitaria e schema di Arneth nell'uomo sano. The Effect of Tropical Climate on the Differential Leucocyte and Arneth Counts* [*—Polichinco Sez. Prat. 1938 Oct 3 Vol 45 No 40 pp. 1805-1808 1811-1814*]

In continuation of his studies on the effect of the sudden change of climate from Italy to Abyssinia on Europeans in normal health [this *Bulletin* 1938 Vol 35 pp 839 and 845] the author now reports the results of the differential leucocyte and the Arneth counts carried out twice on 34 normal individuals. The examinations were made on blood taken first on board ship on entering the Red Sea and second about one month later in Direddau. Compared with the first examination the second showed that in the majority there was relative polymorphonuclear neutrophil leucopenia and relative lymphocytosis. The difference in these percentages is not great but appears to be statistically significant. There is a shift to the left in the Arneth index. These changes may persist for some months and although improvement later takes place the condition is not usually restored to the normal for temperate climates but corresponds with that found in the natives.

C H

MAEGRAITH (Brian) *The Polynuclear Count in the Australian Aborigine.—Australian Jl Experim Biol & Med Sci 1938 Sept. Vol 16 Pt 3 pp. 241-244 With 1 fig*

Arneth counts on blood films from forty-seven apparently healthy pure-blooded Australian aborigines of both sexes gave the following mean percentages: I 33.5 II 42.3 III 20.4 IV 3.5 and V 0.3 with a weighted mean of 1.95. This shows a marked shift to the left compared with the mean of whites living in England or Melbourne and is in keeping with the results of other polynuclear counts done on both natives and white people living in hot climates. [See also this *Bulletin* 1931 Vol 28 p 837]

F Murgatroyd

SAINT ETIENNE (J) *Sur un cas d'éosinophilie massive [A Case of "Massive Eosinophilia."]*—*Rev Méd Française d'Extrême-Orient* 1938 May Vol. 18, No 5 pp 532-538 [Summary appears also in *Bulletin of Hygiene*]

The author states that in the hospital of Lanessan, Tonking, he has been struck by the number of patients showing a high eosinophilia. The case here detailed is certainly peculiar and worth recording.

[May 1939]

A boy of 12 years who had been in good health until December 1936 when he sustained a fracture of the right tibia and luxation of the head of the left humerus with fracture of the surgical neck in a motor accident. The first fracture healed readily, the second necessitated resection of the head of the humerus. He was in hospital for five months with oscillations of temperature. Examinations of blood, urine of discharge from the wound and serological tests yielded nothing positive.

In January 1937 a differential leucocyte count gave 83 per cent. polymorphonuclears and 3 per cent. eosinophiles. In March he was noticed to be pale and for the preceding month had complained of being easily tired. The liver was enlarged and the spleen was palpable but there was no gland enlargement. On 14th March red cells numbered 4,340,000 and white 22,300 per cmm. 82 per cent. of the latter being eosinophiles. This being unexpected the count was repeated a next two months the red ranged up to 5,280,000 and the white between 52,000 and 14,600 (the last in May) and eosinophiles between 83 and 55 per cent. (the lowest also in May when the general condition had improved).

Repeated examinations failed to reveal any definite cause for this remarkable eosinophilia, except for a few *Trichuris ova*, there were no signs of helminthic infestation. The Casoni test for hydatid was negative. There was no skin disease no allergic condition (asthma etc.) no myeloid leukaemia. By examination there remained two hypotheses: an eosinophilic leukaemia, a name proposed by AUBERTIN and GIRON in 1921 or some autonomous affection of some blood-forming organ or tissue a primary disease of the spleen (noted by CHALLIER and LEVRAT). There was a little splenic enlargement in this patient and some marrow disturbance resulting from the fracture of the neck of the humerus, but this seemed inadequate to account for the blood changes. The author consequently designates it as essential massive eosinophilia until something more positive is discovered regarding its aetiology. (See also PIRERA, *Bull. of Hyg.* 1939 Vol 14 p 224.)

FAIRLEY (N. Hamilton) BROMFIELD (R. J.) FOY (Henry) & KOWDI (Athena). Nutritional Macrocytic Anaemia in Macedonia. A Preliminary Report.—*Trans. Roy Soc Trop Med & Hyg.* 1938. Aug 25 Vol 32 No 2 pp 133-173. [25 refs.] Discussion pp 173-182. [WILLS (Lucy) VAUGHAN (Janet) NAPIER (L. E.) McROBERT (G. R.) FRASER (G.) FAIRLEY (N. Hamilton)]

During a previous study of blackwater fever the authors were impressed by the frequency and severity of the anaemia encountered in Macedonia. The anaemia which persisted despite antimalarial treatment and iron medication was in a number of cases megalocytic and was regarded as falling into the category of tropical macrocytic anaemia. This year the authors studied the situation in more detail and the present paper records a wealth of haematological observations which they summarize as follows —

1. It is suggested that the title tropical macrocytic anaemia be changed to nutritional macrocytic anaemia, and that two sub-groups be recognized (1) non-haemolytic, (2) haemolytic.

2. In Macedonia nutritional macrocytic anaemia is predominantly of haemolytic type. It is prevalent amongst the refugee peasants occurring especially during pregnancy and is found in patients coming into hospital for malaria and blackwater fever.

3. Males as well as females are affected. It is most common in females during the child bearing period owing to the added nutritional demands of pregnancy and lactation.

4. The haematological and biochemical data and the clinical findings in a group of thirty seven cases of nutritional macrocytic anaemia associated with pregnancy are analysed and discussed.

5. The red cell counts of three infants born of severely anaemic mothers suffering from this disease showed little if any deviation from the normal being 5 600 000, 6 730 000 and 6 980 000 erythrocytes per cmm. The mothers' counts were 1 293 000, 1 145 000 and 1 425 000 erythrocytes per cmm. respectively.

6. A study of sternal marrow smears indicates that there is a panmyelopathy characterized by erythropoiesis with megaloblastic degeneration, the production of pathological precursors of the white cell series, and an abnormal condition of the megakaryocytes.

7. This state of affairs is reflected in the peripheral blood by a megalocytic anaemia, a tendency to leucopaenia with a shift to the left and a decrease in the platelet counts.

8. Purpuric manifestations are seen in approximately 25 per cent. of cases and are associated with thrombocytopenia. The count in five purpuric cases averaged 29 270 platelets per cmm.

9. There is no evidence of vitamin C deficiency in the diets of these patients and the thrombocytopenic purpura is regarded as originating in a pathological condition of the marrow.

10. In a number of cases of tropical macrocytic anaemia of haemolytic type an increased mean corpuscular volume was found to be associated with a normal mean corpuscular diameter and an increased mean corpuscular thickness.

11. These data indicate that a condition of megakospherocytosis exists but before this can be accepted as correct further observations are necessary to eliminate the possibility of undue corpuscular shrinkage with Jenner staining.

12. The pathology of two cases is described in detail and evidence is presented that the splenomegaly resulted from chronic malaria, and the enlarged nutmeg liver from chronic venous congestion due to heart failure secondary to anaemia.

13. Microscopic sections showed a very marked decrease in the Malpighian corpuscles and lymphoid tissue in the spleen and considerable activity and hypertrophy of the R.E. cells in both spleen and liver.

14. Malarial pigment was demonstrated in the Kupffer cells of the liver and the endothelial cells of the spleen. haemosiderin which was present in considerable quantity in the liver and distributed mainly in the outer zone of the lobules adjacent to the portal canals, was less evident in the spleen.

15. The diets of the refugee population in general and of our patients in particular were deficient in sources of animal protein and fat such as meat, chicken, milk and butter and were similar in many respects to the diets of people in the tropics who develop tropical macrocytic anaemia.

16. The non-haemolytic type of nutritional macrocytic anaemia is rare in Macedonia, but when it occurs uncomplicated dietary deficiency appears to be the basis of the condition.

17. In the common haemolytic type some additional haemolytic factor is implicated. It is suggested that this is not a direct parasitic effect on the red cell, but is due to the phagocytosis of abnormal red cells derived from a pathological marrow by the R.E. system which becomes activated and hypertrophied as a result of chronic malaria infection.

[May 1939]

In the subsequent discussion Dr Lucy WILLS suggested that the nutritional deficiency was some factor distinct from the liver principle and that it would be a mistake to fix attention too closely on sources of liver principle itself or of Castle's extrinsic factor. Although agreeing with the theory of a nutritional deficiency she pointed out that experimentally macrocytic anaemia with megaloblastic marrow can result from haemolysis. Discrepancy between Price Jones curves and mean corpuscular volume was probably a matter of staining but the effect of increased bilirubinaemia was due to technique. Dr Janet VAUGHAN did not think the discrepancy was due to technique and found it associated with increased fragility in certain anaemias of pregnancy as in acholuric jaundice. Dr L. E. NAPIER remarked that in India microcytosis, possibly due to diet or worms, was common and that anaemias which might elsewhere be termed normocytic represented there macrocytic anaemias. He had also concluded that macrocytic anaemia was due to diet and malaria. Lt.-Col. G. R. McROBERT pointed out that histamine-resistant achylia associated with macrocytic anaemia may become normal after treatment and stressed the importance of differentiating such cases from true pernicious anaemia. Dr WILLS added that histamine-resistant achlorhydria may be associated with deficiency of vitamin B₁₂, which may be corrected by administration of marmite or liver. Dr G. FRASER emphasized the gravity of nutritional anaemia complicated by malaria in Assam, its resistance to treatment and its grave prognosis.

F. Mergalroyd

CHAUDHURI (Sujata) & MANGALIK (Vannali) Idiopathic Hypochromic Anaemia. Its Aetiology, Diagnosis, Treatment and Report of Four Such Cases.—*J. Indian Med Assoc.* 1939 Nov Vol 8 No 2 pp 78-85 [27 refs]

This paper gives a summary of iron deficiency anaemia and describes in detail four cases. The authors point out that chronic iron deficiency especially in the face of increased demands for iron as happens particularly in women is responsible for a good deal of chronic ill-health, and that this type of anaemia is far more common in India than is generally believed. They deprecate uncritical and wasteful treatment with liver preparations in anaemias which can be cured comparatively cheaply by iron.

F. Mergalroyd

SCHREITENMAYER (A) & LANCASTER (R. L.) Sternal Pancreas, with Special Reference to its Application in Tropical Diseases in South China.—*J. Trop Med & Hyg.* 1939 Nov 1 Vol 41 No. 21 pp 341-345

Most of the material of this paper has been previously published elsewhere and has been reviewed in this Bulletin [1939 Vol 35 p 849]. The present paper adds that in smallpox the typical changes in the bone marrow consist of a myelotic reaction combined with an increase of the reticulum and plasma cells.

SHUKERS (Carroll F) LANGSTON (William C) & DAY (Paul L.) The Normal Blood Picture of the Young Rhesus Monkey.—*Folia Haematologica* 1938. Vol 60 No 4 pp 418-424 [23 refs]

The paper describes the technique employed and the results obtained in studying the blood pictures of nineteen young healthy rhesus

monkeys (*Macaca mulatta*) maintained for relatively long periods under standardized laboratory conditions. For each blood constituent approximately one hundred and fifty determinations were made. The maximum and minimum values obtained give a false idea of the dispersion of the data for healthy animals as few determinations fell near the extremes and most of the results were grouped closely around the mean. The middle 68 per cent of the data fell within the following ranges, which are tentatively suggested as normal for immature animals of this species: volume of packed cells 36-44 per cent, haemoglobin 10.9-13.5 grams per 100 cc, erythrocytes 4 600 000-5 800 000 per cmm, reticulocytes 0.5-0.7 per cent, leucocytes 9 700-20 500 per cmm, neutrophils 20-52 per cent, lymphocytes 44-74 per cent, platelets 318 000-623 000 per cmm, and clotting time 32-124 seconds.

A table which summarizes the results obtained by previous workers is given, and the paper is of value in view of the use that is now being made of the rhesus monkey for experimental purposes and particularly for haematological studies, since the haematopoietic system of these animals behaves in a manner remarkably similar to that of man.

RIVOALEN (A.) Le rôle du système réticulo-endothélial dans les maladies coloniales, infectieuses et parasitaires. [The Reticulo-endothelial System in Infectious and Parasitic Diseases].—*Les Grandes Endémies Tropicales* 1938. Vol. 10. pp. 76-97.

SIMMONS (James Stevens) The United States Army's War in the Air against the Mosquito-borne Diseases.—*Amer. J. Med. Sci.* 1938. Aug. Vol. 196. No. 2. pp. 153-167. With 3 figs. (1 map) [47 refs.]

This is a review of mosquito-borne diseases so far as they occur in the regions in which the United States Army normally operates. The control of these diseases (yellow fever, dengue, malaria and equine encephalomyelitis) is viewed particularly from the standpoint of the military authorities. Troops may be called upon to operate in regions where jungle yellow fever is prevalent and therefore obtain no protection from the usual methods of control of *Aedes aegypti*. The cost of controlling *Aedes* is such that it is not practised in regions where yellow fever is absent, such as the Philippines; yet an outbreak of dengue might jeopardize the success of a campaign. In the Panama Canal zone, although the incidence of malaria among the coloured employees has remained at about 16 per thousand for the last 20 years, the incidence among the troops in that zone is twice or three times as great. This is attributed to lack of resistance and to the army posts being located nearer to the unsanitized jungles. The conclusion is reached that specific prophylactic agents, either drugs or vaccines, are more suited for military purposes than the elimination of the insect vectors.

V. B. Wigglesworth

HALL (Maurice C.) The Bedbug, Its Relation to Public Health, Its Habits and Life History, and Methods of Control.—*Public Health Rep.* 1937. Supp. No. 129. 7 pp.

This is a short account of the biology, habits and control of the bed bug *Cimex lectularius* L. There is little to indicate that the

author has studied the more recent literature on the insect and the report is to say the least naive. The importance which is apparently attached to the rôle of *C. lectularius* in disease transmission is scarcely warranted by the present uncertain knowledge of the status of this insect as a natural vector.

Some errors in the report occur in the following statements —

Cimex hemipterus normally a parasite of birds and bats in the Old World sometimes becomes a parasite of man. *C. lectularius* (*holandicus*) is, of course as great a pest of man as *C. lectularius*. Checking development by starvation may result in additional moulting periods. Feeding and developing practically cease at 50°F. Hatching and moulting cease at 56°-57°F (13-5°C). The temperatures which are most favourable lie between 64 and 82°F and the author himself states 8 lines above that large numbers of the bugs are "killed by temperatures of 96° to 100°F or more when accompanied by fairly high degrees of humidity. Nothing is known about the effect of humidity over this temperature range however although MILLARBY (1935) has shown that at 104°F (40°C) and 111.3°F (44°C) with exposures of 24 and 1 hour respectively humidity had no effect. Fumigation by means of burning sulphur is also very effective. Sulphur fumigation although widely used is not very reliable, and has as many critics as advocates.

Ho (Ch 1) The Significance of the Female Terminalia of House-Flies as a Grouping Character.—*Ann Trop Med & Parasit* 1938, Oct 12 Vol 32, No 3, pp 257-312. With 13 figs.

The precise identification of "house-flies" is *Musca domestica* and its close relatives is exceedingly difficult. It is also important because different members of this group breed in different ways and are not equally important in hygiene. The inherent difficulties of identifying these insects have been by no means diminished by some of the papers written on the subject.

The author of the present paper takes the view that the most fundamental differences in the genus *Musca* relate to reproduction. He calls attention to the three types already familiar in one the female lays batches of rather small eggs in the second she lays larger eggs with pedicels a small number at a time in the third she deposits single larvae which have already reached the second or even third stage. The author finds corresponding differences in structure in the terminal segments of the female and bases his classification of the species on these characters. Whether the classification and points of difference will "work" time alone can show but it appears that the system is reasonable and the present paper sound.

MORIOKA (Koichi) Experimental Studies on the Biological Behaviours of *Trichomonas hominis* Part III. The Influence of Temperature, Oxygen and Various Additional Substances on the Rate of Growth and Vitality of *Trichomonas hominis* in Tanabe's Medium. Part IV. The Phenomena of Increasing and Diminishing Phases of Multiplication of *Trichomonas hominis* of Stimulated Nutrition, and the Changes in Viscosity of the Culture Medium. Part V. Effects of Various Osmotic Pressures on Food Ingestion by *T. hominis*. Part VI. On the Vital Staining of *Trichomonas hominis*. Part VII. The *Trichomonas hominis* and its Relation to the Intestinal Bacteria, with Reference to the Influence of Trypanotoxin and Bacteriophage on the Parasite. Part VIII. The Fermentation of Carbohydrates. Part IX. The Production of Hydrogen Sulphide by *T. hominis*. Part X. The Ability of *Trichomonas hominis* to produce Indole.—*Taiwan Igakkaï Zasshi* (*Jl Med Assoc Formosa*) 1938. Apr. Vol. 37 No 4 (397) [In Japanese pp 635-647 649-656 658-668. With 8 charts 671-677 English summaries pp 648 657 669-670 677] and May, No 5 (398) [In Japanese pp 838-849 [15 refs.] 851-860 With 4 charts. [14 refs.] 862-865 [13 refs.] 866-868 English summaries pp 850 861 865 869]

In these investigations the author studies the growth and vitality of *Trichomonas hominis* in Tanabe's medium under varying conditions. It was found that the addition of haemoglobin mucin and starch stimulated the growth. It was also noted that during the course of subculture every two days there were periods of active growth fluorescent period, followed after an interval of 14 to 16 days by a period of poor growth decadent period. These periods occupied 4 to 6 days.

During the active growth period the culture medium became viscous as a result, presumably, of a mucin-like substance secreted by the flagellates. The effects of variations in concentrations of salts (sodium chloride potassium chloride calcium chloride and sodium citrate) were also studied. It was found that the activity as judged by the number of starch grains ingested was greatest when the salt concentration was a little below that of tissue fluids. At other concentrations the vitality of the flagellates was lowered.

In their reaction to vital strains of which 35 were tested on the flagellates it was found that the basic dyes were those which gave a positive result. The granules taking up the stain were mostly those in the anterior part of the organisms. The various bacteria associated with the flagellate were investigated as regards any influence they might have on the cultures. *Bact. faecalis alkaligenes* exerted a stimulating influence on the cultures as also did a number of bacteriophages including those of *Bact. coli commune* *Bact. typhosum* and certain dysentery bacilli.

By comparing the changes which take place in certain media in which bacteria are growing with those which occur in exactly similar media when the bacteria are accompanied by trichomonas it was determined that the flagellates stimulate the decomposition of various sugars added to the medium and in other media give rise to sulphuretted hydrogen and indol.

Escomet (Edmundo) La tricomonomas vaginal, vesical, intestinal y gingival. Su terapéutica específica. [Specific Treatment of Vaginal, Vesical Intestinal and Gingival Trichomonas Infections.]—*Ger Med de Caracas* 1938 Mar 3] Vol. 45 No. 6, pp 86-93

This is a general article on the various trichomonas infections of man and the methods of treatment which have given successful results in the author's experience.

HORN (Arthur E.) Notes on Public and Private Health Control in Tropical Africa.—VIII Convegno Volte Roma 4-17 ottobre 1938 10 pp

It is not yet possible to tell whether races indigenous to temperate zones can successfully and with unimpaired vigour inhabit the tropics for generation after generation though evidence from Central America and Northern Australia indicates that it may be possible. Climate is a factor beyond the power of man to change in the present state of knowledge but in Tropical Africa the control of the associated endemic and epidemic diseases is essential to successful colonization.

A brief description of the general medical organization adopted in the British Dependencies in Africa is given, and mention is made of the medical education of natives and of the Health branch with its subdivisions designed to concentrate on diseases of special importance. The efforts of the Medical Departments must be seconded by other resident Europeans and for this reason officials recruited by other means must not only be physically fit, but also, as part of their preliminary training, must be made familiar with the nature of the diseases and insanitary conditions they may meet. The advantages of local and home leave and of sufficient exercise and recreation are emphasized. European women, whether employed as nurses, teachers etc. or carrying out their domestic duties as wives of residents can maintain as good health as men, but in only a few parts of Tropical Africa do children remain beyond the age of 10 or 12. Pregnancy is more trying than in temperate climates.

Neurasthenia is not uncommon and may result from overwork and ill-balanced conditions. Modern facilities however of travel, communication and contact through broadcasting are improving the lot of colonial officers and though the problem of permanent settlement is not yet solved, the present results justify confidence in the future.

WALSH (Groesbeck) & POOL (Robert M.) Disease and the Negro.—*Amer J Med Sci* 1938 Aug Vol. 193 No 2, pp 252-291

A footnote to this paper notes "This contribution is the foreword of a book of the same title upon which the authors are at present engaged. Attention is called to the observed variations in form, movement and structural differences etc. between the negro and the white man. The diseases of the two races are said not to differ in any essential detail and it is added that during 18 years of diagnostic research the normal findings were for all practical purposes identical and provided no evidence of true racial differences. Yet trained observers have noted that disease patterns of the two races do appear to differ in main respects and in an attempt to discover whether any common

cause could be held responsible for the increased frequency of some diseases and the diminished frequency of others among coloured patients a special investigation was undertaken. In view of the fact that clinical and laboratory records failed to produce evidence of true racial differences in regard to disease it was believed that former investigations were founded on too narrow a base since the mental aspect of the problem had not received the attention its importance deserved. White people are said to reflect an attitude conditioned by a greater knowledge of the subject of human sickness—though the educational campaign by which the laity have become acquainted with the ills of the flesh has by no means proved an unmixed blessing—they appear in consequence to have developed an alertness in regard to the state of their health and are inclined to magnify the physical and physiological changes which characterize the life processes of the human organism. The negro on the other hand appears to live at peace with the various organs of his body and his attitude towards all forms of sickness seems to be one of disregard and of the belief that in the end such troubles will tend to right themselves.

In these circumstances it is stated that the great mass of symptoms without any underlying discoverable lesions which bring thousands of patients to the physician suffering from what are termed functional disorders serve no such end in the case of the negro who is thus spared the fear of many diseases because they have never taken definition in his mind. On the other hand the occurrence of what is defined as organic disease is higher in the negro than in the white such misfortunes are also met with in more advanced stages for as a rule they are only disclosed after long periods of progress. Here the negro's disregard of all forms of disease acts to his detriment. It is claimed that if the white man employed the same emotional defences his history of disease would parallel that of the negro that up to the present no psychogenic origin of the noted differences in disease patterns has been suggested that despite present difficulties these theories may yet be fully proved and that the study of disease in the negro will advance rapidly all knowledge of the psychogenic factors of disease as it occurs in the two races.

Attention is called to the fact that the two cultural levels are so entirely different that two taking-off places are provided for the comparative study of the problem though in course of time this opportunity will be lost since already in certain communities where the two races are inclined to mingle more freely the attitude of the negro towards disease is gradually becoming to resemble that of the white. In the search for a genotypic form of disease in the negro the sum total of his personality must be taken and not merely the physical workings as they are shown in his body for whatever has been an element of strength in his workaday life remains with him when he takes to his bed through sickness since sickness is not a separate life into which he enters shutting all doors of his past life behind him.

P Granville Edge

DE BOER (H S) Health Propaganda amongst Indigenous Races in the Tropics.—*Jl Roy San Inst* 1938 Oct Vol 59 No 4 pp 286-296

The author emphasizes that the complex mixture of races languages and customs which is the rule in tropical countries, adds enormously

to the difficulty of education. An encouraging fact, however is that the number of educated Natives is constantly increasing, and that, especially in Africa literature in the Native dialects is avidly sought. He considers that preventive and curative medicine should go hand in hand. The value of the spoken word in health education is greatest when it is used in the form of quiet informal discussion with elders and chiefs who, as a rule take their responsibilities seriously. Posters the cinema and magic lantern broadcasting, models and health shows are discussed and the excellent plan by which, in Uganda, model houses are built and occupied by picked Natives on condition that the occupants take every opportunity to show their friends and acquaintances around is mentioned. Attention should be paid especially to the education of the young, and in this work the co-operation of Missionaries and members of the Education and Administration Departments is of the greatest value. The work is difficult and often disappointing and requires tireless attention to follow-up and maintenance but it is necessary that it should be undertaken.

It is heartening to know that a worker of long experience in Africa pays to the Natives the deserved tribute of intelligence and responsibility.]

REVIEWS AND NOTICES

ROME. *COMITATO ROMANO PER L'ASSISTENZA ANTIMALARICA. L'Opera del Comitato Romano per l'Assistenza Antimalarica dal 1921 al 1935* [The Achievements of the Roman Committee for Anti Malaria Assistance from 1921 to 1935]—98 pp With 47 figs. on 32 plates & 2 folding maps 1938 Rome Luigi Proja Via Emilio Faà di Bruno 7

Much has been written in recent years about Italy's outstanding achievement in converting malaria-stricken uncultivated wasteland in the neighbourhood of Rome into productive agricultural areas with flourishing townships and villages inhabited by prosperous and healthy people. That transformation has now been completed and the present report gives a detailed and interesting description of persistent effort crowned with success.

The *Comitato Romano per l'Assistenza Antimalarica* was founded in 1921. Its object was to promote and intensify the prevention and treatment of malaria in the Province of Rome. The return of soldiers after the war with fresh strains of plasmodia had increased the incidence of the disease. In the early years chief attention was given to the distribution of quinine. Subsequently the construction of canals, training of water courses, land reclamation, controlled agriculture, road construction and the building of hygienic dwellings were accompanied by the creation of health and social services and the provision of adequate medical care for the population. Two large scale maps and 47 excellent photographs assist the reader to obtain an idea of the transformation that has been effected in so short a time and the magnitude of this excellent example of *bonifica integrale*.

Norman White

BOTREAU ROUSSEL [Médecin-Général, Directeur de l'Ecole d'Application du Service de Santé des Troupes Coloniales (Pharo)] with the collaboration of M^l ASSALI DEJOU HUARD MONTAGNÉ PALES & ROQUES [Chirurgiens des Hôpitaux Coloniaux, Professeurs agrégés du Pharo] *Clinique chirurgicale des pays chauds*. [Clinical Surgery in Hot Climates] Préface du Pr Ch LENORMANT—pp vi+335 With numerous illustrations. 1938 Paris Masson et Cie 120 Boulevard Saint-Germain [80 fr.]

It is refreshing if a little chastening to read the views of experienced clinicians from a different school.

Such is the position of an English reader of this excellent and practical book. For example emetine was apparently used by Magendie but fell into disuse to be rediscovered only by Sir Leonard ROGERS in 1912. Again the ravages of the amoeba are widespread even to urinary amoebiasis while it is stoutly denied that the *F. bancrofti* plays the rôle of causal agent in elephantiasis attributed to it by Manson and his followers. Any connexion between the two, if not imaginary must be coincidental! Open operation is preferred for liver abscess to aspiration which is dismissed with scant notice.

Such matter however will be considered by readers in the light of personal experience and does not detract from the value of the book for those practising abroad. Excellent is the care with which common

Other sections on tests and microscopic methods, on dietetics and foods on sterilization, disinfection and chemotherapy X rays, radium and electrotherapy give much varied and useful information. It is not possible to indicate here all the ground covered, though it may be truly said that the reputation of the "Extra Pharmacopoeia" as an almost indispensable source of quick and accurate information is fully maintained by this volume.

SUMMARY OF RECENT ABSTRACTS

V LEISHMANIASIS*

A VISCERAL LEISHMANIASIS

Epidemiology

Cases of kala azar are described by various authors in France Italy and China (p 177) PÉNU and BLATON (p 809) mention three children from the Vosges the Ardèche region and from the Grenoble area suffering from kala azar. None of them had ever been to the endemic region in the south of France.

In the Naples area LAURINSICH (p 858) found that infantile kala azar occurs endemically and may be limited to one or two streets in a village. It commences most commonly in infants of 12 to 18 months and the first symptoms are most frequently seen from June to September especially in the latter month. From 1916 to 1926 the numbers seen increased as treatment became popular but since then have declined probably owing to the influence of treatment.

Kala azar is widespread in the eastern half of the Province of Argolis Greece and KIRIMILIDIS (p 859) shows that it resembles the disease found in other endemic areas. In one group of villages it assumed epidemic form. MOLLOW (p 866) records the definite diagnosis by liver and bone marrow puncture of the first autochthonous case of kala azar in southern Bulgaria and thinks that the disease exists on the Black Sea coast.

ANDERSON (p 858) shows that the number of cases reported from Tunisia has now reached 131 and discusses the epidemiology of the disease (in the original paper). In the Fung province of the Sudan HENDERSON (p 178) reports that the majority of cases of kala azar show their first symptoms between August and February. The disease attacks mainly children and young adults and is most liable to occur among those in a state of malnutrition though cases occurred in the well fed police. A history of familial infection was not uncommon.

TARTAGLIA (p 182) reports that 7-8 per cent of dogs in Split were found to be suffering from kala azar. Human cases were commoner

* The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938 Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

in villages than towns and *P. major* has been demonstrated wherever the cases occur. DOXATHEX and LESTOQUARD (p. 872) studied the course of canine kala azar in Algiers. No symptoms may be shown for weeks or months, even in heavily infected animals. Relapse of symptoms may occur. Exposure to reinfection is constant and is sometimes followed by exacerbation of symptoms. Canine kala azar was found in 5 of 83 dogs examined in Dakar by CURASSON *et al.* (p. 871). One was in good health. LEZ (p. 182) found kala azar in one stray dog of 90 examined in Peiping, and in a house dog associated with a child suffering from the disease.

Actiology

SANGIORGI (p. 177) reports the finding of two distinct types of parasite in a spleen smear from an adult patient with kala azar in Italy. The distinction between them was not that between *L. donovani* and *L. infantum*.

LAURENSICH (p. 177) adds goat's milk after separation of fat, to the liquid of condensation of \ N \ medium for the culture of leishmania. PAONI (p. 878) also uses goat's or cow's milk in place of blood, with \ N \ medium, for the cultivation of leishmania from kala azar and oriental sore.

KHAW (p. 873) succeeded in infecting the mole rat (*Mosopalex fontanieri*) and the ground squirrel (*Citellus danielsoni mongolicus*) with *L. donovani* in China. NA CURRA (p. 875) successfully infected the hamster, rhesus monkey and dog with the leishmania of S. American kala azar and produced cutaneous lesions in the two latter animals by injecting cultures of the parasite of S. American cutaneous leishmaniasis. ADLER (p. 873) infected the Syrian hamster with cultures of S. American visceral leishmania. The old view that the leishmania could not infect laboratory animals (which was regarded as a differentiation from *L. donovani*) cannot therefore be maintained.

CHAGAS *et al.* (p. 873) review present knowledge of kala azar in South America. Leishmania were found in 41 of 47,000 specimens of liver examined by the viscerotomy service for yellow fever. The disease and the organism differ very little, if at all, from kala azar and *L. donovani* of the Old World, but the differences between the mucocutaneous leishmaniasis of S. America and oriental sore are more pronounced. There is therefore more justification in differentiating *L. braziliensis* from *L. tropica* than *L. chagasi* from *L. donovani*. The distribution is fairly general in N.E. Brazil and the Chaco district of the Argentine. DEANE (p. 875) also notes the similarity of the kala azar of Brazil to that of the Old World.

Transmission.

SOUTHWELL and KIRSHNER (p. 860) maintain that proof of the infectivity of flagellate forms of *L. donovani* has not yet been obtained and therefore that the transmission of kala azar is the result of the deposition on the skin of leishmania forms when an infected insect is crushed. WENYON, however, comments that successful infection has been produced by the bite of sandflies in India, and that fluid on which infected sandflies have fed, and which contains flagellate but not leishmania forms, is infective.

MALAMOS (p. 863) failed to transmit kala azar from hamster to hamster by the bite of the dog tick *Rhipicephalus sanguineus*. Successful infection by the injection of crushed ticks, therefore

probably only indicates the capacity of leishmania to survive for varying periods in the gut of certain blood-sucking arthropods.

THEODOR (p 862) records that one specimen of *P. langeroni* was found in a kala azar area of the Sudan. This is the first record of one of the major group from that area. SUN and WU (p 861) found that 11 out of 537 *P. chinensis* examined in North China were naturally infected with *L. donovani*. Flagellates were found in the mid-gut hind-gut and proventriculus. *P. chinensis* is the chief if not the only vector in that region. These authors also (p 862) succeeded in infecting *P. chinensis* and *P. sergenti* var *mongolensis* from man and hamsters but the infection in the latter tended to die out when the blood was digested. RAYNAL (p 862) also shows that *P. chinensis* is the most widespread species in North China. It is most abundant in June and hibernates as a larva. It has been found infected in nature is readily infected from man and hamsters and although transmission by bite has not been achieved, the intraperitoneal injection of crushed infected insects into hamsters easily produces infection.

Pathology

PAI and HU (p 867) have not found any evidence of leucolysin in kala azar to account for the reduction of leucocytes. They point out that a fallacy in counting leucocytes may arise from the tendency of these cells to adhere to glassware and this accounts for most of the apparent reduction in numbers. These authors (p 868) show that in infected hamsters there is anaemia and leucopenia reduction in small lymphoid cells increase in large lymphoid cells and also in polymorphonuclear neutrophils due to extramedullary proliferation in the spleen and elsewhere. This does not occur in man.

As a result of agglutination tests, DA CUNHA (p 866) concludes that leishmania possess thermostable flagellar antigens and thermolabile somatic antigens.

MALAXOS (p 179) failed to immunize hamsters against *L. donovani* or to cure infection by giving immune serum prepared in rabbits but the latter procedure tended to prolong the disease. The addition of immune serum to cultures tended to retard growth but there was no specific action. The same author (p 180) reports an unusual course of *L. infantum* in producing infection in the pancreas of a white mouse.

Clinical

By the use of Shortt's technique of producing straight-ended blood films in which numbers of leucocytes are gathered WANG (p 178) found leishmania in 39.1 per cent of 23 proved cases of kala azar.

D OELSCHITZ (p 869) in France places most reliance on sternal puncture and on the increased density of the serum under the influence of organic antimony compounds as judged by photometric methods in the diagnosis of early kala azar. Bone marrow examination was successful in providing a diagnosis in a patient reported as having contracted kala azar in Valencia by LEMIERRE *et al* (p 865). The various serum abnormalities gradually disappeared under treatment.

Puncture of lymphatic glands has been a successful diagnostic procedure in four cases of childhood kala azar in the hands of GIRAUD *et al* (p 868).

GIRAUD and GAUBERT (p 868) point out the dangers of spleen puncture and record three deaths. All other methods of diagnosis should first be attempted but the risk of spleen puncture is less than

that of prolonged antimony treatment carried out on presumptive diagnosis alone. HENDERSON (p. 178) in 300 patients in the Sudan found leishmania always in the spleen in 1 per cent. in the blood and in 7.5 per cent. in the nasal mucus.

SHORTT and SWAMINATH (p. 890) have found *L. donovani* in the nasal mucus of 6 of 15 further patients with Indian kala azar and infected a hamster with one specimen. This patient came to Coimbatore from Malabar in neither of which districts has kala azar previously been reported [See also this *Bulletin* 1938 Vol. 33 p. 18.]

ANDERSON and DISDIER (p. 869) found that the complement fixation test of Nattan-Larrier and Grunard-Richard was not sufficiently specific to be of value in the diagnosis of kala azar. NICAUD *et al.* (p. 864) describe a patient with kala azar contracted in the south of France. The formal-gel test was intensely positive within a few seconds and the globulin and euglobulin level was markedly increased. Diagnosis was not made until over a year after the onset and the infection was heavy. DEANE and DEANE (p. 184) found that the formal-gel test was positive within 4½ minutes in each of four patients with South American kala azar. In other diseases and in normal persons the shortest time was 11 minutes and in the majority it was an hour or more. GASPERINI (p. 837) shows that like the formal-gel reaction, the reaction of Camptopetros is modified if the serum is subjected to ultrafiltration before use. It would appear that the molecules of proteid responsible for these reactions are not all of the same size. The details of the test are given in the original abstract. Henry's reaction similarly does not occur with such serum.

RUPNEV (p. 859) diagnosed the first case of visceral leishmaniasis in Daghestan by Ray's reaction, Frey's adrenalin test and by finding leishmania in the monocytes of blood films. None was seen in spleen smears.

HERK (p. 866) records simultaneous cutaneous and visceral leishmaniasis in a native of the Sudan. PANJA (p. 878) describes nodular lesions of the tongue in which leishmania were found. This appears to be the first time that tongue lesions have been described in dermal leishmaniasis following kala azar. WRIGHT (p. 178) shows that retinal haemorrhages into the posterior segment of the eye appear to be the only conditions having relation to kala azar and malaria. They probably depend on the severity of the anaemia rather than on the toxæmia.

PICCINELLI (p. 866) suggests that the rapid response to treatment of a case of typhoid fever with kala azar may have been due to some kind of antagonism between the two diseases. NAPIER (p. 178) considers that if kala azar is accompanied by some other disease the kala azar should be treated first but it is important to know that antimony treatment appears to aggravate pulmonary tuberculosis.

CHAGAS and ROMANA (p. 179) describe two cases of a disease resembling kala azar with leishmania in the endothelial cells of liver and spleen puncture material, in the Argentine.

DE OLIVEIRA (p. 874) describes typical kala azar in a boy in Brazil, cured by iofradin and neostibosan and CHAGAS and CHAGAS (p. 875) discuss the epidemiological features of this case.

Treatment

ERVEN (p. 870) showed that the activity of the pentavalent compounds is associated with a histocyte response in the blood, and

the beneficial action in kala azar is probably due to a double action one on the parasites and one on the tissues. Trivalent compounds like souadin are inactive.

HIKUTH and SCHMIDT (pp 182-870) used the European hamster for testing drugs controlling infection by liver puncture and serological tests. By giving solustibosan the toxicity of which is low larger amounts of antimony can be administered than in the case of other pentavalent organic compounds. One cc contains 20 mgm. antimony and 6 cc. corresponds to 0.39 gm. neostibosan. WANG and LEE (p 871) found that it is possible to give to Chinese hamsters much larger doses of antimony than were used by certain earlier workers. Thus 0.4 gm. neostibosan per kilo body weight subcutaneously or intramuscularly twice weekly to a total of 7 gm. per kilo cured 50 per cent. of the infected animals.

WEESE (p 180) found that solustibosan in reasonable doses does not produce local irritation on injection. The dog excretes 80 per cent. of the antimony in 24 hours as against 50 per cent. when neostibosan is used. STRUTHERS (p 180) agrees with WEESE that the mouse will tolerate more antimony in the form of solustibosan than in that of neostibosan. He gives in man intravenous injections of 2 cc. (42 mgm. antimony) followed by 6 cc. on alternate days (or sometimes daily) to a total of 59 to 84.5 cc. Solustibosan will cure kala azar and is relatively non-toxic. Solustibosan was tried in the treatment of 10 patients by NAPIER *et al* (p 181). It contains 20 mgm. antimony in 1 cc. and was given intramuscularly either daily or on alternate days to a total of 0.96 to 1.74 gm. antimony. All were probably cured. YATES (p 181) administers solustibosan to a total dosage of 80 cc. for every 100 lb. body weight. The daily dose may be increased and in 9 cases the course was completed in 5 days. In these progress was better than in those whose course was longer. Several adults were given injections of 20 cc. without showing toxic effects and in all, 95.1 per cent. of 82 patients were discharged improved.

HENDERSON (p 178) in the Sudan gives as a routine treatment a course of neostibosan followed by one or two courses of tartar emetic. Children respond readily. LAURINSICH (p 858) in Naples uses tartar emetic average number of doses 20 to 40 in infantile kala azar and the mortality is now only 6.35 per cent. in treated cases. The drug is given twice weekly. He considers that tartar emetic is more active than the organic antimony compounds.

D OELSCHITZ (p 869) uses ureastibamine for kala azar in the south of France and pushes it to the limit of tolerance so as to eradicate the infection by a single course and avoid producing antimony-resistant strains. Injections of liver extract appear to increase the tolerance to organic antimonials. The patient described by LEMIERRE *et al* (p 865) was successfully treated by ureastibamine after neostibosan had failed.

LE HULUDUT (p 182) obtained satisfactory results in kala azar with anthomaline. PANJA (p 878) treats post kala azar dermal leishmaniasis with concurrent pentavalent arsenic and antimony compounds.

PICOURY (p 872) notes the appearance of pustules breaking down to ulcers in dogs treated for kala azar by antimonials. *Leishmania* probably concentrated owing to the inflammatory reaction occur in the tissues of these ulcers.

Owing to the uncertainty as to the method of transmission of kala azar in the south of France, D OLESENITZ (p. 869) considers that the only available methods of prevention are the early identification and treatment of cases.

B CUTANEOUS LEISHMANIASIS.

Epidemiology

A translation by Hoare (p. 876) of a paper by BOROVSKY in 1898 establishes that the latter and his colleague SHULGIN in Tashkent were the first to recognize the parasite of oriental sore (known as Sart sore or Pendeh sore) to give an accurate description of its structure, to realize its protozoal nature and to suggest its transmission by a blood sucking intermediate host.

VIGNE and DURAN (p. 877) describe oriental sore in a man of 45 who had returned to Marseilles four months previously after a visit to Crete. HOVNASTAY *et al.* (p. 183) describe an outbreak of oriental sore in a newly constructed refugee camp near Aleppo. Sandflies abounded during the construction work and within a year the disease appeared in 181 individuals in 45 of 127 families. Seven acquired it for a second time but the attacks were mild. When the site was finally cleared the flies became less numerous and the incidence fell.

POGGI (p. 183) records cases of oriental sore in Abyssinian natives, and MORITI (p. 877) one in an Italian soldier in the same district. Certain nodular ulcerative or eczematous lesions in the south of the Cameroons suspected by HERVÉ (p. 877) as oriental sore, have now been proved by the discovery of leishmania. No evidence of visceral infection could be obtained.

Transmission and Pathology

ADLER (p. 860) shows that a Cretan strain of *L. tropica* (normally transmitted by *P. sergenti*) only with difficulty infected *P. papatasi* when the flagellate emulsion ingested was made up with 50 per cent. inactivated rabbit serum, but did so readily with 10 per cent. serum. A Palestinian strain (normally transmitted by *P. papatasi*) caused infection of *P. papatasi* readily regardless of the concentration of serum.

SINTOX (p. 863) produced oriental sore in a European whom he inoculated with serosanguineous fluid containing leishmania from an ulcer on the nose of a dog in the Punjab. A volunteer inoculated from this European also developed a papule in which leishmania were found. From experiments with volunteers, BERNIERIAUX (p. 863) concludes that *Stomoxys calcitrans* which readily feeds on oriental sores, is capable of transmitting infection mechanically and that it may possibly transmit visceral leishmaniasis in the same manner.

BOGLIOLO (p. 183) points out that the granuloma caused by *L. tropica* is at times indistinguishable from tuberculous lesions of the skin. EVANS (p. 878) found leishmania in nodules, which resembled tubercles, on the arm of a man in Irak. GONZALEZ *et al.* (p. 184) studied the lymphangitis which occurred in 12 per cent of cases of cutaneous leishmaniasis in Paraguay. Lymphadenitis is also present and the enlargement is due to proliferation of the reticulo-endothelial system with giant cell formation. Leishmania are constantly present.

Clinical.

BRUMPT (p. 879) describes a patient who had oriental sores on hand and foot and who developed complete blockage of the oesophagus.

This cleared under ureastibamine treatment and was probably one of the rare instances of mucous membrane involvement in oriental sore of the Old World.

Although cutaneous leishmaniasis in the Sudan resembles either post kala azar dermal leishmaniasis or oriental sore KIRK and DREW (p 877) find that there is no clear distinction between the distribution of kala azar and oriental sore such as has been observed in India.

GASPERINI (p 185) produced an allergic reaction with glandular enlargement by the injection of an antigen prepared from cultures of *L. donovani* in a patient showing ulceration of the lip YOUNG (p 184) describes an Indian woman with nodules and local anaesthesia of the skin regarded as leprosy until leishmania were found Tartar emetic ointment cured the condition

GONZALEZ and OLIVERA Y SILVA (p 183) describe cutaneous leishmaniasis in Paraguay

Treatment

MANSOY BAHR (p 879) found good results to follow the use of cignolin (a refined product of chrysophanic acid) in the treatment of oriental sore Cignolin paint (qv) may be applied daily to the sore and for the more chronic cases cignolin ointment (qv) is used.

RAYMOND (p 185) obtains the best results in oriental sore by thorough scraping under gas anaesthesia applying pure carbolic and covering with adhesive plaster or elastoplast for 14 days. When this is removed complete healing is found in about 90 per cent. of cases. Repetition may be necessary. HOLMES (p 185) also advocates this treatment but found that trivalent antimonials were also effective

C Wilcocks.

LEISHMANIASIS

PRÉCIS OF ABSTRACTS IN THIS SECTION

A Visceral Leishmaniasis

ABRAMOV (p 443) finds that kala azar occurs quite commonly in children and adults in certain highly malarious districts of Yugoslavia

ADLER *et al* (p 443) working in a town in Crete in which there were two centres one of kala azar and one of oriental sore found that *P. major* is the vector of the visceral disease and *P. sergenti* of the cutaneous Flagellates from *P. sergenti* produced oriental sore in a volunteer Canine kala azar is common in the areas of human disease and in measures for eradication both house and street dogs must be dealt with. Various sandflies are described.

AKAR (p 444) reports kala azar from Turkey ROBINSON (p 445) records the first case from Transjordan.

KIRK (p 445) concludes that leishmaniasis is endemic in certain areas of the Sudan sporadic in others. Visceral disease occurs in rural districts in the vicinity of water and vegetation but oral and cutaneous infections may be found in the same areas. Immigrants are more susceptible than indigenous natives *P. langeroni* is the only sandfly whose distribution bears relation to kala azar but the existence of some reservoir host is possible

SCHRETZKEMAYER *et al* (p 445) describe an outbreak in troops in Canton which was apparently introduced by men from an endemic area in the north. Jaundice was a feature in a number of patients. Treatment with neostibosan and solustibosan was successful. No investigation on transmission could be done.

CHAGAS *et al* (p 446) investigated visceral leishmaniasis in Brazil. The clinical features are those seen in the Old World. No infection was found in 1446 wild animals, but was discovered in 7 dogs and 1 cat. *P. longipalpis* was found. DA CUNHA (p. 447) re-emphasizes that the so-called *L. chagasi* cannot be differentiated from *L. infantum* or *L. donovani* and that it can produce infection in hamsters, monkeys and dogs. He also (p 447) demonstrated that these organisms are found to be identical by means of serological tests.

LOWE (p 447) shows that for growth, *L. tropica* and *L. donovani* like *T. cruzi* require ascorbic acid, haematin and an unknown substance present in serum. ARCHETTI (p 448) found that Reichenow's medium of citrated blood and Ringer solution, used in the cultivation of trypanosomes, is very suitable for the growth of leishmania. GARILLO and LAURENCIA (p 449) record success in cultivating leishmania in tissue cultures prepared from the embryo of the hamster.

FERRIRA *et al* (p 449) show that the parasite of S. American kala azar is able to develop in the sandfly (*P. intermedius*). These flies occur in and around the houses of patients. CHAGAS (p 449) succeeded in infecting laboratory bred *P. intermedius* and *P. longipalpis* from a dog with a skin lesion due to *L. chagasi*.

KRIEGER (p 449) concludes from experiments that serum antibodies htu to *L. donovani* *in vitro* have no curative properties *in vivo*.

CHRAID and POTINCO (p. 450) in the original paper summarize present knowledge of kala azar. VALLETTEAU DE MOUTILLAC *et al* (p 450) describe a meningeal syndrome which they regard as having been due to kala azar.

CHUNG (p 450) regards sternal puncture as the best method for diagnosing kala azar in hospitals, dispensaries and rural stations. The technique is given. DA CUNHA and DIAS (p 451) describe the preparation of alcoholic leishmania antigen for serological work.

DOLLEWITZ (p 451) details certain clinical features in kala azar and describes a treatment in which 34 gm. neostibosan was given during a period of 2½ months. DOLLEWITZ *et al* (p. 451) give the highest tolerated doses of antimony preparations continued over long periods in the treatment of kala azar. With ureastibamine, 0.5 cgm per kilo. body weight can be given daily until over half a gram per kilo. has been given but careful watch for intolerance is necessary. WAAG (p 452) finds that in experimental kala azar much more antimony can be given in the form of solustibosan than of neostibosan or ureastibamine but more is required for cure. MATTHEWSON and WATSON (p 452) treated a patient successfully with stibamine gluco-side (neo-tam) after failing with foudrin.

B Cutaneous Leishmaniasis

VIGAR (p 452) wrote a general account of oriental sore.

VASSI (p. 453) found 300 cases of oriental sore in Abruzzi in three months of 1938. *P. macdonovae* is probably the vector. ESNAULT and LOUBET (p. 453) report the first case of oriental sore seen in South Oran for 12 years.

HIGOUMENAKIS (p 453) considers that the parasite of oriental sore in endemic areas is actually that of kala azar which has lost virulence through many skin passages. Parasites from sporadic cases of oriental sore have retained much of their virulence and can produce visceral infections in animals.

SHALOM (p 454) points out that scars left by oriental sores may lead to ectropion and its complications. CAWSTON (p 454) describes a condition diagnosed as espundia in a Zulu.

PORTE (p 454) found that although local treatment was unsuccessful intravenous neostibosan rapidly produces cure. FLARER (p 454) injects a solution of atabrin into the skin round oriental sores and has thus cured 14 patients. CASTELLANI and AMALFITANO (p 454) use a fuchsin paint locally. Sores healed in 2 to 3½ months in three cases. REYES ORIBE (p 455) obtained very satisfactory results with large doses of foudadin combined with intravenous yatren in muco-cutaneous leishmaniasis.

ABRAMOV (G D) *Le problème du kala-azar chez l'adulte* [Kala Azar in the Adult.]—*Bull Office Internat d'Hyg Publique* 1938 Oct Vol 30 No 10 pp 2201-2206 With 2 figs.

Since 1933 cases of kala azar have been regularly encountered in Yugoslavia in the district lying between Lake Scutari and the Adriatic Coast. During the four years up to 1936 the disease has been diagnosed in 13 children and in 7 adults. During 1937 50 suspected cases were examined by means of blood films made from the lobe of the ear. In 16 of these leishmania were found. Of these 7 were children and 9 adults. In some cases diagnosis was established by the discovery of leishmania in scrapings from cutaneous ulcers which were present while in other cases positive cultures were obtained. It is evident that in the malarious districts where the observations were made kala azar occurs quite commonly amongst children and adults of all ages.

C M Wenyon

ADLER (S) THEODOR (O) & WITENBERG (G) *Investigations on Mediterranean Kala Azar XI. A Study of Leishmaniasis in Canea (Crete)*—*Proc Roy Soc Ser B* 1938 Aug 5 Vol 125 No 841 pp 491-516 With 3 figs [15 refs.]

Having established by a brief survey carried out in 1932 in Athens and the vicinity of Argos that the distribution of *Phlebotomus major* corresponded closely with that of kala azar and was therefore a probable vector of the disease it was decided to test this point more thoroughly by an intensive study of one locality. For this purpose Canea in Crete was chosen because it is a centre of both visceral and cutaneous leishmaniasis the two diseases however occurring in different parts of the town. Hagios Joannis a small district measuring 300 by 250 metres and situated at the south-eastern corner of the town accounted for 70 per cent. of the cases of kala azar. This small focus is about 1 kilometre distant from the old Turkish town which is practically free from the visceral disease though it is an intensive focus of the cutaneous infection. The most striking difference between the two districts is the presence of gardens and vegetation in the

where the disease had not previously been noted. The first case was diagnosed through the discovery of leishmania in a malaria patient. During the next five months a further 83 cases were identified. They were all in officers or soldiers except three which were in women who however had been employed by the military authorities. A number of the cases were in men who had never left the Canton district, while others were in soldiers who had come from \ China, where the disease is endemic. It seems clear that the infection had been introduced with these men from \ China.

The disease appeared to follow the usual course though association with malaria or other infections was common. In 24 of the cases jaundice was a feature. In one case there supervened a condition of acute atrophy of the liver. As regards treatment, neostibosan or solistibosan was employed with good results in most cases. Three of the patients died as a result of serious complications.

Observations on dogs and sandflies in this area have not yet been carried out, but attempts to do so will be made as far as the exigencies of war permit.

CRAGAS (E.) DA CUNHA (A. Marques) FERREIRA (L. Castro) DEANE (L.) DEANE (G.) GUIMARÃES (F. \) VON PAUMGARTEN (M. J.) & SÁ (B.) Leishmaniose visceral Americana. (Relatório dos trabalhos realizados pela comissão encarregada do estudo da Leishmaniose Visceral Americana em 1937) [Report of American Kala Azar Commission for 1937]—*New Inst Ostraldo Cruz.* 1938. Vol. 33 No 1 pp. 89-229 With 12 maps & 40 plates.

This lengthy report deals with a study of kala azar which was carried out in the municipality of Abaeté in the State of Pará, Brazil, where during 1937 eight cases of the disease were discovered. The investigation involved the study of the cases clinically a morphological and experimental investigation of the causative organism and a detailed epidemiological survey including the collection and examination of large numbers of insects and vertebrates of all kinds. Of the eight human cases seen, seven were in children, while one was in an adult. These do not appear to have revealed any features which have not been recognized in the well known kala azar of the Old World. The examination of captured wild animals 1448 in number brought to light no cases of infection, but amongst domestic animals, 7 dogs and 1 cat were found infected. A very large number of biting insects of all kinds were collected. There were mostly mosquitoes but *Phlebotomus longipalpis* was captured on a number of occasions. All the details of the animal and insect examinations and the relationship of the human cases to the general population of the district are given in a series of comprehensive tables, maps and charts. A number of photographs shows the type of dwelling in which the cases occurred. These are mostly isolated thatched wooden huts standing alone amongst trees and scrub in, or at the margin of, the forest.

The whole investigation, judging from the mass of detail in the report was carried out with the utmost care and thoroughness and though nothing very new has come to light, the material thus made available may be of great service to future observers.

- i. DA CUNHA (A. Marques) Infections expérimentales obtenues en partant de la leishmaniose viscérale américaine. [Experimental Infections with S American Visceral Leishmaniasis.]—*C R Soc Biol* 1938 Vol. 129 No 27 pp 428-430
- ii ——— Infecções experimentais na leishmaniose visceral americana. [Experimental Infections with S American Visceral Leishmaniasis.]—*Mem Inst Oswaldo Cruz* 1938 Vol. 33 No 4 pp 581-598 With 9 plates. English summary

1. In a previous communication the author and E. CHAGAS (this *Bulletin* 1937 Vol. 34 p 569) reported the failure to infect animals with the parasite of S American kala azar. Further experience has shown the author that such infections can readily be produced if younger cultures of leishmania than those previously employed are used for inoculation. Up to the date of writing successful infection of hamsters (*Cricetus cricetus*) macaques and dogs has been effected the last however only after injection of leishmania derived from naturally infected dogs. In the case of the hamsters there was a tendency to swelling of the feet while the skin of the abdomen became roughened erythematous and friable. Apart from these features the infections in the animals were similar to those produced by the parasites of kala azar from other countries. The successful infection of animals with *Leishmania chagasi* the name given to the parasite of S American kala azar which however cannot be differentiated from *L. infantum* or *L. donovani* has already been reported by the author himself and by ADLER (this *Bulletin* 1938 Vol. 35 p 875).

ii In the second paper further details of the infections produced are given while it is recorded that one dog had been infected with cultures of a human strain of the South American parasite. It is again emphasized that the parasite is identical with *Leishmania infantum* C M II

DA CUNHA (Aristides Marques) A aglutinação e o diagnóstico diferencial das leishmanias. [Agglutination and Differential Diagnosis of Leishmanias.]—*Brasil Medico* 1938 Sept 17 Vol. 52. No 38 pp 849-855

The author has carried out a number of serological tests with strains of *Leishmania donovani*, *L. infantum*, *L. tropica*, *L. brasiliensis* and the leishmania of the recently discovered S American kala azar for which the name *L. chagasi* has been suggested. His procedure has been to prepare in rabbits agglutinating sera for all the strains by injection of culture forms of the organism. With these sera and cultures of the various strains absorption tests were made. The results of these are given in a series of eleven tables. The outcome has been that the author has come to the conclusion that the parasite of S American kala azar is identical with that of the Mediterranean disease which bears the name *L. infantum* C M IV

LWOFF (Marguerite) Le pouvoir de synthèse des leishmanies. [The Synthetic Power of the Leishmanias.]—*C R Soc Biol* 1939 Vol. 130 No 5 pp 406-408

The author has already shown that blood necessary for the cultivation of *Trypanosoma cruzi* contains three essential substances

of which two have been identified. These are haematin and ascorbic acid. The unknown substance is contained in the serum. As regards leishmania, most observers agree that blood is an essential constituent of all media which permit continued cultivation. The author finds that certain species of leishmania will not grow in peptone media containing serum alone, or washed red blood corpuscles alone, but that when both are present good growth occurs. The serum contains an unknown factor but the washed red blood corpuscles contain haematin and ascorbic acid. Two species *L. cerasiodactylis* and *L. agamas* both parasites of lizards, will grow perfectly well in peptone media to which haematin and serum has been added, whereas two strains of *L. tropica* and one of *L. donovani* required in addition ascorbic acid and thus have the same requirements as *T. cruzi*. It may be that the two lizard leishmania do not require ascorbic acid. On the other hand it is possible that minute traces of this substance, or of some related substance were actually present in the medium and that the differences noted between the different leishmanias are quantitative rather than qualitative as regards their need for ascorbic acid. One fact is clear namely that all the trypanosomidae, whether parasites of animals or plants require haematin. Furthermore some of the more highly specialized forms like the trypanosomes of vertebrates and particularly those which have two hosts need in addition ascorbic acid and one or more unknown substances which are contained in serum.

ARCHETTI (Italo) Ein einfacher Nährboden für Leishmanien. [A Simple Medium for Leishmania].—*Arch f Schiff's u Trop Hyg* 1938. Dec. Vol. 42. No. 12. pp 547-549

The author has found that the medium employed by REICHENOW for the cultivation of trypanosomes is very suitable for the growth of leishmania. It is prepared as follows. Into a pointed centrifuge tube are introduced 1 cc. of citrated human blood (0.5 cc. of citrate solution and 0.5 cc. of arm blood) and 1 cc. of Ringer solution. The tube is then kept in the ice chest till the cells have settled to form a layer of red blood corpuscles covered by a layer of leucocytes. In this medium the leishmania multiply in the leucocyte layer where large numbers of flagellates free and in rosettes are found.

C M IV

GAVERILOV (W) & LAURENCEK (S) Application d'une méthode de culture de tissus à l'étude des protozoaires. [Application of a Tissue Culture Method to the Study of Protozoa].—*Ann Soc Belge de Méd Trop* 1938. Mar 31. Vol. 18. No. 1. pp 41-56. With 13 figs. on 7 plates. [13 refs.]

In this article the authors describe the successful cultivation of leishmania in tissue cultures prepared from the embryo of the hamster. The cultures were made up with heparinized blood, embryonal fluid and extract of spleen. To a mixture of these ingredients the embryonal tissue to be cultivated was added. The culture when established was inoculated with cultural forms of leishmania. It was possible to trace the penetration of the flagellates into the cells, their development into rounded leishmania forms and their multiplication. The various appearances are shown in a number of macrophotographs of the infected tissue cultures.

C M IV

FERREIRA (L. Castro) MANGABEIRA (O) DEANE (L.) & CHAGAS (A W) Notas sobre a transmissão da leishmaniose visceral americana. [Transmission of American Visceral Leishmaniasis].—*Hospital* Rio de Janeiro 1938. Nov. Vol. 14 No 5 pp 1077-1087 With 16 figs.

In this preliminary report the authors describe experiments which they have carried out with sandflies (*Phlebotomus intermedius*) and S American kala azar. It has already been reported that in the Eastern part of Brazil where endemic foci of kala azar exists dogs and a cat as well as human beings have been found infected. Collecting sandflies which were observed to have fed on an infected dog and dissecting them some days later it was shown that development of leptomonads had occurred in the intestine of some of them. It is thus evident that the parasite of S American kala azar is able like other forms of leishmania to develop in sandflies.

It is shown that the sandflies occur in and around the houses of kala azar patients while their breeding places have been located near these houses. It was possible to breed the flies in the laboratory and something of the technique employed for this purpose is described. Laboratory bred sandflies fed on an infected dog have so far failed to acquire an infection. The paper is illustrated by a number of photographs depicting breeding places of the flies the apparatus used for laboratory rearing of flies and other features of the work which is being continued.

CHAGAS (A W) Infecção de *Phlebotomus intermedius* pela *Leishmania chagasi*. [Infection of *P. intermedius* with *Leishmania chagasi*].—*Brasil Medico* 1939 Jan 7 Vol. 53 No 1 pp 1-2. With 2 figs.

Previous observations noted in papers reviewed in this number have shown that the parasite of S American kala azar will undergo development into leptomonads in both *Phlebotomus longipalpis* and *P. intermedius*. These facts were ascertained by dissection of wild flies after they had fed on naturally infected dogs. In the present paper are described experiments with laboratory bred flies fed on an infected dog which revealed a skin infection with leishmania. Both *P. intermedius* and *P. longipalpis* were infected in this way.

C M W

CALCUTTA ANNUAL REPORT OF THE ALL INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH 1937 [LAL (R B) Director]—[Kala Azar p 25 KRISHNAN (K V)]

Normal human serum and serum from cases of kala azar have *in vitro* a lytic action on cultural forms of *Leishmania donovani*. These sera as also that of rabbits immunized with a leishmanial vaccine do not influence in any way the course of infection in mice produced by the inoculation of emulsion of heavily infected hamster spleens. Immune serum and neostibosan administered repeatedly to infected mice failed to bring about a cure. From these observations it appears that antibodies act on leishmania only *in vitro* and that their presence *in vivo* does not help in bringing about a cure.

GIRAUD (Paul) & POINÇO (Robert) Diagnostic et traitement de la kala-azar méditerranéenne de l'enfant et de l'adulte. [Diagnosis and Treatment of Mediterranean Kala Azar in the Child and the Adult.]—*Marseille Méd.* 1933. July 5-15 Vol. 75 No. 19-21 pp. 75-82.

This is a general account of kala azar based on 155 cases in children and adults seen in the south of France. It contains nothing new but a good summary of present-day knowledge of all aspects of the disease.

C. M. II

VALLETTEAU DE MOUILLAC DELISCOUET & DELACOUX DES ROSEAUX Syndrome méningé au cours de la leishmaniose infantile. [Meningeal Symptoms in Infantile Kala Azar]—*Arch. Méd. et Pharm.* Nov. 1933 July-Aug-Sept Vol. 129 No. 3 pp. 760-768.

The case described was a typical one of kala azar in a child of four years, the disease having apparently been contracted in Cherbourg where it is becoming increasingly common. Treatment with neostibosan was instituted, it being the intention to give three courses with intervals of fifteen days between them. The response to the first course was immediate and satisfactory but a day or two before the second course was commenced there was fever and later symptoms of meningitis on account of which the second course which had been commenced was discontinued. Lumbar puncture yielded a purulent cerebrospinal fluid under pressure. The cells chiefly polynuclear and lymphocytes, were so numerous as to be uncountable. As a precautionary measure 30 cc. of antileishmanogenic serum was administered. It was found, however, that the fluid was bacteriologically sterile while guinea-pig inoculations failed to reveal any tubercular infection.

A second lumbar puncture gave a fluid with fewer cells while at a third a perfectly clear fluid was obtained. The meningeal symptoms disappeared and the course of antimony treatment was resumed. There was no further mishap and the third course was given without any reaction the child making a complete recovery. The origin of the meningitis is discussed and it is regarded as a rare and unusual manifestation of the leishmanial infection.

C. M. II

CHUNG (Huei-lan) A Sternal Puncture Technique and Its Clinical Value with Especial Reference to Its Usefulness in the Diagnosis of Kala-Azar.—*Chinese Med. J.* 1933. Nov. Vol. 54 No. 5 pp. 397-408. With 4 figs. on 2 plates. [13 refs.]

Since 1936 at the Peiping Union Medical College it has been the custom to practise sternal puncture for the diagnosis of kala azar or the study of the bone marrow cells. In all 350 such punctures have been made and kala azar diagnosed 171 times. The author is convinced that sternal puncture is the best method for diagnosing kala azar in hospital, dispensaries and rural stations. After considerable experience the author has found that the best procedure is to use a shortened lumbar puncture needle which is inserted in the mid line at an angle of 30 or 40 degrees at the level of the upper half of the second or third intercostal space. The needle with the stylet in it, is pushed with a boring action through the anterior lamina. When the marrow cavity is reached the stylet is removed and a syringe for aspiration attached.

to the needle. In the author's experience a local anaesthetic (novocain) is seldom necessary except with nervous individuals or patients over 30 years of age whose sternal cortex is usually thick and hard.

C M II

DA CUNHA (A. Marques) & DIAS (Emmanuel) Reacção de fixação do complemento nas leishmanioses. [Complement Fixation in the Leishmaniasis.]—*Brasil Medico* 1939 Jan Vol. 53 No 5 pp 89-92.

The authors have prepared a leishmania antigen by the following technique. The parasites are grown on the surface of blood agar plates for 8 to 15 days. The growth is scraped off and washed twice in physiological saline following which the centrifuged deposit of leptomonads is shaken up with ten volumes of acetone. After one or two days the acetone is removed and the sediment dried completely at 37°C. The material is then triturated and weighed. To it is then added 1 cc of absolute ethyl alcohol for each centigram and the mixture placed at a temperature of 37°-40°C for 20 days. The alcoholic antigen which is then of a brown colour may be kept at ordinary laboratory temperature or in the cold.

D OELSNITZ. Le traitement d'attaque du kala azar [Intensive Treatment of Kala Azar]—*Bull et Mém Soc Méd Hôpît de Paris* 1939 Mar 6 55th Year 3rd Ser No 7 pp 321-324

The case described is one of kala azar in a chamber-maid twenty five years of age. The disease was apparently contracted in Nice. Treatment was carried out with neostibosan which was administered almost daily for about two and a half months in doses of 0.5 gram till a total of just over 34 grams had been given. A complete cure resulted. The author notes particularly that this case illustrates certain features of the disease in adults to which he has called attention on a number of occasions. These are the slow development of the disease in a series of remissions and relapses the character of the anaemia, the changes in hepatic function the cutaneous pigmentation, the menstrual disturbances the frequency of adenitis of the epitrochlear glands and the course of development of the various biological reactions.

C M IV

D OELSNITZ SAURIN RAUBAUDI & DANIEL. Un nouveau cas autochtone de kala azar de l'adulte [Endemic Kala Azar in an Adult.]—*Bull et Mém Soc Méd Hôpît de Paris* 1939 Mar 6 55th Year 3rd Ser No 7 pp 316-321

The authors remind readers that during the last seventeen years in the South of France they have had under their care 150 cases of infantile and 15 cases of adult kala azar. They trace the development of their ideas regarding the best form of treatment till they reach the procedure which they now adopt namely the administration as frequently as possible of the highest tolerated doses continued over a long period. In the case of ureastibamine a dose of half a centigram per kilogram of body weight can be given daily till a total of over half a gram per kilo of body weight has been administered. During this

intensive treatment a careful watch has to be kept for signs of intolerance. With other organic antimony compounds the above doses may be exceeded.

WANG (C W) Solustibosan and Ureastibamine in Treatment of Kala Azar in Chinese Hamsters.—*Proc Soc Experim Biol & Med* 1938. Dec. Vol. 39 No 3 pp 418-421

The author has tested the toxicity and therapeutic value of solustibosan to normal hamsters and to hamsters suffering from experimental kala azar and has compared it with neostibosan and ureastibamine. In terms of the antimony content much more can be given in the form of solustibosan than in the form of either of the other two drugs, ureastibamine being the most toxic. As regards infected animals much more antimony in the form of solustibosan was required to bring about a cure than either of the other two. In this respect, ureastibamine is the most and solustibosan the least potent of the three drugs. During the tests on infected animals more of them died after ureastibamine than after solustibosan, but this was the result of the greater ulceration caused by the first of these, both drugs being given subcutaneously owing to the impossibility of carrying out intravenous injections in hamsters.

MATHIESON (Don R.) & WATSON (B. A.) Kala Azar.—*Jl Amer Med Assoc* 1909 Jan. 28 Vol. 112 No. 4 pp 308-309 With 2 figs.

The case described is that of a Chinese student who was found to be suffering from kala azar after he had gone to the United States. He was treated with fousadin given intramuscularly on alternate days till 125 mgm. had been given. As this drug did not appear to be controlling the disease it was decided to try stibamine gluconate (neostam). A total of 2.08 gm. was administered (presumably intravenously) in forty three days. A complete recovery occurred. During the fousadin treatment the patient's condition became so desperate that the treatment was stopped. The day following, the patient's temperature fell dramatically and his condition

VANNI (Vittorio) Ricerche sulla leishmaniosi cutanea endemica negli Abruzzi. Nota preventiva. [Researches on Endemic Cutaneous Leishmaniasis in Abruzzi.]—*Ann d'Igiene* 1938. Sept-Oct Vol. 48 No. 9-10 pp 520-528. With 7 figs.

Oriental sore has already been reported as common in the Province of Abruzzi on the East coast of Italy. The author reports that in the three months May to July 1938 he encountered there about 300 cases. These occurred mostly in the coastal rural districts with the exception that cases were less common on either side of the rivers which run from west to east through the province. Sandfly collections revealed two species *Phlebotomus macedonicus* and *P. papatasi*. In sections of a specimen of the former species it was seen that the pharynx was packed with flagellates which had the structure of leptomomas. It seems clear that these represent developmental forms of *Leishmania tropica* and that this sandfly is a vector of oriental sore in the district.

ESVAULT (P) & LOUBET (R.) Sur un nouveau cas de bouton d'Orient observé dans le Sud oranais. [A Fresh Case of Oriental Sore in South Oran.]—*Arch Inst Pasteur d'Algérie* 1938 June Vol. 18 No 2. pp 210-212. With 1 plate

The case described is a typical one of oriental sore in a young Arab who contracted the disease in the South Oran district of Southern Algeria. The interest of the case lies in the fact that it is the first to be seen in this area for 12 years though medical men have been constantly in the district attending to the needs of the inhabitants. The last cases five in number were seen by CÉARD in 1924-1925 so that it would appear that for some unexplained reason the disease occurs in small outbreaks separated by long intervals of time

HIGOUMENAKIS (G. H.) Beitrag zur Studie der Beziehungen zwischen Haut und Eingeweide-Leishmaniose (Orientbeule und kala-azar). [Relation between Oriental Sore and Kala Azar.]—*Arch f Dermat u Syph* 1938 Oct 20 Vol. 178 No 2. pp 133-151 With 7 figs. [23 refs]

The author gives a detailed account of several atypical cases of oriental sore in Greece which he regards as new types of the disease. The lesions in these cases were multiple and were of long duration. In one case there was a history of 15 years. In a case of kala azar in a child there appeared a number of skin lesions resembling oriental sore. Though leishmania were not found in these it is concluded that they were cutaneous manifestations of the generalized infection. This case leads the author to discuss the general question of the relationship of oriental sore to kala azar. He favours the view that the parasite of oriental sore in endemic foci of the disease is actually that of kala azar which through many skin passages has decreased in virulence and has thus ceased to produce generalized infections. The parasites from sporadic cases of the disease have, however, retained much of their virulence as evidenced by their power of producing visceral infections in experimental animals. This long and somewhat discursive paper is illustrated by a series of excellent photographs showing the types of lesion described.

SHALOM (E.) Effects of Scars of Baghdad Boils of the Lids.—*Jl. Egyptian Med Assoc.* 1939. Oct. Vol. 21 No. 10 pp 678-680.

The author writing from Baghdad, points out that the scars left by oriental sore of the eyelid may lead to ectropion and the various conjunctival and corneal complications which may follow this condition. In severe cases these may lead to blindness. C M IV

CAWSTON (F Gordon) Ulcero-Granulomatous Affection of the Nose in Zululana.—*South African Med J.* 1939. Nov. 26. Vol. 12. No. 22. pp. 854-855. With 1 fig

The case described is that of a Zulu man 30 years of age who was suffering from a condition which had developed since childhood and had finally destroyed the whole upper jaw nose septum and left eye, exposing the uvula and epiglottis. The condition was diagnosed as espondia, though no leishmaniasis could be found. Improvement in general health and in hearing which had been affected, followed a series of antimony injections C M IV

PORTER. La médication stibite dans le traitement du clou de Biskra. [Antimony Treatment for Oriental Sore].—*Ann de Méd et de Pharm Colon* 1939. July-Aug-Sept. Vol. 96. No. 9 pp 731-732

Oriental sore is relatively common in Algeria, particularly in the palm groves between Biskra and Tougourt where it is known as "clou de Biskra". Local treatment has done little to influence the duration of the sores, which eventually heal spontaneously. Certain antimony derivatives, such as the pentavalent diethylamine-aminophenyl stibonate (neostibosan) administered intravenously bring about a rapid cure. Generally an injection of 10 centigrams followed by one of 20 centigrams and then five of 30 centigrams, the injections being given twice a week are enough to bring about healing of the sore in a short time. C M IV

— ARER (Franco) Nuovo metodo di cura per la leishmaniosi cutanea (bottom d'Oriente) [New Cure for Oriental Sore].—*Boll Istituto Siroterap Milanese* 1939. Aug. Vol. 18 No. 8. pp 469-473. German summary (10 lines)

The author states that solution of atabrin injected into the skin round oriental sores rapidly destroys the parasites and cures the disease. The dose administered at one sitting commences at 0.05 to 0.1 gram dissolved in 1 or 2 cc. of distilled water and is increased at subsequent sittings to 0.3 gram. In some cases only a single injection was required to bring about a cure which has been effected in 14 cases. C M IV

CASTELLANI (Aldo) & AWALFITAKO (G) Treatment of Oriental Sore (Leishmaniasis Cutanea) with Fuchsin Paint.—*Jl Trop Med & Hyg* 1939. Feb. 1. Vol. 42. No. 3 pp 33-34. With 2 figs.

The authors have treated three cases of oriental sore with a fuchsin paint prepared as follows. Saturated alcoholic solution of basic

fuchsin 10 ml. 5 per cent phenol solution 100 ml filter and add boric acid 1 gram and two hours later acetone 5 ml two hours later resorcinol 10 grams is added. The mixture is kept in a dark-coloured stoppered bottle. The sore is cleared of scab and scales by moist dressing of boric acid and resorcinol applied for two days. The fuchsin paint is then applied twice daily to the sore while 2 c.c. of the same solution is given intramuscularly every other day. The solution may also be injected into the nodule or around it. Presumably the solution referred to is the paint itself but whether this is so is not quite clear. Three cases all from Africa, were treated the sores healing in two to three and a half months. *C M W*

REYES ORIBE (Hector) *Leishmaniosis tegumentaria americana. Modificaciones en el tratamiento asociación Yatren Fuadina. (Tratamiento Mazza.) [Yatren-Fouadin Treatment of S American Cutaneous Leishmaniasis.]—Prensa Méd Argentina 1938. Dec. 28 Vol 25 No 52. pp 2465-2475 With 6 figs. English summary*

In this article the author discusses a number of remedies which have been employed for the treatment of muco-cutaneous leishmaniasis in S America. These have not given very satisfactory results and he himself has been disappointed in the therapeutic effect of various antimonials. Accordingly on Professor Mazza's suggestion, he combined treatment with large doses of fouadin with intravenous injections of yatren. This was administered in a daily dose of 2 cc of a 3 per cent solution till 40 to 60 cc. had been given. The results of this combined treatment are described as being excellent. *C M W*

TROPICAL OPHTHALMOLOGY

A REVIEW OF RECENT ARTICLES. XXXI*

Conjunctiva—The nature of the epidemic of ophthalmia which raged in Europe during the Napoleonic campaign and after the return of the French and British troops from Egypt has always offered material for discussion. LAW¹ after a comprehensive review of the literature concludes that though trachoma was well known in Western Europe before the Egyptian campaign yet a consideration of the history of the disease suggests that much of the subsequent infection was brought from Egypt. The troops were also heavily infected with gonorrhoeal ophthalmia. [The description of the epidemic by Larrey Napoleon's surgeon-in-chief quoted by the author points to the existence of diverse causes—keratomalacia being one of them.]

Spring Catarrh—LYONS² has made a careful study of vernal catarrh in Egypt. The essential feature of the disease is an intermittent

* For the 30th of this series see Vol. 35 pp 855-857

¹ LAW (Frank W.) Egyptian Ophthalmia. —*Brit Jl Ophthalm* 1939 Feb Vol. 23 No 2. pp. 81-83 [11 refs.]

² LYONS (F Maxwell) The Biomicroscopy of Spring Catarrh.—*Tweefik Ann Rep Memorial Ophthalmic Laboratory, Giza, Cairo 1937 Appendix No 2 pp 1-13 With 6 coloured plates & 4 figs. [12 refs.]*

exudation of fibrin and wandering cells from certain groups of the conjunctival capillaries. This exudation may occur from the new formed vessels in trachomatous pannus as well as from the normal subconjunctival capillaries. It is likely to be best marked in areas where there is little mechanical resistance to leakage as in the interpalpebral portion of the bulbar conjunctiva. The tarsal conjunctiva, being firmly bound by fibrous bands to the tarsal plate is unable to accommodate the exudation, which consequently exudes through the epithelium and forms a sticky film on the surface. The epithelial layer soon becomes uprooted at the points of its weakest attachment and is ballooned out into broad papillae which undergo vascularization. The author minutely describes the corneal changes induced by exudation from the vessels of the limbus and of any existing trachomatous pannus. Early symptoms of the disease are (1) a general sallow appearance (2) a sensation as if something was crawling beneath the lid (3) a brilliant surface sheen of the conjunctiva with an opalescence of the tissues (4) a local eosinophilia combined with a tacky fibrinous discharge.

Purulent Ophthalmia—FERRÁNDEZ³ has reported strikingly successful results in eight cases of gonorrhoeal ophthalmia from the use of sulphamidamide, 2.6 gm. of the drug was administered daily for the first three days in four evenly-spaced doses of 0.65 gm. On the fourth day one dose was omitted so that the total amount on that day was 1.65 gm. The last two patients received no local treatment and were treated with sulphamidamide exclusively yet they recovered just as rapidly as the others.

Trachoma—Events during the past twenty years have led to a considerable increase in the incidence of trachoma in Greece in some localities this is as high as fifty per cent. according to CONSTATOS and CHARANIS⁴. These authorities review the measures taken and to be taken to control the disease. A special trachoma section of the Ministry of Health and Public Assistance was instituted ten years ago this works in cooperation with the departments of Education War and Admiralty. The school index method will mostly be employed.

fect foci of infection and the campaign will then be on a broad basis. About one hundred dispensaries will be opened and the staff for these will be trained in four or five months in the large towns. Special provision for trachomatous orphans and special companies in the army will be made in the General Hospitals and in the factories throughout the country. A 100-bed Home for trachomatous orphans and special companies in the army will be instituted for trachomatous soldiers. The programme will last for five years and will cost about twenty million drachmae. The Cross Society started a trachoma dispensary in 1925 in the infected district of Laurium, and in 1931 opened a dispensary in Athens under the direction of Dr J. S. CHARANIS. This confirms the claim made by KELLER that a close connexion

exists between trachoma and gonorrhoea. (J. S. CHARANIS & FERRÁNDEZ (Ricardo F.) Sulphamidamide in Gonorrhoeal Ophthalmia. Preliminary Report—*Ann J. Ophthalmol.* 1933 July 1933. No 7 pp 763-766 With 1 fig.

(Lefebvre F.) & CHARANIS (Jean S.) La lutte contre le trachome en Grèce. *Internat du Trachome* 1933 Oct. Vol. 15 No 4. With 6 figs.

The authors have prepared a proposal of symptoms of trachoma décrits par Keller. *Internat du Trachome* 1933 Oct. Vol 15 No 4. 9 refs.]

exists between trachoma and syphilis. He considers that though the diseases more or less often may be associated yet they are not necessarily so. Trachomatous pannus certainly exists and it cannot be mistaken for interstitial keratitis. Should an individual suffer from both syphilis and trachoma general treatment will act on the syphilis and the trachoma will be ameliorated. The follicle in trachoma differs from that in folliculosis in that it yields to crushing and leaves a cicatrix this is claimed to be a pathognomonic characteristic. The dissemination of the disease in the French Colonies is described by MARQUE⁶ who states that it is almost unknown in the small colonies and is rarely seen in Madagascar. It is however very common in Indo-China and most prevalent in the African Colonies. The author describes the disease and the organization necessary for its suppression. Much of the latter however involves greater expense than the colonies can afford and attention should in the first place be directed to improvement of rural hygiene propaganda, and education of the local practitioner in dealing with trachoma.

JULIANELLE SORY SMITH and LANGE⁷ have experimented with tartar emetic in the treatment of trachoma and have described their technique and results. The character of the latter leads them to conclude that the drug may possibly be of some use in certain varieties of the disease. The benefit seemed to be most marked in cases with corneal complications and in those which had been subjected to graftage. As might be expected sulphanilamide has been fairly extensively tried in the treatment of trachoma. KIRA McKELVIE & HUSSEIN⁸ report favourable results in the Sudan and found it particularly beneficial when corneal complications were present. They state that compared with present methods of treatment sulphanilamide therapy is simpler and much less painful but its permanent effectiveness has still to be ascertained. LOE⁹ has used the drug in the case of 140 patients and says that his experience has made him extremely sanguine. GRADLE¹⁰ has also had good results in 41 patients and thinks it may prove a new means of combating the more acute stages. He states that the drug is not free from danger and should only be employed when medical observation every twenty four to forty-eight hours is possible.

Cataract—The influence of general nutrition in the causation of cataract has been discussed by YUDKIN¹¹. He concludes that the disease is unlikely to be due to any single factor but is produced by many conditions a disturbance of the general metabolism being one of the most important. The prescription of a well-balanced diet properly supplemented with vitamins must play an important part in the prevention and treatment of the disease.

vaccines. Good results are obtained and the virus in the dried faeces remains active for as long as one year.

JORDAN and FLETCHER (p. 472) note that if 4 per cent. of ammonia is added to a local cresylic disinfectant it destroys lice and eggs in one hour.

ZIA and LIU (p. 472) point out the dissimilarity between the agglutinin production for *Rickettsia* and the Weil-Felix reaction in *Uyospalax fontanieri* infected with typhus virus.

PIERI (p. 472) reviews the history of boutonneuse fever. OLMER and OLMER (p. 473) consider that although the virus of boutonneuse fever is most closely allied to that of Rocky Mountain fever (and less so to the others of the typhus group) it is distinct. BOISSEAU (p. 473) inoculated himself with the virus of boutonneuse fever and describes the course of the local lesion and general disease.

GIBBONS (p. 474) shows that Rocky Mountain fever has been endemic in Western Canada since 1917 but no evidence of infection was found in 30 000 ticks collected.

PILCHER (p. 474) records cases of Rocky Mountain fever in Massachusetts. FLIPPER (p. 474) discusses typhus in Pennsylvania. JORDAN (p. 475) notes that 32 of 38 cases of Rocky Mountain fever reported in Iowa occurred in rural areas and most were associated with dogs heavily infested with *D. variabilis*. This tick was proved to harbour the virus in certain localities. BISHOPP and SMITH (p. 475) describe the bionomics of *D. variabilis* the principal, if not the only vector of Rocky Mountain fever and a vector of other diseases. Low relative humidity is probably the most important limiting factor. Various mammals may be infested but the dog is the main host. Methods of control are given. The abstract cannot be summarized further.

BRIGHAM (p. 477) shows that endemic typhus virus can be maintained in the numerous native field mice of Alabama, and (p. 477) details a number of wild rodents susceptible to endemic typhus virus in the same area. DAVIS and PARKER (p. 477) found that cross immunity tests of two strains of virus of Rocky Mountain fever of two different serological types in man, failed to show immunological differences in rabbits.

DIAS (p. 477) uses the term Brazilian spotted fever for the endemic typhus of São Paulo and Minas Geraes. The serological reactions and the fact that it is transmitted by ticks of the *Amblyomma* genus show the similarity to Rocky Mountain and boutonneuse fevers. TRAVASSOS (p. 478) shows that dogs may form a reservoir of endemic typhus and that this is transmissible by *Amblyomma striatum* in São Paulo. DE MAGALHÃES (p. 478) succeeded in infecting guinea-pigs with typhus by naturally infected *Amblyomma cayennense* in Minas Geraes, and (p. 478) describes the pathological appearances found in man.

GUNTHER (p. 478) considers that the vector of the endemic typhus of New Guinea (which resembles tsutsugamushi fever clinically and serologically) is a mite either a rare species or a rarely infected common species. HEINEMANN (p. 479) reports three cases of a second infection with pseudotyphus in the Dutch East Indies. The intervals between infections were from 1 to 2½ years, and little if any immunity is developed.

DAVIS *et al.* (p. 479) discovered infection with a new virus probably similar to that of Q fever of Australia in specimens of *D. andersoni*.

in Montana. The virus passes Berkefeld N and W filters but not a Seitz disc. Various rodents could be infected but no protection was given against Rocky Mountain virus. Transmission by nymphs and adult ticks developed from infected larvae was proved and eggs of infected adults developed to infective larvae. Rickettsia-like bodies were constantly found but were very slender and resembled *Bartonella bacilliformis*. The virus is cultivable in tissue culture. There is no cross immunity with Rocky Mountain fever.

ARCHER (p. 481) isolated *Proteus inuar* from a laboratory mouse

LECCISOTTI (G). La Weil Felix nella popolazione murina di Taranto [The Weil Felix Reaction in the Rats of Taranto].—*Pathologica* 1938. Dec 15 Vol. 30 No 566 pp 522-524. English summary (3 lines)

The author tested the serum of 93 rats (55 *Mus decumanus* 35 *Mus rattus* and 3 *Mus musculus*) caught in Taranto. Three strains of *Proteus* were used, *Felix Siniaco* and *Mel.* Forty-seven sera (39 *decumanus* and 8 *rattus*) were positive to a dilution of 1 in 100.

The author points out that these rats act as reservoirs and may transmit to man by their fleas mild endemic typhus of the nature of Brill's disease. But since according to certain workers the virus of murine typhus may give rise to classical human typhus the importance of this rat reservoir in a Mediterranean port is obvious. C B

BLEWITT (Basil). Fevers of the Typhus Group in the Bhim Tal Area, Kumaun Hills, U.P. India. Being a Report of an Investigation carried out into the Alleged Incidence and Nature of Typhus Group Fevers in the Bhim Tal Area Kumaun Hills, July 1938.—*Jl Roy Army Med Corps* 1938 Mar-Apr-May & June Vol. 70 Nos. 3 4 5 & 6 pp 157-167 241-245 312-315 379-387. With 1 map & 6 charts. [30 refs.]

The Kumaun Hills lie between the Terai foot-hills and the main range of the Himalayas at an altitude of 4 000 to 8 000 feet with numerous deep valleys and, in the locality under discussion a series of small lakes. Three of these lakes Bhim Tal Sat Tal and Naukuchhiya Tal lie in the Bhim Tal valley about nine miles from Naini Tal the Headquarters of the Eastern Command. This valley is about five miles in length by two in breadth and runs in a south-easterly direction through the hills. Along this valley runs one of the main trade routes from the plains to the hills and on to Tibet. There is much traffic along this road especially in the summer months. The majority of the local inhabitants are also nomadic and spend the summer in the hills and the winter in the plains.

Bhim Tal village is situated at the top of the lake on ground which is marshy in the rains but in the summer is covered with grass and scrub. During the hot weather the palace here has been occupied for the last 15 years by the Maharajah of Jind who brings with him annually about 500 people guests officials and servants and many dogs all these return to the plains in the cold weather. The Rajah and his household spend most of their time shooting in the valley and

surrounding hills but so far no cases of typhus have been reported among them. At Sat Tal the principal house and bungalows are in the possession of an American Mission and missionaries from the plains come up here in the hot weather for short periods of leave and to convalesce after illness. During the last six years no cases of typhus have occurred among the people.

So long ago as 1913 typhus was reported in the Bhim Tal area, Captain McKECHNIE I.M.S. [unpublished report] investigated the outbreak in that year and came to the conclusion that the cases, 32 in all were of true louse-borne typhus. Further sporadic cases have been reported from time to time in the same area. In 1916 Major (now Sir John) MEGAW [this *Bulletin* 1917 Vol. 9 p. 499] was camping in the Bhim Tal valley and contracted typhus fever and was of opinion that the vector in his case, was a tick. In 1926 one fatal case of typhus was reported. In 1932 four cases, two of which were fatal, and in 1936 two further cases. All these were Europeans visitors to the district and mostly officers on leave who had spent much of their time in the scrub and jungle around the lakes.

The author of the present paper who was stationed at Bareilly in the United Provinces, decided to investigate the question of typhus from the point of view of the vector. A field laboratory was established at Bhim Tal during the summer of 1936 a system of extended drives on a frontage of one-quarter of a mile was carried out from one end of the area to the other.

Three methods of collection were employed —

1 Removal and collection of ticks from all animals, cattle etc., met with during the course of the drive

2 Dragging the area with cloths and flags for collection of seed ticks

3 Removal of ticks from dogs and from coolies employed in carrying out the drives. Some thousands of ticks were collected in this way and about 1 000 were examined. 60 per cent. of these were *R. sanguineus* and *Hyalomma aegyptium*. These ticks were crushed in a mortar and emulsified and injected intraperitoneally into guinea pigs rabbits and white rats. Some of the ticks were also fed on rabbits and guinea pigs then crushed and injected into experimental animals. Twenty-six animals only were used owing to the difficulty of obtaining experimental animals no more were available. 614 ticks were fed and injected.

In one or two of the animals there was a slight febrile reaction but no definite typhus infection and in none of the rabbits or rats was there any positive Weil-Felix reaction. There is, therefore no indication from this work that infected ticks are numerous in and around Bhim Tal if they do exist.

The author is inclined to agree with McKECHNIE that the outbreak in 1913 was due to louse-borne infection and he also considers that the subsequent cases may be explained in the same way—susceptible people coming into close contact with natives carrying infected lice. He explains the occurrence of the disease in the Bhim Tal valley as being due to imported infection along the trade route which passes through the valley the camps and villages in the valley being the first stopping place on the road from the plains to the hills. His conclusions are that true louse-borne typhus is endemic in the Kumaun hills and that the geographical position of Bhim Tal on the main road to and from Almora and Tibet explains the occurrence of the disease.

in that valley and so far as his work went there was no evidence to support the theory that the cases which had occurred in and around Bhim Tal were due to the bites of infected ticks. *D Harvey*

FEDERATED MALAY STATES ANNUAL REPORT OF THE INSTITUTE
FOR MEDICAL RESEARCH FOR THE YEAR 1937 (KINGSBURY
(A Neave) Director) [Typhus-like Fevers. pp 106-120
LEWTHWAITE (R.)]

Wild rats were trapped in the town of Kuala Lumpur and from these two strains of the virus of endemic typhus (shop typhus) were obtained by inoculation into guinea-pigs which had been fed on a deficiency diet. Fever enlarged spleen and scrotal swelling without necrosis were noted in these animals. Rickettsia were seen in stained smears from the tunica vaginalis. This virus when injected into the eyes of rabbits caused a modified reaction which died out after the 3rd or 4th passage this is similar to the results obtained with the virus from cases of the disease and differs from the marked reaction which follows injection of the virus of tsutsugamushi fever (scrub typhus). The Weil Felix reaction was positive for *Proteus* $\Lambda 19$ up to a dilution of 1/1500. Rats were readily infected these developed high fever with high mortality. There was complete cross immunity between these two strains obtained from the rats and a virus previously isolated from a local case of endemic or urban typhus fever. Wild rats were caught in a plantation on which numerous cases of tsutsugamushi fever had occurred but only a few cases of endemic typhus. The brains of four of these rats were pooled and emulsified and this emulsion was inoculated into guinea-pigs and a strain of virus of endemic typhus was obtained. This strain when inoculated into the eye of rabbits gave the reaction of murine typhus yet the curious fact was noted that of 13 rabbits infected six gave a positive Weil Felix reaction with *Proteus* $\Lambda 19$ while two agglutinated *Proteus* $O\lambda K$ and nine were negative. This strain gave complete cross immunity with the strain isolated from the town rats and also with the human strain but the results with a virus of tsutsugamushi fever were indefinite. Cross infection in the eyes of rabbits with this strain and a strain of tsutsugamushi fever were obtained for instance one eye of a rabbit was inoculated with virus E endemic typhus a modified reaction followed and a positive Weil Felix reaction for *Proteus* $O\lambda K$ yet on inoculation of the virus of tsutsugamushi fever into the sound eye a maximum reaction followed. This virus ($\Lambda 19$) isolated from the plantation rats was utilized in transmission experiments with the rat flea and guinea-pigs from one of the guinea-pigs utilized a definite $O\lambda K$ or tsutsugamushi fever virus was obtained. An apparent mutation of the rat strain E took place from $\Lambda 19$ type of virus to λK type. This point is being further investigated. It is suggested that when the four original rats were pooled both viruses may have been isolated. Some 1 000 mites were taken from the captured rats and examined but no virus was isolated although some of these mites were actually taken from the four rats from which strain E was isolated.

Some Weigl lice vaccine was obtained from Europe and tested against the local strains of virus but no protection could be demonstrated. Some other vaccines were also tested by ageing of virus drying virus and coating with yolk of egg on oil and lanolin but without success. *D H*

RAYNAL (J.) Sur le typhus exanthématique de Changhaï (concession française). [On Typhus in Shanghai.]—*Bull. Soc. Path. Exot* 1938. July 6. Vol. 31 No 7 pp. 662-669

The author refers to a previous note on the same subject [see this Bulletin 1938 Vol. 35 p 781]. Since the publication of this note three new facts have emerged (1) an epidemic has been observed in the month of March 1938 (2) the virus has been isolated from two of the cases (3) a virus has also been isolated from rats caught in houses of patients.

In 1937 enormous numbers of refugees poured into Shanghai and the French concession was overcrowded. Cases began to appear in February and increased in March and April. Although these cases were severe the mortality was low 10 per cent., and the disease did not spread. The virus which was isolated from the cases produced fever and orchitis in guinea-pigs and was apparently identical with the virus isolated from the rats. The cases were therefore probably murine typhus.

D H

BLANC (Georges) & BALTAZARD (M.) with the collaboration of A. DOMNADIEU La contamination par voie muqueuse, mécanisme habituel de transmission du typhus murin dans la nature. Rôle du virus sec des déjections d ectoparasites dans l'épidémiologie des typhus. [Infection through the Mucous Membranes is the Usual Method of Transmission of Murine Typhus in Nature. The Role of the Dried Excreta of Ectoparasites in the Epidemiology of Typhus.]—*Bull. Acad. Méd.* 1938. July 28. 102nd Year 3rd Ser Vol. 120 No 27 pp. 109-114 With 2 charts. [22 refs.]

Forty mgm. of dried flea excreta, which had been kept for four months was dissolved in a small quantity of water and given to two men to drink. Twenty mgm. of dried excreta was placed on the nasal mucous membrane of two other men, and in two others 5 mgm. was placed on the conjunctivae. Of these six men, one who had been inoculated by the nasal route developed fever there was no reaction in the five others. However when these five were tested 65 days later by injection of living virus, three were found to be immune. It would appear therefore that at least four of the six men experimented on had been infected.

The authors have found that the dried excreta of infected lice or fleas may retain virulence for at least 12 months. In this way it is possible that infection may be carried over from one epidemic season to another without any actual cases occurring in the non-epidemic period. They suggest that louse-borne typhus infection may also be by the oral route with dried lice excreta.

During the course of their investigation they came across one mendicant from whose person and clothing they collected no fewer than 20,000 lice and "a mass" of dried excreta.

D H

STARZYK (Jean) Vitalité, virulence et pouvoir immunisant de *Rickettsia prowazeki* conservés en dehors de l'organisme du pou. [The Vitality Virulence and Immunizing Power of *Rickettsia prowazeki* maintained outside the Organism of the Louse.]—*Arch. Inst. Pasteur de Tunis* 1938. Sept. Vol. 27 No. 3. pp. 263-281 With 12 figs.

In the first series of experiments emulsions of the intestines of infected lice were made in the following liquid media, human serum

guineapig serum horse serum and in normal saline solution These were kept at laboratory temperature and tested by inoculation into lice by the intestinal route. It was found that the best medium for the preservation of the virus was human serum lice could be infected up to six days the percentage of red lice that is lice with maximum infection was also greater in those injected with the emulsion in human serum

In the second series of experiments dried material was utilized

1 Intestines of infected lice removed and dried in vacuo

2 Lice excreta dried similarly

3 Whole infected lice dried and kept at laboratory temperature or at +5 C

At laboratory temperature the virus was still infective after 30 days in the whole lice after 58 days in the excreta and after 60 days in the intestines

When the dried materials were kept at +5°C the following results were obtained

Dried excreta, still infective 4½ months

Dried intestines still infective 6 months

Dried lice still infective 3 months.

[These figures are taken from an *erratum* published subsequently]

All these were proved by injection into normal lice and the subsequent emulsifying of these lice and injection into guineapigs which became infected

The author points out that this is a simple way of maintaining the virus in the laboratory and also of sending the virus to other places From the epidemiological standpoint it is of vital importance as it shows that infection may be carried not only by living but by dead lice or the dried excreta of lice and also explains how infection may be carried by or on the clothes of infected persons even after many months

[It is interesting to note that recently attention has been called to the risk of infection from dried excreta of lice in the paper by BLANC above and the present paper The British Trench Fever Commission under the Chairmanship of Sir David BRUCE and of which Professors BACOT and ARKWRIGHT were members insisted more than 20 years ago on the importance of this method of infection.]

LE CHUITON (F) & PENNANÉACH (J) Essais de transmission du typhus murin au cobaye par la voie respiratoire. [Attempts to transmit Murine Typhus to the Guinea-pig by the Respiratory Route.]—*Bull Soc Path Exot* 1938. July 6. Vol. 31 No 7 pp 559-561

The strain of virus used was that of Toulon murine typhus (ship typhus) An emulsion of the brain of infected guineapigs was injected directly into the lungs of two normal animals. Both developed fever and were immune when tested later The same inoculum was injected directly into the trachea no fever resulted but the animals were found to be immune later It is possible that in making these injections small wounds may have been made and the infection resulted from absorption of virus through these lesions Accordingly guineapigs were

placed in a glass vessel and sprayed with the infective emulsion but no infection resulted nor was immunity produced.

The conclusion reached is that the respiratory route of infection can be only exceptional. [Possibly if dried excreta of infected fleas had been used the results would have been different.] D H

PHILIP (Cornelius B.) & PARKER (R. R.) The Persistence of the Viruses of Endemic (Murine) Typhus, Rocky Mountain Spotted Fever and Boutonneuse Fever in Tissues of Experimental Animals. —*Public Health Rep* 1938. July 22. Vol 53 No 29 pp 1246-1251

Rats, ground squirrels and mice were used in this research.

From rats infected with the endemic typhus virus the virus could be isolated from the brain up to 370 days and from the spleen up to 153 days. In 30 days the infection had disappeared from the tunica.

In mice the virus could still be recovered after 150 days from the brain and 130 days from the spleen. In squirrels the virus could not be recovered after 30 days from brain or spleen. With the virus of Rocky Mountain fever and boutonneuse fever neither mice rats nor guinea pigs showed any infection after 30 days. D H

- i. BORSEAU (R.) Technique simple et économique de conservation et d'entretien du virus de la fièvre boutonneuse. [A Simple Technique for the Maintenance of the Virus of Boutonneuse Fever.] —*Bull Soc Path Exot* 1938 Nov 9 Vol 31 No 9 pp 791-794
- ii. ——— Transport à distance du virus de la fièvre boutonneuse conservé *in vitro* [Transport to a Distance of the Virus of Boutonneuse Fever in Vitro.] —*Ibid* pp 794-796

i The entire testicle with the adherent tunica is removed from an infected guinea pig and immediately placed in a test tube containing a solution of two parts glycerine and one part normal saline. In this solution the virus remains active for 1 day at room temperature and if kept at 0°C for 11 days and at -10°C. for at least 40 days.

ii The test tube containing the testicle can be placed in a metal case cooled to -10°C then the case can be packed in ice in a flask and sent to a distance by air and then utilized for injection of animals, etc. This has been successfully accomplished by the author.

HITZ (Siegfried) Cultivo de la *Rickettsia prowazeki* in vitro [Cultivation of *Rickettsia prowazeki* in vitro] —*An. Escuela Nac Ciencias Biol Mexico* 1938. Oct.-Nov.-Dec. Vol. 1 No 1 pp 7-28. With 5 figs on 4 plates. [45 refs.] English summary.

The present report describes, after some short considerations about the relations among the different typhus fever strains, followed by a short historical introduction, a method to cultivate *Rickettsia prowazeki* in vitro based on the classical one of Mastrand and Mastrand, adopted to the culture of *Rickettsia* by Nigg and Landsteiner. We have introduced some modifications to this method, as the substitution of Erlennmeyer flasks by test tubes and Tyrode's solution by human ascites. With this method we obtained satisfactory results, comparable to those obtained with the original method. The strain was cultivated throughout more than 20

generations having observed a growth curve similar to that of bacteria in the series of cultures in which the number of rickettsiae was determined daily. The virulence of the cultures was proved by inoculation into guinea pigs which developed the symptomatology of typhus fever immunity to reinoculation and showed rickettsiae in the tunica vaginalis. The morphological study of the cultures colored by methods extensively described shows the form of propagation of the germs their exclusively intracellular position and a possible invasion of elements of the connective tissue of the muscles.

Judging premature the attempt to cultivate the *Rickettsia prowazeki* in cell free media the author expresses the hope that a detailed study of the factors prevailing in Martland cultures will solve the question. The germ of typhus fever should be considered more closely related to the bacteria than to the filtrable virus, especially to those of the haemophilus group which need for their growth certain substances produced by cells.

VIOLLE (H.) *Expérimentation sur le typhus exanthématique murin* [Experiments with the Virus of Murine Typhus.]—*Marseille Méd* 1938 July 5-15 Vol 75 No 19-20 pp 29-36

Three types of fever of the typhus group are met with in the south of France —

1 A few imported cases of true louse-borne typhus these do not spread

2 Murine typhus on board ships in Toulon harbour

3 Boutonnoise fever

The author obtained blood from cases of fever on a ship in Toulon harbour and inoculated this into rats and guinea pigs a virus was isolated and passaged it was found that in white rats the virulence of the virus was much enhanced by passage and especially in rats fed on a deficient diet. Guinea pigs had only a mild febrile reaction with periorchitis. In rabbits and puppies there was no fever but the virus could be recovered from these animals up to five months in the rabbits and three months in young dogs.

Pigs also could be infected and showed a very definite rash in these animals also the infection was inapparent but the virus could be recovered up to three months. All these animals could be infected readily by feeding them on infected material such as brain of guinea pigs or urine of white rats.

Blood taken from patients during the fever and allowed to clot then mixed with bread and fed to rats infected these animals.

Rats and guinea pigs could also be readily infected by intradermal injection of small quantities of infective material in a fine needle. The virus was readily destroyed by carbolic acid and other diluted disinfectants.

The thionine is prepared as follows. Dissolve the powder to saturation in distilled water precipitate with 10 per cent. solution of caustic soda filter and wash in water dissolve in 2 per cent. carbolic.

The secret of the process is that the stain should not be allowed to act for more than 30 to 50 seconds, then differentiate with absolute alcohol for 2 seconds. The stain should be kept for some time before use the authors prefer this method of staining to Giemsa. D H

LIT (P Y) ZIA (Samuel H.) & WANG (K C) Serological Studies on Subjects vaccinated against Typhus Fever.—*Proc Soc Experim. Biol. & Med* 1938 June Vol 38 No. 5 pp. 682-684

Doctors and nurses exposed to typhus infection in Peking Medical College Hospital were inoculated with loose vaccine. Material from 100 infected bee was inoculated in each person in three doses at weekly intervals. The reactions of the sera of these persons were studied, the sera were tested against emulsions of *Rickettsia* and also *Proteus* X19 emulsion.

The results of the tests are given in tabular form of 121 sera tested 37 gave negative reactions with *Rickettsia* emulsions, 16 gave negative reactions with *Proteus*. The majority of the sera were tested in the first three months after inoculation. D H

PIJPER (Adrianus) & CROCKER (C G) Rickettsioses of South Africa.—*South African Med. J* 1938 Sept 10 Vol 12. No. 17 pp 613-630 With 17 figs. [105 refs.]

A résumé of the work done by the authors on the local or South African types of typhus fevers with suggestions for further intensive research.

As has already been shown there exist in South Africa at least three types of typhus fever namely tick bite fever epidemic typhus presumably louse-borne and sporadic or murine typhus. These three diseases are more closely allied to one another than to the similar diseases of other countries. Tick bite fever resembles boutonneuse fever clinically primary sore rash etc. but cross immunity experiments between these two viruses were negative. The epidemic typhus of South Africa resembles the same disease in other countries but differs in that mortality is less and also the sera of cases agglutinate as a rule *Proteus* O\19 only in low dilutions and in addition agglutinate *Proteus* O\2 and O\K. A series of rabbits were inoculated with the virus of South African typhus and the serum of these animals agglutinates *Proteus* OY12 OX2 and OYA whereas when rabbits are inoculated with the virus of European epidemic typhus virus agglutinins are produced for *Proteus* O\12 but not for O\2 or O\K.

post-mortem results are detailed and excellent photographs are reproduced showing *Rickettsia* in enormous numbers in the peritoneal fluid. The strains of murine typhus used were Mexican and Tunis No. 1.

PIJPER (Adrianus) & CROCKA (C. G) Rickettsioses of South Africa.—*South African Med J* 1938 Sept. 10 Vol. 12, No. 17 pp 613-630 With 17 figs [105 refs]

A résumé of the work done by the authors on the local or South African types of typhus fevers with suggestions for further intensive research.

As has already been shown there exist in South Africa at least three types of typhus fever namely tick bite fever epidemic typhus presumably louse-borne and sporadic or murine typhus. These three diseases are more closely allied to one another than to the similar diseases of other countries. Tick bite fever resembles boutonneuse fever clinically primary sore, rash etc. but cross immunity experiments between these two viruses were negative. The epidemic typhus of South Africa resembles the same disease in other countries but differs in that mortality is less and also the sera of cases agglutinate, as a rule *Proteus* OX19 only in low dilutions and in addition agglutinate *Proteus* OX2 and OXK. A series of rabbits were inoculated with the virus of South African typhus and the serum of these animals agglutinates *Proteus* OX19 OX2 and OXK whereas when rabbits are inoculated with the virus of European epidemic typhus virus agglutinins are produced for *Proteus* OX19 but not for OX2 or OXK.

The sporadic typhus of South Africa is as elsewhere a disease of rats but this disease also produces agglutinins for *Proteus* O\19 O\2 and OXA in the sera of patients

The virus of epidemic typhus of South Africa as the author has already shown immunizes against sporadic typhus and tick bite fever. The virus of sporadic typhus (S.A.) immunizes against tick bite fever but not against epidemic typhus. Tick bite fever does not immunize against either of the other two viruses. D H

MATHEW (R V) *Endemic Typhus in North Queensland.*—*Med J Australia*, 1938 Sept 3 25th Year Vol. 2, No 10 pp 371-377 With 2 maps 4 figs & 3 charts

There are two types of typhus group fevers in North Queensland in one the sera agglutinate *Proteus* X19 and correspond to urban or shop typhus rat typhus in the other the sera agglutinate *Proteus* OAK in some of these cases there is a definite primary sore but in others no such lesion can be found and these latter resemble scrub typhus of Malaya.

During two years 1935-1937 some 300 cases of fever were investigated by the author in North Queensland. Of these 77 were definitely diagnosed as belonging to the typhus group. All of the six cases in the X19 class lived and worked in the towns whereas the cases in the XA class occurred in field workers especially among those who were engaged in clearing scrub or working in fields recently cleared.

Bites of mites and ticks are of frequent occurrence amongst those moving about on the scrub lands. In 17 of the XA cases a cutaneous inoculation lesion was present resembling the characteristic lesion at the site of the mite bite of Japanese River fever yet in one of these cases a tick had been removed from the skin at the site of the lesion some days previously. No lesion was noted in 30 XA cases and in 24 enlarged and painful lymphatic glands were noted. A rash was observed in all of the 6 X19 cases. Of the XA cases rash was observed in 35 and was not observed in 8. Of the XA cases 23 were mild 22 moderately severe 10 severe and 5 of grave severity. There were four fatal cases.

Animals were inoculated with blood from the cases and also with emulsion of brain from a fatal case. One hundred and four rodents rats and bandicoots were examined for the Weil Felix reaction and attempts were made to isolate a virus from the animals which gave a positive reaction but without result. ii. — Quelques examens hématocytologiques sur 4 cas de typhus exanthématique endémique. (Some Haematological Examinations on 4 Cases of Endemic Typhus).—*Ibid.* pp. 375-380

i. The acidophile cells (polymorphs) show a slight increase after the inoculation due probably to the injection of foreign protein the numbers of these cells then fall to normal but there is a second rise just before and during the fever. Eosinophile cells remain at normal or may be slightly reduced. In animals in which there was a high eosinophile count before inoculation there was a marked fall in the numbers during the fever.

Large mononuclear cells may be five times as numerous during the fever. Lymphocytes are decreased when the polymorphonuclear cells are increased, but there is a late (up to 48 days) increase in convalescence.

ii. Three phases in the cases were considered (1) The period of the fever up to the defervescence (2) the period of falling temperature (3) convalescence.

Resumé.—Increase of red cells was noted in only one case, 1 million per cmm. There was a return to normal 4 days after apyrexia. Leucopenia was noted during the febrile period and was more marked during defervescence but leucocytosis was observed during convalescence. Polymorphs were normal or slightly diminished during the fever and this diminution of numbers is also noted in convalescence. Eosinophiles disappear during the fever returning to normal in convalescence. Lymphocytes are generally augmented during the fever and a marked and prolonged lymphocytosis during convalescence was the chief item in the blood picture. D H

PETETAKIS (M.) Le typhus endémique bénin d'origine murine en Grèce (Benign Endemic Murine Typhus in Greece).—*Bull. Soc. Path. Exot.* 1938. Nov. 9. Vol. 31. No. 9 pp. 848-855.

The author has repeated the work of Professor LEROUX and confirmed it. He himself has recently observed 12 cases of the disease in and around Athens. A clinical description is given. A murine typhus virus was isolated from the patients and also from rats caught in the same districts. The differential diagnosis is discussed. 'boutonneuse fever' can be distinguished by the characteristic rash and by the presence of the primary sore. Also endemic typhus occurs in association with rats, 'boutonneuse fever' in association with dogs and dog ticks. D H

RISQUEZ (Jesús Rafael) FIGARELLA (Jorge) & VAN PRAAG (Antonio) Primer comunicación clínica sobre tifo exantemático en Venezuela. (Exanthematic Typhus in Venezuela).—*Rev. Med. de Caracas*, 1938. July 31 & Aug. 15. Vol. 45. Nos. 14 & 15. pp. 210-214, 225-234.

The authors give notes of eleven cases of fever with a roseolar exanthem in which they were able to exclude as causes malaria, enteric

(typhoid and paratyphoid) and undulant fever. Two of them gave a positive Weil Felix reaction with serum diluted to 1 in 800. Three others are mentioned in a postscriptum footnote whose sera also gave the reaction in the same dilution. More exact bacteriological reactions to the different types of *Proteus* have not yet been worked out.

SCHWEICKHARDT (Erwin) Die Verbreitung des Fleckfiebers in Mexiko und der gegenwärtige Stand seiner Bekämpfung und Behandlung mit Schutzimpfstoff und Heilserum. [The Distribution of Typhus Fever in Mexico and the Present Position in Regard to Prevention and Treatment by Vaccines and Sera.]—*Arch f Schiffs u Trop Hyg* 1938 Aug Vol. 42. No 8 pp 350-366 With 12 figs. [26 refs.]

In Mexico there are numerous cases of typhus with many deaths in the Central States and only a few mild cases in North Western districts adjoining the United States these latter are probably cases of murine typhus. There is no typhus at all in the North East or in the tropical South West coastal districts. 1700 deaths from typhus were reported in 1936. Blood taken from cases during the fever and injected into guineapigs produced fever with orchitis in these animals it was noted that there was a strong affinity of the virus for the endothelial cells of the serous membranes. This is taken advantage of in the method of ZINSSER [this *Bulletin* 1937 Vol. 34 p 485-486] in the preparation of vaccines from the numerous *Rickettsia* found in infected and irradiated rats. The *Rickettsia* thus obtained are killed by formalin and the vaccines prepared in this way have produced protection against the Mexican type of typhus although they do not protect against the European virus to the same extent. Horses have been immunized with massive doses of this vaccine and the sera of these animals have been employed in the treatment of cases of typhus fever and in the experimental protection of guineapigs. Twenty patients were treated and marked improvement was noted in 13 of these there were only three deaths in treated cases whereas the usual mortality rate in untreated cases has been 40 per cent. BLANC (Georges) & BALIAZARD (Marcel) Vaccination contre le typhus exanthématique par virus sec de typhus murin provenant de puces infectées [Vaccination against Exanthematic Typhus by Dried Murine Typhus Virus obtained from Infected Fleas.]—*C R. Acad Sci* 1938 Sept. 26 Vol. 207 No. 13 pp. 547-548.

The faeces of fleas (*X. cheopis*) which had been fed on infected white rats were collected and dried *in vacuo*. When required for injection

the dried faeces were suspended in a special saline solution and bile in a dilution of 1/150 is added.

Over 1 000 persons have been vaccinated with this bile treated vaccine. The immunity of these persons has been tested by injections of doses of living virus. Only three gave any febrile reaction. The dried faeces can be preserved for long periods, up to one year and the virus remains alive and potent. The material can be readily sent to a distance and vaccines prepared on the spot. D H

JORDAN (J H) & FLETCHER (A. E.) A Note on Disinfection with Particular Reference to Typhus.—*Chinese Med J.* 1938 July Vol. 54 No. 1 pp 71-72.

Tests were made on lice infested clothes with a local liquid disinfectant containing cresylic acid and phenols but without success however it was found that if 4 per cent. of ammonia was added to the disinfectant lice and eggs were all destroyed in one hour. Walls and furniture were washed with the solution and clothes were soaked in it. D H

ZIA (Samuel H) & LIU (P Y) Dissociation of *Rickettsia* and *Proteus* X 19 Antibodies in Experimental Typhus Infections.—*Proc Soc Experim. Biol & Med* 1938 June. Vol. 33. No. 5 pp 685-687 With 1 text fig

In this research a small rodent (*Myosorex fontanieri*) was employed it was found that these animals were readily infected with typhus virus and when infected the serum gave a strong positive Weil-Felix reaction. The animals were infected by the injection of guinea pig brain and were tested over long periods, blood being drawn off from time to time.

Rickettsia emulsions and emulsions of *Proteus* X19 were employed. It was found that the agglutinins for *Rickettsia* appear early and disappear quickly. The Weil-Felix reaction appeared later and lasted longer also the results were not parallel in the same animal one would give a high titre for *Rickettsia* and low Weil-Felix, another a low titre for *Rickettsia* and a high Weil Felix reaction these results agree with those obtained in vaccinated persons by the same observers. BOISSEAU (R.) *Sur un cas de fièvre boutonneuse expérimentale observé chez l'homme. [On a Case of Experimental Boutonneuse Fever observed in Man.]—Bull Soc Path Exot 1938 Oct 12. Vol. 31 No 8 pp 743-752. With 2 figs. [21 refs.]*

On 1st June 1938 the author inoculated into the skin at the back of his left forearm a minute dose of boutonneuse virus This virus had originally been isolated from dog ticks and had then been passaged for over 40 generations in guineapigs it could thus be regarded as a fixed and pure virus. The inoculation was made with a fine needle directly under the epidermis. In 36 hours there was some redness and slight thickening could be felt at the site of inoculation in 48 hours the lesion had increased in size and a small papule appeared

Local lesion 12 days after the inoculation into the skin of a minute dose of boutonneuse virus. [Photographed by Dr LORANDO]

[Reproduced from the *Bulletin de la Société de Pathologie Exotique*]

In the centre no pain was felt and there was no fever. On the 4th day the centre of the primary sore became definitely black. On the 5th day the sore had increased in size but no swollen or inflamed glands could be detected. On the 6th day the primary sore had reached its zenith and measured about 3 cm. in diameter and the black centre about 1 cm (see Fig). It was extremely tender but the surrounding skin was perfectly normal and not sensitive. On the 7th day from inoculation the sore began to recede and at the same time the invasion of the general system commenced. The temperature rose to 39°C. and a rash was noted on the arms and legs. Muscle pains were noted on the following day the lumbago and pains in the legs were acute. On the 12th day headache began and lasted for 3 or 4 days. macromela also was persistent throughout the illness. Neuralgia and carache were specially troublesome also pains in the joints. The writer sums up his experience as follows "a malady without real gravity but affecting all the organs of the body." The Weil-Felix reaction was positive for *Proteus* OX19 in 1/200 dilution. D H

GIBBONS (R. J.) *Sylvatic Plague and Rocky Mountain Spotted Fever Surveys, in Western Canada, during 1938.*—*Bull. Brit. Columbia Board of Health.* 1939 Mar Vol. 9 No. 3. pp. 30-33.

In most such surveys the outcome to be expected is the finding among rodents of a widespread infection or an epizootic. This however was not the case on the present occasion, where a cooperative effort was made to cover the provinces of Alberta and British Columbia, including the seaports of Vancouver and New Westminster. The staff was vaccinated as a preliminary with Rocky Mountain spotted fever vaccine.

In summary it was found that — 1 (a) Rocky Mountain spotted fever has been endemic in Western Canada since at least 1917. (b) No evidence of infection with the Rickettsia of Rocky Mountain spotted fever was found in 30,000 ticks collected, although *Basil. tularensis* infection was found. 2 No evidence of *P. pestis* infection was encountered in 3,569 wild rodents and 7,582 rodent fleas of Alberta and British Columbia nor in the 1,277 rats and 1,178 rat fleas of Vancouver and New Westminster. W F Harvey

PILCHER (Lewis S.) *Rocky Mountain Spotted Fever in Massachusetts. Report of a Case.*—*New England JI of Med.* 1938, Sept. 15 Vol. 219 No. 11 pp. 378-382.

A case of Rocky Mountain fever eastern type, which occurred in Massachusetts in July 1937 is reported. Two other cases which received their infection in Massachusetts during July 1937 but were treated in Rhode Island, have also been recently reported. These cases are apparently the first instances of this disease to be diagnosed in the New England area. D H

FLIPPIN (Harrison F.) *Typhus Fever in Pennsylvania.*—*Amer. JI Med Sci.* 1938 Aug. Vol. 196 No. 2 pp. 248-252. With 2 figs. [19 refs.]

An historical account of the incidence of typhus in Pennsylvania. The last reported outbreak of epidemic typhus was in 1883. endemic

typhus was first reported in 1911 and 27 cases have been recorded up to date. It is suspected that some of these were Rocky Mountain fever
D H

JORDAN (Carl F.) *Rocky Mountain Spotted Fever and Tick Survey in Iowa.*—*Amer Jl Public Health* 1938. Dec. Vol. 28 No 12. pp 1411-1414

During the five-year period 1933-37 2 190 cases of Rocky Mountain spotted fever were reported in the United States as a whole distributed as follows —

	Per cent
The Mountain and Pacific States	65.5
South Atlantic States	27.4
North and South Central States	5.4
New England and Middle Atlantic States	1.7

The first case of spotted fever in Iowa State was reported in 1933 and to date 38 cases have been officially notified. A clinical description of the cases follows: the mortality rate was 24 per cent although the majority of the cases were mild. Nearly half the patients were children and 32 out of the 38 cases occurred on farms or in rural areas and most were associated with dogs heavily infested with ticks (*D. variabilis*).

A tick survey was undertaken and numerous ticks were collected and sent to Montana for examination: practically all were *D. variabilis* the animal hosts of these ticks besides the dog were cows, sheep, horses, goats and also squirrels, rabbits and wood chucks. Ticks collected from the Indian Reserve where cases had occurred and also from a farm where three children had had spotted fever (one died) were proved to harbour the virus of Rocky Mountain spotted fever

BISHOPP (F. C.) & SMITH (C. N.) *The American Dog Tick, Eastern Carrier of Rocky Mountain Spotted Fever.*—*Circ. U.S. Dep. Agric.* Washington D.C. 1938. Apr. No 478. 25 pp. With 13 figs. [15 refs.] [Summarized in *Rev. Applied Entom.* Ser. B. 1938. Dec. Vol. 26. Pt. 12. pp 249-251.]

A detailed account is given of the bionomics of *Dermacentor variabilis* Say which is the principal if not the only vector of Rocky Mountain spotted fever in the central and eastern portions of the United States where an average of 140 cases occurs annually with a death rate of 25 per cent. It is also a vector of tularemia in man and animals and of anaplasmosis (*Anaplasma marginale*) in cattle. It is a serious pest of dogs causing severe irritation and loss of condition and often infests horses.

It is widely distributed throughout the United States east of the Rocky Mountains, in western and northern California, and in parts of Oregon: it is most abundant along the eastern coast from Massachusetts to Florida. It seems likely that low relative humidity is the most important factor limiting its distribution and abundance in the eastern states. It is most numerous in areas covered with grass or underbrush and occurs less frequently in forests where the species of mice that serve as hosts of the immature stages are less numerous. The dog is the chief host of the adults though others of the larger mammals may also be infested. Rabbits appear to be of little importance and birds are not attacked.

Unengorged adults live for long periods: one female kept under observation lived at least 968 days and possibly as much as 1 053. Adults, as well as other stages, require considerable moisture and if kept under

dry conditions live for much shorter periods. The longevity of adults that have attached to hosts is comparatively short. Most of the male and slightly engorged females that are removed from a host die within a few weeks, though occasionally one may live for 5-6 months. This is of some importance, since the organism causing Rocky Mountain spotted fever is activated in the tick by feeding and such partly engorged ticks may transmit the disease during a very short period of attachment. Engorgement of females, which is retarded by the absence of male, normally requires 8-13 days. Pairing takes place on the host 4-6 days after attachment, but is always preceded by a feeding period in both sexes. The preoviposition and oviposition periods varied with the temperature from 3 to 24 days and 14 to 32 days respectively. Eggs are laid in large masses in protected places on the ground—a female usually lays between 4,000 and 6,500 and dies 3-36 days after the completion of oviposition. The larvae remain in masses on the soil or on low growing vegetation and if conditions are sufficiently moist, survive for long periods. In the laboratory the maximum period was between 345 and 377 days. The average period for engorgement was 4-14 days. During the winter the period during which the larvae dropped from the host was distinctly prolonged though the period of engorgement was almost identical whether the hosts were kept in a warm or a cool room. The engorged larvae seek shelter on the soil surface. The period from dropping to moulting is markedly influenced by temperature—it varied from 8 days at about 84 F to 87 days at about 55°. The maximum longevity of unfed nymphs kept on moist sand was between 274 and 309 days, but most of them did not live more than 6 months. The period required for engorgement averaged 5-2 days. The period from dropping to moulting ranged from 17 to 105-109 days, being greatly prolonged during cold weather.

The seasonal incidence of the adult ticks is discussed; it varies in different parts of the United States, but, in general, the adults are most abundant in spring and early summer and their numbers diminish sharply in the hot dry months in late summer. In the south, they have been taken in every month of the year and breeding continues, though at a slower rate throughout the winter. In the colder parts of the country overwintering may take place in all stages but the egg. As few females become engorged and lay eggs in late summer most eggs hatch before the onset of winter. Unfed adults found completely quiescent in clumps of bunch grass became active in a short time when warmed. Larvae and nymphs occur on mice and other small mammals throughout the winter—their numbers increase after periods of mild weather and decrease almost to nil after severe weather. It appears that ticks that engorge during the winter all moult during a comparatively short time in spring.

Climatic factors are probably the chief ones exercising natural control of this tick, and of these excessive dryness is the most important. *D. variabilis* is very resistant to cold. Predators such as poultry, wild birds and mice doubtless destroy many ticks, especially engorged females. The need for further work on the parasite *Hemertellus hoodi* How is emphasized. In areas where there is an abundance of both small and large animals, the complete control of ticks by artificial means would appear to be almost impossible but in certain areas large wild animals suitable as hosts for the adults are few or absent, and under such conditions the treatment of dogs would probably result in satisfactory control, particularly if measures were also taken to reduce the numbers of meadow mice (*Microtus pennsylvanicus*) the principal hosts of the immature stages. An effective dip or wash for dogs can be made by dissolving 1 oz. soap in 1 U.S. gal. water and adding 2-4 oz. derris powder with a rotenone content of 4 per cent. This treatment, which should be applied at intervals of 5-6 days, will greatly reduce the number of ticks that become attached and prevent engorgement and reproduction. Derris powder is easier to apply but is not so effective and should be used at shorter intervals (2-3 days). Other measures recommended include clearing undergrowth and

keeping grass closely cut, especially near habitations etc., and the use of clothing designed to prevent infestation when it is necessary to traverse infested areas.

BRIGHAM (George D) *Endemic Typhus Virus in Mice*—*Public Health Rep* 1938 July 22. Vol 53 No 29 pp 1251-1256 [14 refs]

Endemic typhus virus can be maintained in native field mice which are numerous in the typhus area of Alabama. In the cotton mouse the virus was transferred through 16 generations before it was lost. In old field mice the virus has been carried through 36 passage generations. The virus has been found to survive 141 days in the cotton mouse 141 days in the old field mouse and 78 days in the golden mouse D H

BRIGHAM (George D) *Susceptibility of Animals to Endemic Typhus Virus. (Second Report.)*—*Public Health Rep* 1938 Nov 25 Vol. 53 No 47 pp 2078-2079

In a previous report from the same laboratory at Alabama it was reported that several species of field mice and rats were susceptible to endemic typhus virus also a typhus virus had been isolated from an old field mouse captured in the district. In addition it is now reported that the grey squirrel fox squirrel cotton tail rabbit swamp rabbit chipmunk and skunk are all susceptible to inoculation with the virus. But racoons and the grey fox are not susceptible D H

DAVIS (Gordon E) & PARKER (R. R.) *A Comparative Study of Two Strains of Rocky Mountain Spotted Fever Virus with Special Reference to the Well-Felix Reaction.*—*Public Health Rep* 1938 Aug 26 Vol 53 No 34 pp 1525-1531 With 6 charts

It was found that there were five types of serological reaction with various strains of *Proteus* in patients suffering from Rocky Mountain fever. Thus

- | | |
|---|---|
| (1) $\lambda 19$ high titre | $\lambda 2$ low titre |
| (2) $\lambda 19$ low | $\lambda 2$ high |
| (3) $\lambda 19$ positive | $\lambda 2$ negative |
| (4) $\lambda 19$ negative | $\lambda 2$ positive |
| (5) $\lambda 19$ titre equal to $\lambda 2$ | $\lambda 2$ titre equal to $\lambda 19$ |

Two strains of virus were isolated from patients of types (2) and (3) and comparative studies made of these two strains. Cross immunity tests were carried out but no immunological difference could be made out. Rabbits were inoculated with the two strains but no difference in immunological or serological response could be detected. Strain 3 which produced only agglutinins for *Proteus* O $\lambda 19$ in man produced agglutinins for both strains in rabbits. Protection tests were carried out and it was found that immune sera of either strain neutralized the other D H

DIAS (Emmanuel) *O cão como provável reservatório do vírus da febre maculosa brasileira. [The Dog as a Likely Reservoir of the Spotted Fever of Brazil.]*—*Brasil Medico* 1937 Dec 18 Vol 51 No 51 pp 1245-1247 [12 refs]

The denomination of *Brazilian spotted fever* is now used for the São Paulo type of endemic typhus or the exanthematic typhus of

Minas Geraes. Ticks of the *Amblyomma* genus namely *A. striatum* and *A. cajennense* are known vectors and they are found in dogs. Moreover the serum of such dogs gives a positive Weil-Felix reaction with varieties of *Proteus* namely to 1 in 640 with *Proteus* HAK up to 1 in 320 with *Proteus* OY19 OY2 and HX1 to 1 in 160 with *Proteus* HX19 HXK and OXL and to 1 in 80 with *Proteus* HX2 and HXL. This fact brings the Brazilian type of fever more closely into line with Rocky Mountain spotted fever carried by the dog-tick *Dermacentor variabilis* and boutonneuse fever by *Rhipicephalus sanguineus* found on dogs on the Mediterranean littoral. TRAVASSOS (J) Le chien réservoir de virus possible du "typhus exanthématique de São Paulo" [The Dog as a Possible Reservoir of the Virus of São Paulo Typhus].—*C R Soc Biol* 1938, Vol. 129 No 24 pp. 74-76.

The author has already shown that ticks of the species *Amblyomma striatum* taken from dogs captured in the quarter of São Paulo where the fever occurred were infective for guinea-pigs. Four dogs were caught and killed in one case a Weil-Felix reaction for *Proteus* X19 in a dilution of 1/160 was obtained, the blood and organs were injected into guinea-pigs in two of these slight fever was noted and these two animals when tested later were immune. Dogs can be infected by injection of virus and the Weil-Felix reaction becomes positive and the blood of the dogs was shown to be infective by the 11th day after inoculation. D H

DE MAGALHÃES (Octavio) Typho exanthematico em Minas Geraes. (IIa comunicação.) [Typhus Fever in Minas Geraes].—*Brasil Medico* 1938, July 9 Vol. 52 No 28, pp 634-638. With 1 fig

The author has previously reported that typhus in Minas Geraes may be transmitted by ticks and occasionally by the bug *C. lectularius*. In the present communication he records more details of animal experiments with *Amblyomma cajennense* as the vector. He finds that the tick having fed on an infected animal becomes infected and after an interval of 30 hours remains infective for life. When allowed then to feed on a guinea-pig the latter contracts the disease with an average incubation period of 5-4 days. H H S

DE MAGALHÃES (Octavio) Typho exanthematico em Minas Geraes. Anatomia pathologica. [The Morbid Anatomy and Histology of Typhus exanthematicus in Minas Geraes].—*Brasil-Medico* 1939, Jan Vol 53 No 5 pp 104-113 With 14 figs

This article cannot be abstracted those interested must consult the original. In it are described the naked-eye changes seen in the viscera—heart spleen, liver pancreas kidneys, brain, etc.—and the pathological histology of the lesions. H H S

GUNTHER (Carl E. M.) The Probable Vector of Endemic Typhus in New Guinea.—*Med J Australia* 1938, Aug 6, 25th Year Vol 2, No 6, pp. 202-204

Clinically and serologically "endemic typhus" of New Guinea resembles tsutsugamushi fever. The sera of patients agglutinate

Proteus XK and not 119. By analogy therefore the vector should be a larval mite. Larval mites are abundant in New Guinea where they are called in pidgin English *bush mokka*. In patients suffering from fever there is always a history of a recent stay in mite infested country. The primary sore is always found at one of the sites favoured by the mites. The ordinary bites of mites give rise to intense itching and are usually infected by scratching whereas the primary sores in fever cases are not itchy and are rarely secondarily infected.

Although practically every person who goes into the bush and swamps is bitten freely by mites only a few cases of fever are met with each year. This may be explained either by the supposition that the vector is one of the rare species of mites or that the common mite *Trombicula hirsuta* is only rarely infected. This mite is frequently found on man and is a parasite of birds but also of the bandicoot. The numerous mites from the birds would not be infective whereas the few derived from the rodents might be. Other species of mite may carry the infection from one rodent to another but they do not attack man.

D H

HEINEMANN (H.) Over reinfecties met pseudotypus (mijtekoorts) [Reinfection with Pseudotypus (Mite Fever)]—*Geneesk Tijdschr v Nederl Indië* 1938 Nov. 29 Vol. 78 No. 48 pp. 3037-3040. With 1 plate & 2 charts.

A European was bitten on 24th July 1938 by mites. He developed a small round ulcer on the thigh on the same day and fever a week later. The course of the affection was typically that of pseudotypus and this would not have required special notice but for the fact that the same patient had had an attack of the same disease a year previously. Little if any immunity seems to have been given by the first attack for the second one was even more severe. Out of 256 cases of pseudotypus recorded in hospital there were found the present case included three of second infection and the intervals to this second infection were 1 year, 2½ years and 18 months respectively.

DAVIS (Gordon E.) COX (Herald R.) PARKER (R. R.) DYER (R. E.) A Filter-Passing Infectious Agent Isolated from Ticks. I. Isolation from *Dermacentor andersoni*. Reactions in Animals, and Filtration Experiments [DAVIS & COX]—*Public Health Rep* 1938 Dec. 30 Vol. 53 No. 52 pp. 2259-2267. II. Transmission by *Dermacentor andersoni* [PARKER & DAVIS]—*Ibid* pp. 2267-2270. III. Description of Organism and Cultivation Experiments [COX]—*Ibid* pp. 2270-2278. IV. Human Infection [DYER]—*Ibid* pp. 2277-2282. With 1 fig.

In the spring of 1935 200 ticks (*Dermacentor andersoni*) were collected from Nine Mile Creek about 30 miles from Missoula in Montana. These ticks were divided into four batches of 50 and each batch was fed on a normal gumeapig. One of the gumeapigs developed fever on the 12th day after the ticks had been placed on it and ran a high and continuous fever and died on the 20th day. Four cc. of blood was taken from this animal on the 2nd day of the fever and this was inoculated intraperitoneally into two other gumeapigs both developed a similar fever and both died. Post-mortem appearances

were similar in all three, namely enlarged lymph glands swollen dark red smooth spleen, and some injection of the testes and tunicae.

This infection has been maintained ever since in guinea pigs by the intraperitoneal or subcutaneous injection of blood or spleen of infected animals. When the inoculation was made subcutaneously there was a local inflammatory reaction at the site of injection. Thrice washed red cells from an infected guinea pig still retained the infection. Immunity to the disease was present for at least 115 days after the fever.

Filtration

Blood was taken from an infected guinea pig on the 3rd day of fever this was placed in citrate solution and centrifuged. The citrated plasma was then filtered through a Mandler filter and 1 cc. of the filtrate was injected into two guinea pigs. Both developed fever and died and both showed the typical post mortem appearances. Further filtration experiments on similar lines have conclusively shown that the infectious agent readily passes through Berkefeld V and W filters but it was not found possible to pass the virus through a Sertz disc. The spleen of an infected guinea pig was removed and placed in glycerine. From time to time portions were removed and emulsified and injected into normal animals. After 16 days in glycerine infection was produced in guinea pigs and there was evidence that the virus was still active up to 80 days. White rats and white mice were readily infected by the injection of blood or spleen of infected guinea pigs but rabbits and monkeys were resistant. Squirrels and chipmunks could also be infected with the virus.

Guinea pigs which had recovered from this virus infection were not resistant to infection with the viruses of typhus or Rocky Mountain spotted fever nor vice versa.

Transmission in Ticks.

A series of experiments was carried out on the transmission of the virus by means of ticks, *D. andersoni*. Larvae were fed on infected guinea pigs and it was found that nymphs and adults developed from these larvae were capable of infecting normal guinea pigs. Eggs were collected from some of these infected ticks and the larvae which developed from these eggs infected guinea pigs when they were allowed to feed. Clean nymphs and adults fed on infected guinea pigs were collected after feeding and emulsified and injected into normal guinea pigs these also became infected. blood was taken from the infected guinea pigs, the serum filtered and injected into other guinea pigs, which in turn became infected and showed the usual post-mortem appearances enlarged lymph glands and swollen smooth dark red spleen. When the infected tick emulsion was injected into guinea pigs which had recovered from the previous attack of the fever they did not react.

Description of Organism

Guinea pigs were infected and killed at intervals during the febrile period, smears were made from the tunicae and from the exudate on the enlarged spleen, these smears were stained by Giemsa stain. No "inclusion" bodies were seen but numerous minute delicate extracellular and intracellular pleomorphic Rickettsia-like organisms were observed. emulsion of spleen of an infected guinea pig was centrifuged and filtered and injected into two guinea pigs, both became

infected and the same Rickettsia-like bodies were found in stained smears of the spleen exudate in these animals. The pleomorphism of these small bodies is very marked rods bipolar rods diplobacilli filamentous forms chains of cocci and nests of cocci in the cytoplasm of cells were all noted.

These small bodies resemble typhus Rickettsia closely but are more slender and minute they also resemble *Bartonella bacilliformis* in Carrion's disease but are not seen in the red cells do not grow in Noguchi's medium and when injected into the eyebrow of monkeys no verruga nodules are formed.

In tissue culture the virus was readily cultivated and carried in transfer in subcultures the medium used was minced chick embryo tissue in human ascitic fluid. The small Rickettsia could be demonstrated in the tissue cells in every transfer. The conclusion is that the infectious agent isolated from ticks resembles Rickettsia in every respect except that it has not been found in the tissue of the ticks.

In 1928 NOGUCHI isolated from ticks collected in the same district in Montana a similar filter-passing virus. Although Noguchi found that monkeys could be infected with the virus it is quite probable that the two infections are identical.

A worker in the laboratory who had handled infected ticks and guinea pigs became infected with the fever. 5 cc of his blood taken on the 6th day of illness and injected into guineapigs proved infective and this strain of virus has been passaged for 20 generations in guineapigs. The serum of this patient neutralized the original strain of virus isolated from the ticks. There was no cross immunity between this human strain of virus and the viruses of typhus or Rocky Mountain spotted fever. It is probable that this new virus is similar to that of the so-called Q fever of Australia [see this *Bulletin* 1938, Vol. 35 pp. 62, 63].

ARCHER (G. T. L.) *Proteus musar* isolated from a Mouse.—*Jl. Roy. Army Med Corps* 1938 Aug. Vol. 71 No. 2. pp. 106-108.

An organism isolated from the heart blood of a mouse in the laboratory was shown to have all the character of *Proteus musar*, alcoholized suspensions of this bacillus were agglutinated by *Proteus* O & K serum but not by H & 19 or H & 2. Cross agglutination and absorption tests carried out established complete identity with the type strain obtained from the Lister Institute.

DENGUE AND SANDFLY FEVERS

PRÉCIS OF ABSTRACTS IN THIS SECTION

WAKIL and HILMY (p. 482) describe the Cairo epidemic of 2,594 cases of dengue in 1937 in which 60 deaths took place from complications in heart or lungs. MAGLIANO and AZZI (p. 482) describe an epidemic of dengue in Abyssinia in which two waves of morbidity occurred, separated by a period of about 10 days when no cases were seen. There were no deaths.

SANNER and DESTHIBATS (p. 483) describe the characters of dengue-like fevers in Dêgo-Suarez.

SHORTT PANDIT and RAO (p. 483) isolated the virus of sandfly fever from the sera of patients. The sera had been in cold storage for a month. Mixture of these sera with sera from convalescent patients inhibited growth. C W

WAKIL (A W) & HILMY (F) *Épidémie de dengue au Caire en 1937* [Epidemic of Dengue in Cairo in 1937]—*Bull. Office Internat. d'Hyg. Publique* 1938, Aug. Vol. 30 No. 8, pp. 1821-1841. With 1 map & 3 graphs. [25 refs.]

The epidemic commenced in the first week of September but the origin of the outbreak could not be traced. 2,594 cases were reported in Cairo itself and these represented about 92 per cent. of all the cases in the country.

The maximum number of cases was reported in the week ending 11th November and the cases ceased at the end of the year. There were 50 deaths due to various complications in heart or lungs. A full clinical description of cases is given. D Harvey

MAGLIANO (GIORGIO) & AZZI (ENRICO) *Epidemia di dengue sulle coste della Mignurtina durante le operazioni per la conquista dell'Impero* [Epidemic of Dengue on the Coast of Mignurtina during the Abyssinian Campaign.]—*Ann. di Med. Nav. e Colon.* 1938, July-Aug. Vol. 44 No. 7-8, pp. 337-344. With 1 fig. & 4 charts.

The earlier cases of the outbreak, which lasted from March-June 1936, were atypical and of an influenzal type: slight fever and joint pains, and rash so little in evidence as to be in some cases overlooked. The morbidity varied as shown in the accompanying graph: 10-12 per cent. in the early days of the outbreak, 18-20 during the acme, then a lull for some ten days and finally a descending incidence of 12-8 per cent. The author divides the outbreak into seven periods. First, extending over the first three weeks of March, characterized by mild and atypical cases; next the period of higher morbidity during the last decade of March and the first of April, followed by a rapid remission and complete absence of fresh cases, both these occupying about 10 days each. Then came a second wave continuing to rise to an acme during the first ten days of May, remaining at the new level for another ten days and during the next four weeks slowly declining. The whole outbreak, therefore, covered nearly four months. The actual number of cases is not stated. None was fatal though one officer died of heatstroke ten days after recovery from an attack of dengue.

Graphic representation of course of epidemic of Dengue from March to June, 1936, on the Coast of Mignurtina.

SHORTT (H E) PANDIT (C G) & RAO (R Sanjiva) The Virus of Sandfly Fever in Culture and Certain of Its Properties.—*Indian J Med Res* 1938 July Vol 26 No 1 pp 229-239

Sera of sandfly fever patients were mixed with a small quantity of normal human serum and inoculated into the chorio-allantoic membrane of chick embryos. The technique followed was similar to that described by the authors in 1933. The virus was also grown in tissue culture consisting of embryo chick emulsion and Tyrode solution in 50 cc flasks. Twenty-seven sera in all were tested out of 13 pooled batches of sera (two samples in each batch) seven gave a growth of virus. These sera had already been in cold store for a month and had been five days on the journey from Peshawar to Madras. When the sera of convalescents from the disease was mixed with the inoculum and held in contact for 30 minutes growth on the egg membranes was inhibited. Inoculations were made into mice but without any definite results although the virus could be recovered from the heart blood and brain of the animals up to nine days after inoculation. Cultured virus was sent to England by air and was successfully subcultured on arrival there

OROYA FEVER AND BARTONELLA INFECTIONS

PRÉCIS OF ABSTRACTS IN THIS SECTION

MACKENHIE (p 484) describes experimental infection with *Bartonella* cultivated from a patient with Oroya fever. A local lesion followed by a granuloma with lymphatic and blood spread and general (but sometimes delayed) symptoms of fever and anaemia, follow and subsequent trauma or intercurrent disease may determine the onset

PITTALUGA (p 484) discusses *Bartonella bacilliformis* transmitted probably by a Phlebotomus or possibly a tick, *B. muris* by rat louse or flea *B. canis* and *B. boris*. Splenectomy transforms a mild anaemia in rats infected with *B. muris* into a grave form. The rôle of the spleen and reticulo-endothelial system in protection is discussed, but it is pointed out that Carrion's disease in man is not comparable with the infection of animals by *B. muris* and *B. canis* or with that in monkeys caused by infection by *B. bacilliformis*

gave positive Weil-Felix reaction with *Proteus* OX19 and OXK and also agglutinated emulsions of *Rickettsia prowazekii*. After several subcultures there was a loss of virulence in the cultures on blood agar but this was re-established when the parasites were subcultured into semi-solid medium. [See also this Bulletin 1929 Vol. 26 p. 519] D H

WEIXMAN (David) On the Cause of the Anemia in the *Bartonella* Infection of Rats.—*Jl. Infect. Dis.* 1938. July-Aug. Vol. 63. No 1 pp 1-9 With 1 fig. [20 refs.]

The *Bartonella muris* anaemia of rats is due to blood destruction and is accompanied by haemolysis. When *in vivo* haemolysis occurs, haemolysis *in vitro* can be demonstrated. Extra corporeal haemolysis takes place with washed erythrocytes suspended in isotonic saline solution and also in serum.

The parasite *Bartonella muris* appears to be the direct cause of erythrocytolysis and thus of haemoglobin liberation for the following reasons —

- (a) It is present within or upon cells when lysis occurs.
- (b) When no parasites are visible there is no lysis.
- (c) Fragmented cells contain parasites.
- (d) The more fragile pale cells are the heavily-parasitized ones.

D H

ALSTED (Gunnar) Studies on Immunity in *Bartonella* Anaemia. *Acta Path et Microb Scandinavica*. 1938 Supp 37 pp 37-59 19 refs.

Previous work has suggested that protection from *Bartonella* infection is due entirely to splenic function yet these parasites disappear from the blood of rats, from which the spleen has been removed after recovery from the anaemia. Also in latent infections there is a mortality of 7 to 30 per cent. whereas in infection after splenectomy 97 per cent. of rats die. Heating kills some but not all of the parasites in blood taken from infected animals. If such blood is injected into rats it produces severe infections but after a prolonged incubation period. The length of the incubation period depends on the number of parasites in the injected blood but the severity of the attack does not. Eleven rats which had survived *Bartonella* anaemia were observed over long periods and it was found that the parasites disappeared from the blood in 28 to 36 weeks after the anaemia had ceased.

Ten of these rats were re-inoculated and 9 were resistant only one showed a slight infection. The spleens of these rats had previously been removed. It is obvious that there is a gradual production of immunity after recovery from anaemia this immunity is much more marked than that which follows a latent infection.

Nine rats which had showed a latent infection for about one month all died of anaemia after splenectomy but of 17 animals which had had latent infections for three months and were then splenectomized only 11 died. It is evident then that latent infections produce some degree of immunity apart from splenic function.

D H

MALARIA

PRÉCIS OF ABSTRACTS IN THIS SECTION

MIRRA (p 488) describes malaria in Entrea where there are hyper-endemic areas. The majority are *vivax* infections. SOEIRO and REBELO (p 488) found parasites (mainly *P. falciparum*) in 47.9 per cent. of natives and 5.7 per cent. of Europeans in 6451 examinations in Lourenço Marques.

DE BUCK (p 489) shows that *A. maculipennis messeae* and *atroparvus* are not sharply separated from one another according to the salinity of the breeding water and VAN TUIEL (p 489) from experiments with *A. maculipennis messeae* and *atroparvus* thinks that if the water in North Holland were rendered more fresh *messeae* would not thereby displace *atroparvus*. BEVERE (p 490) finds *A. maculipennis labranchiae* the most prevalent anopheline in the Foggia province of Italy. SCHLENOVA (p 490) describes the habits of *A. maculipennis maculipennis* the most important vector *A. plumbeus*, *A. bifurcatus* and *A. superpictus* on the Black Sea coast. DANILOVA and BOUDYKO (p 491) show that lagoons near the Sea of Azov are the most important breeding places in that endemic area. *A. maculipennis* is the principal vector. *P. vivax* infection is the commonest in summer and *P. falciparum* in autumn.

EVANS (p 492) shows that *A. maculatus* the local vector in Pahang can breed inside jungle which viewed from outside is apparently safe.

BOYD and KITCHEN (p 492) found that when lots of *A. quadrimaculatus* were fed on patients a significantly higher proportion of infection was obtained when exflagellation was found at the time of feeding than when it could not be demonstrated in *P. vivax* infections. No such difference was noted with *P. falciparum*.

GARNEHAM (p 492) considers that malaria stimulates a reticulo-endothelial response with phagocytosis of parasites in the placenta and that these macrophages are developed from lymphocytes. Relapses following parturition are probably due to removal, with the placenta, of a highly active reticulo-endothelial system. No instance of congenital infection was found in a large series.

BOYD *et al.* (p 493) by experiments on reinfection found that simultaneous inoculation with two strains of *P. vivax* delays the development of homologous immunity to either. SIOLI *et al.* (p 494) describe the course of *P. vivax* infections with known strains. The Madagascar strain was more effective in producing infection in mosquitoes than the two others used, and did so even when gametocytes could not be found in the blood.

BOYD (p 495) observed the density of *P. vivax* in the blood of patients undergoing primary infections, in relation to the course of the clinical attacks. After trophozoite inoculation maximum density was earlier and higher and the attacks shorter than after sporozoite infection.

BOYD and KITCHEN (p 495) report that 3 of 7 patients infected simultaneously with *P. falciparum* and *P. vivax* suffered relapses due to the latter. The primary attacks were characteristic of *P. falciparum* malaria. HEGNER (p 495) considers that the relative malignancy of *P. falciparum* (and *P. knowlesi*) may be due to the property of attacking mature erythrocytes rather than reticulocytes, which is not shown by *P. vivax*.

GERMAIN and MORVAN (p 496) record a long latent period in a patient in whose blood at the first attack both *P. vivax* and *P. malariae* were found. JELINEK (p. 496) describes malaria with long latent period and in one case clinical features simulating cerebellar tumour. AUDEH (p 497) considers that *vivax* malaria may have been the cause of orchitis in two patients. GASIC (p 497) found no value in sternal puncture in the diagnosis of malaria during periods of latency.

FAIGUENBAUM and GASIC (p 497) record the occurrence of agranulocytosis in a patient apparently due to quinine treatment. BORD and KITCHEN (p 497) found that treatment with quinine for a single day had considerable effect in inducing periods of clinical quiescence in patients infected with *P. vivax* especially if given late in the attack. No similar effect was found in *P. falciparum* infections.

DECOURT (p 498) discusses the dygonic action of quinacrine [atebrin]. This inhibits asexual reproduction and gamete formation of schizonts and suppresses morbid phenomena. For the maintenance of this action a dose of 0.3 gm. given thrice monthly is more effective than smaller doses given more frequently. FIELD *et al* (p 498) as a result of the treatment of a considerable number of patients with the three types of malaria, consider that atebrin muscinate though efficient in controlling acute attacks, is not to be recommended for routine administration.

CROFFA *et al* (p 499) prefer plasmoquine to cillonal in the eradication of gametocytes of *P. falciparum*. DE NUOVO (p 500) from observations in induced malaria considers that antimony tartrate shows marked gametocidal properties and may be considered as a causal prophylactic.

BISPHAM (p 500) working in an area with predominantly *P. vivax* infections, confirms the value of atebrin prophylaxis when $4\frac{1}{2}$ grains weekly are administered for four weeks or more. CHARBONNIER (p 501) found that in a post in French Indo-China although prophylactic quinine was not successful the addition of quinacrine and praequine [plasmoquine] once weekly produced marked improvement.

MIRRA (Gudo) Il problema malaria-colonizzazione in Eritrea. [Malaria and Colonization in Eritrea].—*Ann di Med Nav e Colon* 1938 Sept.-Oct. Vol. 44 No. 9/10 pp 428-436 439-443

This is a comprehensive description of Eritrea with special relation to conditions that are responsible for malaria endemicity. An account is given of the geographical divisions of the country, water courses, climate, rainfall, and population which numbers about 600,000 with five to the square kilometre. Breeding places of anophelines are described but no reference is made to species. Severe outbreaks of malaria in the past are referred to as are the results of limited malaria surveys carried out during the past few years from which it appears that there are places in Eritrea in which malaria is hyperendemic. For the country as a whole about 75 per cent of cases are *vivax* infections, 20 per cent *falciparum* and 5 per cent *malariae*. Norman White

SOENKO (Alberto) & REBELO (Antonio) Notas on the Epidemiology and Parasitology of Malaria (according to an inquiry now proceeding in Lourenço Marques).—*Socia African Med J* 1938 Nov 26. Vol. 12 No. 22 pp 841-847 [36 refs.]

The authors state that their work is based on 6,451 blood examinations in Lourenço Marques. Most of their paper however is concerned with

the published observations of other workers on such matters as the reasons for the rarity of *malaria* infections the possible cycle of development of malaria parasites in the reticulo-endothelial system multiplicity of strains of parasite with varying degrees of virulence and other matters on which the authors observations have little if any bearing The blood films were obtained from persons in apparently good health Parasites were found in 47.9 per cent of films from natives and in 5.7 per cent of films from Europeans Upwards of 95 per cent of infections discovered were *falciparum* *P. tenuis* was found cases were rare how many is not stated Three cases of *P. ovale* infection were noted The authors express a preference for the thin film method of examination A II

DE BUCK (A) Eine Lokaluntersuchung ueber das Brüten von Anophelen in Süß- und Brackwasser [Investigations on the Breeding of Anopheles in Fresh and Brackish Water in a Particular Locality]—*Rev. de Malariologia* Ser I 1938 Vol. 17 No 5 pp 344-357 With 1 fig French summary

The author has studied the distribution of two races of *Anopheles maculipennis* (*atroparvus* and *messeae*) in one small region in Holland. In a part of his area the water is consistently fresh in another part brackish

The two races are not sharply separated from one another according to the salinity of the water In the brackish water contrary to expectation 1 to 5 per cent of the eggs are *messeae* and that race contributes about the same proportion to the adults in the stables in the neighbourhood clearly therefore its females do not entirely refuse to lay their eggs in brackish water In the fresh water both races occur either one or the other preponderating to the extent of 80 per cent In those fresh waters in which eggs and larvae of *messeae* are most numerous larvae of *atroparvus* tend to die from an unknown cause. It appears, therefore that the females of *atroparvus* frequently put the eggs in a water in which a high larval mortality will occur

P A Burton

VAN THIEL (P H) Ueber das gemeinsame Vorkommen der Larven von *Anopheles maculipennis atroparvus* und *messeae* in Süßwasser [On the Joint Occurrence in Fresh Water of the Larvae of 4 *maculipennis* Race *atroparvus* and Race *messeae*]—*Acta Leidensia* (Scholae Med Tropicae) 1938 Vol. 12-13 pp 271-278 With 1 plate [Summarized in *Rev. Applied Entom.* Ser B 1939 Mar Vol 27 Pt 3 pp 50-51]

In Holland malaria is confined to the province of North Holland where *Anopheles maculipennis* 51g race *atroparvus* van Thiel, breeds in brackish water its transmission is largely due to the fact that the females of this race feed on man in autumn In the non malarial districts race *messeae* Flin. breeds in fresh water and it has been suggested that *messeae* would displace *atroparvus* if the water in the malarial districts were rendered more fresh The author therefore carried out 29 experiments with mixed batches of newly hatched larvae of the two races in various proportions The larvae were placed in tap water in dishes in three series, so that the surface areas per larva were 4.6 and 15 sq. cm., respectively, but the percentage mortalities in the three series averaged only 15, 17 and 14 In no case did one race dominate the other so that if the water in North Holland were rendered fresh, *messeae* would not thereby displace

atroperius. The results of the experiments were judged by identifying the pupal cases and the characters differentiating these in the two races are described, but the adults were bred out to make certain that the pupae were viable.

BEVERE (Lorenzo). Prime osservazioni sulla fauna anofelinica della Capitanata. [Anopheline Fauna of Foggia Province, Italy].—*Riv di Malariologia* Ser. I 1938. Vol. 17 No 6 pp 362-385 With 1 map [24 refs.]

This report contains a vast amount of information about the diverse conditions found in 18 communes of the Foggia province as these relate to anopheline prevalence and malaria endemicity in each. The anophelines found were *maculipennis* var *labranchiae* *atroperius* *datus* and *typicus* *A. superpictus* and *A. pseudopictus* *labranchiae* was much the most prevalent. A description is given of the climatic conditions, physical and chemical composition of the soil hydrographic conditions with chemical composition of ground and surface waters, anopheline breeding places agriculture domestic animals, the density of the human population and the prevalence of malaria. Works of bonification that are being undertaken are also referred to these as yet are for the most part only in the initial stage. N IV

SCHLENKOVA (M. Tb). Sur la biologie des anophèles des environs de Sotchi [Biology of Anophèles in the Neighbourhood of Sotchi].—*Med. Parasit. & Parasitic Dis.* Moscow 1938. Vol. 7 No 4 [In Russian pp 514-527 With 7 figs. French summary pp 527-529.]

Sotchi is in the Caucasus on the coast of the Black Sea. Four species of Anophèles are found there *maculipennis maculipennis bifurcatus plumbeus* and *superpictus*. The first named is the most prevalent and the most important vector of malaria.

The first male *maculipennis* was found on the 23rd of May and most females began to hibernate in October. This species breeds along the shingle covered banks of little rivers, in artificial pools and irrigation and drainage canals. It is most prevalent in August. The physiological age of females was determined by the size of the ampulla of the oviduct. The curve illustrating the frequency distribution of these measurements is asymmetrical. The first oöcyst infected mosquitoes were in the class 0.007 mm³ the first sporozoite infected in the class 0.035 mm³. The frequency of sporozoites increased with increase in size of the ampulla. Houses and stables serve as day resting places for *maculipennis*. Twenty per cent. of engorged females contained human blood. The oöcyst infection rate was 0.46 per cent. in July 6.18 in August and 5.04 in September. the sporozoite rates in these three months were 2.10 2.80 and 3.57. Sporozoites in September for the most part, showed signs of degeneration. The sporozoite rates for *maculipennis* caught in houses and stables respectively were almost identical and there was no evidence that female *maculipennis* after egg-laying had any preference for shelters previously visited. Gonotrophic disharmony was observed in September and October but not in the summer.

A. plumbeus is second in importance as a vector. It breeds in hollows of trees, in depressions among the roots of trees and in empty

tubs Its prevalence dependent upon rainfall was greatest in spring and autumn Its daytime resting places were most commonly hollows of trees and trunks of trees in thick forest well protected from sunlight—dark and damp places. Houses are visited only at night or at dawn The mosquitoes do not remain there during the day They are found in greatest number at the edge of woods near human habitations Female *plumbeus* only begins to display activity when the relative humidity is as high as 80 per cent and its activity increases with further increase of humidity At low temperatures with high humidity *A. plumbeus* attacks its victims with ferocity It is strongly attracted by domestic animals but in a bathing resort the percentage of *plumbeus* containing human blood was considerable This species will sometimes fly as far as 1.5 kilometres for its food. Of 282 females dissected two were infected.

Larvae of *A. bifurcatus* were found wherever there were pools fed by springs Rare in summer this species was prevalent in autumn and in spring it dislikes heat It has a marked partiality for the blood of domestic animals Only 5 per cent of engorged females contained human blood Commonly found in stables no specimen was found in inhabited houses
A. superpictus was found in very small numbers in houses and stables in the valley of the River Matsesta the most southerly point of the coast of the Black Sea at which it has been found hitherto

DAVILOVA (M I) & BOUDYMIKO (F A) Le rôle épidémiologique de 1 *Anopheles maculipennis* Weig et de 1 *Anopheles hyrcanus* Pall. dans les lagunes de la mer d Azov [Epidemiological Role of 4 *maculipennis* and 4 *hyrcanus* in the Lagoons of the Sea of Azov]—Med Parasit & Parasitic Dis Moscow 1938 Vol. 7 No 4 [In Russian pp 467-498 With 2 figs [12 refs.] French summary pp 498-500]

Large expanses of water and a warm climate with high relative humidity are favourable to the propagation of anophelines near the Sea of Azov Malaria is endemic The lagoons are the most important breeding places of anophelines they are very extensive and inaccessible to antilarval measures The borders of these lagoons with dense submerged vegetation reeds and rushes harbour very large numbers of *maculipennis* larvae *hyrcanus* breeds among the reeds In the marshes anopheline breeding is limited. Artificial collections of water though harbouring numerous larvae are of little malarial importance their extent is not great especially in dry seasons Similarly provisional collections of water formed by the river Protoka may contain many larvae but they quickly dry and only yield one generation of anophelines each season. The potential vectors found were *A. maculipennis* var *moscane* and *atoparvus* *A. hyrcanus* var *pseudopictus* and *A. bifurcatus* Localities near lagoons harbour more adult mosquitoes than do those near marshes or in the centre of the village *A. hyrcanus* was never found in daylight resting places in the latter situations prevalence in July *A. hyrcanus* appears in June and is most prevalent in the middle of August *A. maculipennis* caught in dwelling houses the sporozoite index was 0.45 and the oöcyt index 0.22 per cent

Houses and stables are the favoured daylight resting places of *maculipennis* thick clumps of rushes and reeds are those favoured by *hyrcanus*. The latter species enters houses however in numbers. *A. hyrcanus* is active in its natural shelters throughout the 24 hours it generally feeds in the open air.

All three forms of malaria were found in the village of Grinevskaja river infections are the most numerous at the end of summer *falciparum* infections the most numerous in the autumn. Children and adults suffer in equal proportions. The authors detailed and exhaustive investigations have led to the conclusion that *A. maculipennis* is the most important vector. A II

EVANS (I) An Outbreak of Malaria due to *A. maculatus* breeding inside Jungle at Raub Pahang, 1937—*Jl Malaya Branch Brit Med Assoc* 1938 Sept. Vol. 2 No. 2 pp. 85-87 With 4 figs on 2 plates.

The residential part of Raub is in close proximity to a belt of jungle. Malaria in Raub is carried by *A. maculatus*. *A. nimbrosus* has never been found in the locality. Control by oiling stopped short at the jungle edge. Increase in malaria incidence was eventually found to be due to *A. maculatus* breeding in exposed areas inside the jungle. The appearance of the jungle viewed from outside gave a false sense of security. Attention to these breeding places was rapidly followed by decreased prevalence of malaria. A II

BOYD (Mark F.) & KITCHEN (S. F.) Demonstrable Maturity of Gametocytes as a Factor in the Infection of Anophelines with *Plasmodium vivax* and *Plasmodium falciparum*—*Am J Trop Med* 1938. Sept. Vol. 18. No. 5 pp. 515-520

This is a record of the degree of infection developing in lots of *A. quadrimaculatus* applied once to patients harbouring *vivax* or *falciparum* gametocytes, exflagellation preparations being made on the occasion of each infecting feed. There were 230 lots infected with *P. vivax* and 168 with *P. falciparum*. Not infrequently lots of mosquitoes were successfully infected when exflagellation was not demonstrated. The technique for demonstrating exflagellation was similar to that of SHUTE described by JAMES (this Bulletin 1935 Vol. 32 p. 127). When exflagellation of *P. vivax* was observed, however a significantly higher proportion of lots with an incidence of infection above 75 per cent was obtained. Such a difference was not noted with *P. falciparum*. Exflagellation was more commonly noted in the spring and autumn than in summer and winter. This may be due to air temperature in winter the wards are artificially heated. Mosquitoes applied during spring and autumn showed larger proportions with heavy infection than did mosquitoes applied at other seasons. High gametocyte counts in *falciparum* infections facilitate the detection of exflagellation. A II

GARRHAM (P. C. C.) The Placenta in Malaria with Special Reference to Reticulo-Endothelial Immunity—*Trans. Roy Soc Trop Med & Hyg* 1938 June 25 Vol. 32 No. 1 pp. 13-34 With 2 charts & 8 figs on 2 plates (23 refs) (Discussion pp. 35-48)

In this paper the author gives an account of observations he has made on malarial infections of the placenta in 500 cases of pregnancy

in native women in Kenya. He has noted the very large number of parasites in all stages of development which may be found in the maternal blood spaces. This malarial infection stimulates a reticulo-endothelial response with phagocytosis of parasites similar to that which occurs in the spleen liver and bone marrow in general malarial attacks. Though the reticulo-endothelial cells or macrophages occur in large numbers in the malarial placentas there appear to be no normal cells in the placenta to account for these. The author supposes that lymphocytes reach the placenta in the blood stream and subjected to a malarial stimulus proceed to multiply and develop into phagocytic macrophages as is the case with the lymphocytes in the spleen. An attempt was made to stain the cells of the reticulo-endothelial system with trypan blue by giving to the mother intravenous injections of the drug. The dye was also transfused through the umbilical vein and applied to fresh smears of the placenta. In no case did the cells take up the blue dye though it was shown to penetrate the trophoblastic lining of the villi to stain the fibrocytes and reach the foetus which was always stained blue. The macrophages on the other hand show a marked affinity for neutral red. The fact that the cells which are chiefly concerned in the malaria immunity process fail to stain with trypan blue suggests that it may be erroneous to assume that the specific cells can be blocked with this dye.

In a long series of observations on foetal bloods in cases of heavy placental infections it was not possible to demonstrate in a single instance the passage of parasites from mother to foetus.

It was assumed that the relapses which followed parturition were probably due to the sudden removal with the placenta of a highly active reticulo-endothelial system.

In the discussion which followed the reading of the paper speakers referred to the possible or probable influence of a specific immune substance on the macrophages to the records of absorption of trypan blue by the somatic reticulo-endothelial cells and the indications that actual blockage thus took place to the theory that the parasite of malignant tertian malaria reproduces normally by binary fission rather than by schizogony; to the possibility that the placenta with its malarial infection and macrophage response was actually an extra corporeal depot which exerted no influence on the general immune processes of the body which were carried on by the spleen as had been the case before the development of the placenta.

The author of the paper finally replied to the various questions raised.

The whole paper which is illustrated by microphotographs is the most comprehensive one which has appeared on the subject of the behaviour of the placenta in cases of malignant tertian malarial infection.

BOYD (Mark F.) KUPPER (W. H.) & MATTHEWS (Choice B). A Deficient Homologous Immunity following Simultaneous Inoculation with Two Strains of *Plasmodium vivax*—*Amer J Trop Med* 1938. Sept. Vol. 18 No 5 pp 521-524

The authors have previously shown that patients successfully inoculated with a strain of *P. vivax* develop an immunity which renders them either entirely refractory to reinoculation with that

stram or if successfully reinoculated, they have no clinical manifestations of infection. The present paper records the results of inoculating three patients each with approximately equal numbers of trophozoites of two strains of *P. vivax* intravenously. After varying intervals following the spontaneous or induced termination of the resultant mixed attacks the patients were successively reinoculated with trophozoites of each strain alone. Five of these six reinoculations were followed by short clinical attacks. The primary attacks did not proceed to spontaneous termination but their duration was 53, 89 and 23 days respectively. It appears that the simultaneous presence of two strains delays the development of homologous immunity to either

SIOLI (F) KENTENICH (A.) & BOLDT (Erika) Weitere Erfahrungen ueber die Zucht der Anopheles und ihre Verwendung in der Malariabehandlung der Paralytiker [Further Experience in the Breeding of Mosquitoes and their Use in Therapeutic Malaria.]—Arch f Schiffs u Trop Hyg 1939 Jan. Vol 43. No. 1 pp 1-15 With 10 figs.

In the experiments described in this paper local mosquitoes, species not mentioned, were used for infective purposes. Various improvements in technique are mentioned since the last report in 1938 regarding moisture content of air and use of glass windows in mosquito cages. A certain type of rabbit is used to provide blood meals in the cages and a current of air against which mosquitoes cannot fly is of service during its removal. Rubber gloves are worn by the operator besides the curative action of induced malaria in G.P.I. patients,

the study of new drugs. Three strains of benign tertian parasites have been used: the Original Viennese strain, II, a Rumanian, and III the Madagascar strain, the latter two having been sent from England. The experiments described deal with the last strain, which has not altered its character by passage through human beings and mosquitoes in turn. Thirty-one patients were successfully inoculated out of thirty three attempts. In one case a single mosquito caused infection. The incubation period varied from 10-22 days. There was no relation between the number of bites and incubation time or in the character of the infection. A pure tertian type of fever was rare and generally alternated with quotidian. In ten out of 31 cases the fever subsided spontaneously, six of the 10 patients having been previously inoculated. All the patients had a temperature of 104° or over. In 14 cases parasites were noted before the appearance of fever in seven others the appearance of parasites and fever coincided and in a further seven cases parasites appeared after onset of fever. In twenty-one cases gametocytes were detected 8-20 days after the start of fever while in the remaining 10 cases they were absent, and this was so where fever disappeared without treatment.

Atebrin in 3x0.1 gm doses for 7 days and 8 days later in 3x0.1 gm. doses for 4 days was used in treatment. Quinine in 0.2 gm. doses was found useful in causing abatement of fever.

Regarding mosquitoes the Madagascar strain gave rise to a higher percentage of and more intense infections than, the others. Even in cases where the patient's blood failed to show the presence of gametocytes, infection in fed mosquitoes resulted. Details are given of the

work of the clinic in supplying infected blood and the apparent influence of blood withdrawal on temperature and duration of fever as well as on parasite counts is discussed.

BOYD (Mark F) The Threshold of Parasite Density in Relation to Clinical Activity in Primary Infections with *Plasmodium vivax*—*Amer J Trop Med* 1938, Sept Vol. 18, No. 5 pp 497-503

The observations recorded were made on 77 cases of vivax malaria mostly of the McCoy strain in 56 of which infection was naturally induced (sporozoites) the remainder being infected by the injection of trophozoites. No elevation of temperature that failed to attain 100°F (37.8°C) was regarded as significant of malaria infection. A clinical reaction may be induced by *P. vivax* in densities in the peripheral blood of 10 per cmm. or less whatever the method of infection. Excepting the few days subsequent to the onset the duration of the clinical attack never exceeded the period during which the parasite density remained at 100 or more per cmm. generally, it was shorter in duration. Parasite densities in excess of 25 000 were uncommon a count as high as 50 000 was exceptionally rare. Densities above 25 000 were more common following trophozoite inoculation than in natural infection. After trophozoite inoculation the maximum density was usually observed within 10 days of the first detection of parasites after sporozoite inoculation it occurred later. Counts in excess of 15 000 were most often observed in cases that ran for four weeks or longer. Attacks following trophozoite inoculation terminated with higher parasite counts than did sporozoite induced attacks. Rarely were counts of 500 or less observed at the termination of the clinical attack. The final density bears no relation to the density which provoked the original clinical reaction. That attacks induced by trophozoite inoculation are commonly shorter than sporozoite induced attacks may be due to more rapid immunization by reason of higher parasite densities.

BOYD (Mark F) & KITCHEN (S F) Vernal Vivax Activity in Persons simultaneously inoculated with *Plasmodium vivax* and *Plasmodium falciparum*—*Amer J Trop Med* 1938 Sept. Vol. 18 No 5 pp 505-514 With 5 charts.

The authors recently reported the successful inoculation of patients with *P. vivax* and *P. falciparum* simultaneously by multiple infected mosquitoes (see this *Bulletin* 1938 Vol. 35 pp 424-5). The present paper deals with the subsequent malaria history of these patients. Three of the seven cases in all of whom the initial attack was characteristic of *falciparum* had clinical attacks of malaria attributable to *P. vivax* in the following winter or spring. This renewed activity occurred 235, 236 and 282 days respectively after the onset of the original attack or 226, 174 and 233 days after its induced termination.

HEGNER (Robert) Relative Frequency of Ring-Stage Plasmodia in Reticulocytes and Mature Erythrocytes in Man and Monkey—*Amer J Hyg* 1938 May Vol. 27 No 3 pp 690-718 With 20 coloured figs. on 1 plate [55 refs.]

By examining blood films containing the three common malarial parasites of man the author has studied the relative frequency of

falciparum infections. In this report only patients who received quinine on a single day in one or in divided doses, are considered. Quinine sulphate in capsules was given. A single dose of 20 grams of quinine had very little effect on the strains of *falciparum* studied—a dose of 11 grains or more exercised very decided action on the McCoy strain of *mxar*. The effect was more evident if the acute attack of malaria had lasted eight days or more when the dose of quinine was given. Single doses of 11 grains or more suppressed paroxysms and induced periods of clinical quiescence of varying duration, in the large majority of *mxar* cases. A declining trend in parasite density which lasted several days was also noted. Nothing comparable in *falciparum* infections was noted even after a dose of 20 grains. N IV

DECOURT (Ph) La lutte antiplasmodiale. Ses bases pharmacodynamiques. [Pharmaco-Dynamie Bases of Antiplasmodial Measures.]—Bull Soc Path Exot 1938 Oct 12. Vol. 31 No. 8 pp 760-771 With 4 charts

The mode of action of antimalarial drugs is complex. They exercise in varying degrees schizonticidal gametocidal and anti-sporogonic activities. The last named prevents the fertilization of gametes in the mosquito. In addition to these the author describes a dysgonic action—a conception that is both parasitological and clinical. Under the influence of this action schizonts lose almost entirely their powers of asexual reproduction and gamete formation. From the clinical point of view this action is manifested by the absence of morbid phenomena in spite of the presence of schizonts sometimes numerous in the blood. It is the dysgonic action of quinaquine which engages the attention of the author. The total dose of quinaquine necessary to produce this action at the beginning of treatment is variable depending as it does upon a parasitic factor and an organic factor. The optimum dose necessary to sustain this activity once it is established, is remarkably constant—it approximates 0.25 gm. for an adult. Dysgonic action lasts about three weeks but during this time it weakens progressively. If the parasite is but little aggressive a dose taken twice a month will be sufficient to prevent all morbid phenomena. More frequent administration is necessary if the parasite is aggressive the patient's resistance low and if reinfections are numerous.

The mere presence of quinaquine in the blood is insufficient to explain dysgonic action. A very small dose given daily is much less potent in this respect than the optimum dose given at much longer intervals although the total amount of the drug given by the former method may be greater. Thus a dose of 0.1 gm. given on 3 or 4 days in the week is less effective than one of 0.3 gm. given three times a month. The duration of this dysgonic action is not appreciably prolonged by increasing the optimum dose even by large amounts. There is no relationship between the curve of dysgonic action and that of the concentration of the drug in the blood or tissues. A IV

FIELD (J W) NIVEN (J C) & GUEST (C.) Clinical and Experimental Observations on Atebrin Musonate. With a Note by F E. BYRON.—Bull. Inst Med Res Federated Malay States 1937 No. 2. 24 pp. With 10 graphs. [12 refs.]

The object of the observations recorded was to compare the therapeutic value of atebrin musonate with that of quinine hydrochloride

in the treatment of acute malaria. The patients were Malay Indian and Chinese adults admitted to hospital. They were allotted to the atabrin musonate or quinine group alternately the only patients excluded from one or other of these experimental groups being afebrile cases patients with but few parasites in the peripheral blood, mixed infections or cases with a history of malarial treatment during the preceding three days. The minimum period of observation from the beginning of treatment was one week. Forming the atabrin musonate group were 234 patients 187 *falciparum* 84 *vivax* and 13 *malariae*. In the quinine group were 271 cases 184 *falciparum* 77 *vivax* and 10 *malariae*. The daily dose of quinine given was either one or two grams per 100 lbs body weight for 7 days 29 *falciparum* cases received quinine intramuscularly for 2 days followed by 5 days oral treatment. The remaining quinine cases received the drug by mouth. The doses of atabrin musonate varied from 0.2 gm. a day for two days to 0.3 gm. a day for 3 days some cases received 0.4 gm. a day for 2 days. The atabrin musonate was given intramuscularly except in 34 *falciparum* cases which received intravenous injections.

At the recommended dose of two injections of 0.3 gm. atabrin musonate efficiently controls an acute attack of any kind of malaria. It is a slightly more potent therapeutic agent than oral quinine. Trophozoites disappeared from the peripheral blood and temperatures fell somewhat earlier in the cases treated with atabrin musonate this was most marked in *vivax* infections. As a *falciparum* gametocide atabrin musonate has no advantage over quinine. It was not possible to obtain accurate data of relapse rates. It appeared that two injections of atabrin musonate without supplementary treatment are not sufficient to effect a permanent cure. The authors consider 0.375 gm. to be the optimum daily dose of atabrin musonate given on two successive days this dose controls an acute attack of malaria. Intramuscular administration is the method of choice. As far as local reaction is concerned this drug compares favourably with any other malarial remedy given intramuscularly. Three patients treated with atabrin musonate displayed alarming symptoms of nervous disturbance. One of these was very anaemic the drug is contra-indicated in such cases. The symptoms were temporary in all three cases and followed by no permanent effects.

Five hundred samples of urine from both groups were examined the urobilinuria associated with atabrin musonate treatment is not more marked than that associated with quinine treatment.

The conclusion is reached that in spite of its efficacy in controlling acute attacks of malaria the routine administration of atabrin musonate is not advisable. Oral therapy is the method of choice in the majority of cases [see also this *Bulletin* 1935 Vol. 32 p. 746 1936 Vol. 33 pp. 231 274 275 1937 Vol. 34 p. 776] V. IV

CHOPRA (R. N.) DAS GUPTA (B. M.) & SEN (B.) Studies on the Action of Synthetic Antimalarial Drugs on Indian Strains of Malaria. Cilonal in the Treatment of "Crescent Carriers." —*Indian Med. Gaz.* 1938 Nov. Vol. 73 No. 11 pp. 667-669

This paper describes the treatment with cilonal of four patients harbouring *falciparum* gametocytes. The authors found that a total dose of 0.35 to 0.4 gm. administered in doses of 0.03 gm. three times a day is usually sufficient to eradicate gametocytes of *P. falciparum*.

No ill effects were noted. In spite of this, however the conclusion is reached that plasmoquine is preferable to cibonal—a much smaller dose of the former is effective (0.02 gm. daily for three days). Such small doses of plasmoquine are not at all toxic. A II

DE VITO (Renato) Azione del tartaro stibato sui gametociti del *Plasmodium vivax* e del *P. falciparum*. Ricerche sperimentali. Experimental Research on the Action of Antimony Tartrate on Gametocytes of *P. vivax* and *P. falciparum*.—*Riforma Med.* 1938. Oct. 22. Vol. 54. No. 42. pp. 1599-1601. With 2 figs.

Sixty persons were inoculated with the blood taken from a patient infected with *P. vivax* at the height of a febrile attack, before the appearance of gametocytes. In two cases infection failed to materialize. Of the 58 successfully infected 6 received no treatment, 12 were treated with quinine, and 40 were treated with antimony tartrate. Bisulphate of quinine was given in the following doses, 1.5 gm. a day for the first week, 1 gm. a day for the second week, and 0.5 gm. a day for the third week. The antimony tartrate a 1 per cent. solution in distilled water was administered intravenously on alternate days, beginning with a dose of from 8 to 10 cc. according to the general condition of the patient, increased by 2 cc. to a maximum of 14 cc. The total amount received by each patient was from 120 to 200 cc. The number of patients in whose blood gametocytes developed were—4 of the 6 untreated control, 66.6 per cent. 7 of the 12 treated with quinine, 58.3 per cent. 4 of the 40 treated with antimony tartrate, 10 per cent.

In another series of observations four patients harbouring *falciparum* gametocytes and 5 patients harbouring *vivax* gametocytes were treated with quinine. Eight patients harbouring *falciparum* gametocytes, and 20 harbouring *vivax* gametocytes were treated with antimony tartrate. In the quinine treated cases the gametocytes decreased in numbers very slowly and the persistent gametocytes retained their normal morphology and staining characteristics. In the antimony treated cases the *vivax* gametocytes had disappeared from most of the cases after they had received 10 to 20 cc. and the *falciparum* gametocytes after aggregate doses of from 21 to 40 cc. Even with smaller doses the gametocytes of both species lose their normal appearance their contour becomes irregular, there is vacuolation of the protoplasm, dislocation of pigment, loss of colourability of chromatin and protoplasm and fragmentation. Antimony treatment also produces a marked diminution of splenomegaly. The author concludes that after small doses of antimony tartrate the patient loses the power of infecting anophelines and that the drug may be considered as a causal prophylactic. N IV

BISPRAM (William V.) Final Report on the Use of Atabrine in the Prophylaxis and Treatment of Malaria.—*Amer. J. Trop. Med.* 1938. Sept. Vol. 18. No. 5. pp. 545-564.

The author has previously reported good results from the use of atabrine in the control of malaria in Civilian Conservation Corps Camps in the Southern States (see this *Bulletin* 1937 Vol. 34 p. 218). His final report confirms opinions previously expressed. The personnel of every camp with an admission rate for malaria of two or more cases in a week were given a prophylactic dose of 4½ grains of atabrine a week.

for four weeks this period was extended if the number of cases still exceeded one a week. The vast majority of cases were *vivax* infections. The author concludes that if atabrin be used as a prophylactic under supervision men of susceptible age can live and carry on their various occupations in a highly infected area with a minimum of malarial infection and a maximum of effectiveness. Over 90 per cent of *vivax* carriers can be cleared of all parasites. Untoward reactions to atabrin are almost never encountered and when encountered are of a transient character

CHARBONNIER. Emploi des médicaments synthétiques antipalustres au poste de Muong Boun. [Use of Anti-Malaria Synthetic Drugs in a Military Post.]—*Ann de Méd et de Pharm Colon* 1938 July-Aug-Sept. Vol. 36 No 3 pp 732-734

In spite of the regular administration of prophylactic quinine the post of Muong Boun has year after year suffered from very severe malaria during the hot weather months. From June to September 1937 inclusive the issue of quinine was reinforced by the administration to each member of the garrison every Sunday of quinacrine 0.2 gm and praequine 0.02 gm. There was a consequent marked improvement in the health conditions. There were no serious cases of malaria. Neighbouring posts which were not so treated suffered that year as severely as usual.

TROLLI (G) Paraplégie spastique épidémique Konzo des indigènes du Kwango d'après les médecins du Fonds Reine Elisabeth pour l'assistance médicale aux Indigènes. ["Konzo, Epidemic Spastic Paraplegia of the Congo"]—pp 1-34 With 1 map 1938 Brussels Fonds Reine Elisabeth pour l'Assistance Médicale aux Indigènes du Congo Belge 112 rue du Commerce

The disease here described bears resemblances in several respects to the A and B avitaminosis of Nigeria and the "central neuritis" of Jamaica [see this *Bulletin* 1919 Vol 13 p 372 1936 Vol 33 p 887 888 893 also *Bulletin of Hygiene* 1929 Vol. 4 p. 391 1933 Vol. 8 p 441 1934 Vol. 9 p 487]

The condition which is known locally by the name konzo attacks chiefly children below 10 years of age but adults also suffer. The onset is usually not always abrupt with pain in head and back, paraesthesiae, formication, and a sense of constriction in limbs and back and paresis to paralysis at first flaccid later (and occasionally from the outset) spastic there is muscular atrophy. There are in some cases disturbances of speech and of sight to actual blindness. It is rarely fatal but the sequelae are permanent.

The disease was first described in 1836 among the inhabitants of the Kwango district of the Belgian Congo. The population is sparse and largely nomadic their diet seems to be very varied nothing being refused from ground nuts, fungi and sugar cane to ants, caterpillars, rats, monkeys and palm oil. They also cultivate cassava, sweet potato and millet. It is recorded that they do not suffer from

poverty and destitution and that the less well-to-do are less subject to the affection described than those better off. Diagnosis is discussed beriberi is ruled out for the condition is largely spastic at all events in the later stages, and cardiac complications are not met with other suggestions are acute anterior poliomyelitis and laryngism. It is not uncommon for several members of a family to be attacked. Examination of the blood and of the spinal fluid revealed nothing of moment. The result of further study will be awaited with interest.

CORKILL (N. L.) Tropical Ulcer Observations on its Treatment and Cause.—*Trans. Roy. Soc. Trop. Med. & Hyg.* 1939 Jan 28. Vol 32. No 4 pp. 519-532. With 3 graphs. [17 refs.]

A study of 94 completed treatments of tropical ulcer in the Nuba Mountains area of Southern Kordofan with a discussion of the aetiology.

The Report of the Sudan Medical Service for 1936 showed that after venereal diseases and trauma tropical ulcer ranked next to malaria as a cause of invalidity. The present study deals with patients, Nubas and Arabs admitted to three hospitals in the course of three years. Two forms of treatment are analysed (A) by codliver oil locally and vitamin A concentrate (Essogen) by mouth (B) any other local treatment and no vitamin, the respective recipients in completed cases numbering 49 and 45. The two groups are again divided into old and recent, the old being those with a six months history or recurrences. Analysis of the results shows that though there was little difference between (A) and (B) in recent cases in the old, or chronic cases there was in (A) compared with (B) an increase of 64 per cent. in the healing rate due to codliver oil or vitamin A concentrate or both.

The author writes —

Cod-liver oil appears to be an excellent routine dressing for all skin injuries for it is comfortable and popular and in recent lesions has a healing rate comparable with the average of pooled other treatments. In old and recurrent ulcers and those in which the destructive phase has ceased it is the treatment of election for it favours or causes rapid epithelialization with a minimum of scarring. It is perhaps more costly though perhaps not importantly so, for the time spent in hospital is reduced, and recurrence is less likely as the ulcer heals by epithelialization rather than by scar tissue.

A graph shows the temperature throughout the year admissions for tropical ulcer onsets, recurrences and origin by vesicle. The last three have a peak in May whereas the peak of admissions is in August the May peak is, he says, the annual acme of vitamin deficiency coupled with the hard labour of preparing and sowing the land under cultivation. The patients do not come for treatment till this period is over. The vesicle or papule he believes to be a thrombo-necrosis in a person in a state of malnutrition. He discusses the influence of diet and season. The Sudanese diets are mainly carbohydrate, and poor in protein and for six months in the year (period of intense dryness) deficient in vitamins A, B₂ and C. Another graph shows the healing rate (mm. per day) in relation to malaria and green grazing and a third the effect of malnutrition which is more pronounced in old, recurrent cases.

The author advises the administration of skim milk powder as a dietetic supplement but does not appear to have tried it.

A G Bagshawe.

ROY (B M) Cod-Liver Oil Treatment of a Carbuncle and Two Ulcers.—
Indian Med Gaz 1939 Feb Vol. 74 No 2. pp 93-94
With 3 figs.

Cod liver oil changed twice daily for about one week and thereafter once daily was used as a dressing for one large carbuncle and two ulcers of the leg. Complete healing took place in under three weeks in every case although one of the ulcers had been present for a year. No other treatment except quinine was given. Photographs show that the ulcers were of the usual extensive necrotic type and the carbuncle massive and it is stated that the patients asked for the oily dressing. This method is painless efficient and cheap. C II'

LASSMAN (P) Note préliminaire sur le traitement des ulcères tropicaux avec le sulfanilamide [Treatment of Tropical Ulcer with Sulphanilamide]—*Ann Soc Belge de Méd Trop* 1938 Dec. 31 Vol 18 No 4 pp 581-583

The author noted that ulcers in patients treated for various illnesses with Astreptine a sulphanilamide preparation healed with remarkable speed. He therefore treated 10 patients who had been in hospital with tropical ulcer for periods of from 3 to 13 months by the administration of 5 tablets each of 0.3 gm. four times daily. The ulcers rapidly showed healthy granulations and at the end of 3 weeks all were completely healed and the patients had left hospital.

In confirmation a further series of 30 patients with ulcers chosen by the alternate case method were so treated and the results compared with those of the 30 alternate controls treated by the usual methods. The sulphanilamide group showed 313 hospital days average 10 and were all cured. The controls showed 565 hospital days average 18 and one was still under treatment at the end. Only one patient had ill effects with skin eruption and temperature of 40°C. These cleared up on stopping the treatment. C IV

HULSHOFF (A. A) Klierkoorts [Glandular Fever]—*Geneesk Tijdschr v Nederl Indië* 1938. Oct. 11 Vol. 78 No 41 pp 2514-2524 With 3 charts & 1 fig

The cases of two patients formed the subject of this clinical lecture. The first was clearly one of true glandular fever the second had up to a time all the appearance of a true case and was on the point of being discharged from hospital when he developed a definite attack of malaria with ring forms in the blood.

The blood picture in all types of glandular fever is very characteristic with its relative and absolute mononucleosis in which there are present more large than small lymphocytes and many lymphocytes with polymorphic nuclei—kidney shaped, lobed and Rieder type. There are lymphocytes resembling monocytes, lymphocytes with intensely blue, sometimes vacuolated cytoplasm and lymphocytes resembling plasma cells. It is extremely difficult to give a name to the types present and they are often recorded simply as abnormal lymphocytes. It is this very varied lymphocytic picture which distinguishes glandular fever from lymphatic leukaemia in which the lymphocytes are of very uniform type and in relatively greater number. The first of the two patients had the glandular swellings the blood picture and the heterologous serum agglutination reaction (1-512) to sheep erythrocytes of glandular fever and as there were no throat symptoms

complained of was diagnosed as of septic type. The second case was specially interesting because in spite of almost the same set of symptoms the patient who had been examined for malaria with negative results ultimately did develop malaria tropica and was cured with a quinine-plasmoquine course of treatment.

The author concludes with the remarks — We learn thus from these two cases (1) how difficult even by very careful expert examination, the diagnosis of malaria tropica can be (2) how neither clinical data nor blood examination nor serum test are absolutely diagnostic of glandular fever

- 1 KUBO (Michio) & BABA (Hiroshi) Studies on the Cause of the Endemic Dermatitis in Manchoukoo. (First Report.)—*Jl Oriental Med* 1938, Oct Spec. No [In Japanese pp 1189-1193 With 1 fig [11 refs] English summary pp. 173-174]
- 11 — — & GOMI (Tadakatsu) Studies on the Cause of the Endemic Dermatitis in Manchoukoo. (Second Report.)—*Ibid* [In Japanese pp. 1195-1202. With 4 figs. & 4 plates English summary pp 175-176] [Summary appears also in *Bulletin of Hygiene*]

1 Dermatitis is a troublesome condition well known among workers in the rice-fields of Manchoukoo and particularly in July and August. It affects only the legs and arms—parts which are immersed in the irrigation water. The symptoms are intense itching followed by a papular erythematous rash, occasionally becoming vesicular and later eczematous. In the early stage it is very suggestive of ground-itch from hookworm larvae or that set up by schistosome cercariae. Examination however failed to detect either of these but a number of mites belonging either to the Pediculoidinae or the Tyroglyphidae were present. The authors describe the mite. The local lesions are very like those of "grocers itch" or the "water itch" among Assam tea-plantation workers due to *Rhizoglyphus parasiticus* or the vanilla among those handling vanilla or lastly copra itch due to *Tyroglyphus longior*.

11 In this are recorded the results of experimental work to elucidate the cause of the dermatitis. First mites were collected by filtration of the infested water. Four species were obtained and each was tested. One belonging to the Tyroglyphidae when applied to the skin of a volunteer produced a military papular rash the others did not. Next the legs of volunteers were immersed in water containing grasses and rice plants, the plants being taken washed in well water and applied in more of the same well-water. Thirdly the suspected irrigation rice-field water was similarly tested on volunteers after the water had been filtered. In both these experiments the results were negative. Finally in a stream flowing through the infested area 25 boys stood with legs immersed, and 24 of them developed the dermatitis. Then, more similarly stood in the water after the mites had been filtered off, and none was affected, but when the filtrate was added to water immersion resulted in the production of the dermatitis. The lesions are therefore due not to chemical irritants in the water nor to grasses and plants but to the mite belonging to the Tyroglyphidae. The actual species has not yet been determined.

RAGAZZI (Giorgio) Il cloruro etile nella terapia medica della *Sarco-
psylla penetrans* [Ethyl Chloride in the Treatment of *Tunga
penetrans*].—*Arch Ital Sci Med Colon e Parassit* 1938 July
Vol. 19 No 7 pp 437-438

The author treated a patient whose feet were deformed by literally hundreds of chiggers by spraying the great toe with ethyl chloride. This was so successful that a moderate spray was applied to the whole foot which was then bandaged and the treatment was repeated on alternate days. The patient was cured in a week.

The dose for a single chigger is about 2 cc and bandaging is not necessary. The effect is probably due to toxic action rather than to freezing and this treatment is particularly useful for children.

WANG (Lo-shan) The Action of Paipu *Stemona tuberosa* on Lice.—
Chinese Med J 1938 Aug Vol 54 No 2 pp 151-158

The author describes tests on paipu a Chinese drug which may be used for killing lice.

A watery extract of the plant paipu (*Stemona tuberosa*) has been used for centuries in China as an insecticide. The crude drug may be obtained from Chinese pharmacists.

The author says that 70 per cent alcohol only kills lice if they are immersed for periods of over two hours. He then tests extracts of the crude drug made in alcohol of this strength and finds that if 10 per cent of the drug is soaked in alcohol for three days body lice (*Pediculus humanus*) generally die after being dipped for three minutes. At higher concentrations the liquid kills on even shorter exposures though many of the lice survive for a day or two. Nits may be killed readily by the same solutions. Watery extracts however are much less efficacious. The alcohol extracts were tested on infested people and gave satisfactory results and it appears that the solution is not irritant. The exact action of the drug is unknown. P A Buxton

CAUSEY (O R.) Experimental Intestinal Myiasis.—*Amer J Hyg*
1938 Nov Vol 28 No 3 pp 481-486

PATTON and EVANS in 1929 stated that eggs of Calliphorinae when ingested by man probably would not hatch and larvae ingested would fail to develop. HERMS and GILBERT in 1933 described a case of intestinal myiasis caused by larvae of *Lucilia* *Calliphora* and *Sarcophaga* which they thought persisted for years. CHANDLER in 1936 gave as his opinion that some species of flies which develop as larvae in the faeces of man or animals may live and grow in the intestine. Others however maintain that the presence of larvae in the faeces does not necessarily mean that they came from the alimentary tract.

The experiments of KOMAREK showed that the larvae soon died in the absence of oxygen and he supported the view of PATTON and EVANS that Calliphorinae larvae cannot survive passage through the alimentary canal.

The author has carried out experiments on animals using larvae of *Lucilia sericata* *Phormia regina* *Calliphora erythrocephala* *Sarcophaga*

securifera *Cochliomyia macellaria* and *Drosophila melanogaster*. Larvae of one or other of these were given in food to dogs and cats, young and adult. In every case the larvae were found to be killed or immobilized in the stomach in three hours and those that passed on to the intestine were partially digested. In no instance did living larvae pass through. The symptoms which have been recorded as due to their presence in the alimentary canal must have other cause. H H S

SOLLIER (R) Sur un cas remarquable de myiase du conduit auditif par *Chrysomya bezziana* [Myiasis of the Auditory Meatus].—*Rev Méd Française d'Extrême-Orient* 1938. Oct. Vol. 21 No 8 pp 1016-1018.

MA SALS (Ch) Discussion de l'article du Dr SOLLIER.—*Ibid* p 1019

The author tells of a child of four years brought to hospital on account of ear discharge and pain. Examination revealed larvae and in the course of four days 87 were removed and found to be larvae of *Chrysomya bezziana*. The unfortunate patient was also heavily infested with *Ascaris* and *Trichuris*. Dr Sollier discussing this case speaks of other instances of myiasis in Indo-China due to *Chrysomya megacephala*. H H S

BERTMAN (D S) A Note upon Myiasis due to the Larvae of *Cordylobia rodhaini* Geddes.—*Ann Trop Med & Parasit* 1938. Dec. 21 Vol 32 No 4 pp 431-435 With 2 figs [17 refs]

Larvae of *Cordylobia rodhaini* are not very uncommon in animals they have been found causing myiasis in antelopes, *Cephalophus dorsalis* and *C grimmii*. In the rodent *Crucetomys gambianus* a rat *Rhynchocyon cinnamomeus* a squirrel *Heliosciurus punctatus* and others. Records of infestation of man are however rare. MACFIE in 1917 noted one in a native at Accra, and in 1932 SYMES and ROBERTS reported one in Kenya. Other possible cases occurred in the Belgian Congo (1910 and 1916) in Uala and Ngoko French Equatorial Africa (1913). The case here recorded is that of a man in Mamfe Cameroons from whom 16 larvae were taken and four of these were sent to the Liverpool School of Tropical Medicine for identification. They came from pustules on the neck and forearm of a man of 51 years. The specimens proved to be third instar larvae of *C rodhaini*. One of these and a corresponding stage of *C anthropophaga* are depicted and the differences are detailed in the text. H H S

JOYEAN (Ch) SAUTET (J) & ARTAUD (P) Sur un cas de myiase rampante [A Case of Creeping Myiasis].—*Bull Soc Path. Exot* 1938 Dec 14 Vol 31 No 10 pp 822-824 With 1 fig

A child of 11 months who had been staying during the summer in Corsica was brought by its mother because she had noticed certain skin lesions for a fortnight. At the external superior angle of the left scapula was a subcutaneous raised ridge, tumorous, dark at one end, not inflamed. At the upper part of the front of the right arm was another similar lesion and on the right cheek a similar but larger and inflamed ridge, scratching of which had produced an impetigo-like sore. The contents of the two first were removed and proved to be

larvae of *Gastrophilus haemorrhoidalis*. The third gradually cleared up by local treatment with Dakin's solution. In the summer the child had lain on the ground with little or no covering.

FIALHO (Amadeu). Blastomycose do tipo Jorge Lobo [Blastomycosis of the "Jorge Lobo Type"]—*Hospital* Rio de Janeiro 1938 Oct Vol 14 No 4 pp 903-918 With 10 figs. [14 refs.] French summary

In 1933 Jorge Lobo published (*Anais Brasileiros de Dermat e Sif* No 46) the case of a man of 52 years who for 19 years had had a painful nodule over the sacrum. It was removed surgically, but two years later recurred and lesions became multiple, mostly of a keloid character, but some had a thick purulent discharge. Jorge Lobo grew from this a peculiar blastomycete on Sabouraud's medium. From the case described in the present article the same fungus was grown. The patient was a white man, a native of Brazil, in poor circumstances, who twelve years before had noticed two painless tumours of the right pinna. After growing for some years they had not increased in size and had not affected his general health. One on the posterior aspect was as large as a hen's egg, reddish violet in colour, lobulated but made up of masses from a millet to a hazel-nut in size. From the lobule was another of similar character, both were pedunculated and painless. They were removed and the wound healed up in a month. The characters of the fungus in the tissues and on growth on artificial media are detailed and depicted. The elements are spherical, on an average 10μ in diameter, with a thick capsule, often in short chains or small groups with giant cells at the periphery. As it appears to be a new type of mycosis the author suggests naming it the Jorge Lobo type after its first discoverer.

DICKSON (Ernest C) & GIFFORD (Minnie A.). *Coccidioides* Infection (Coccidioidomycosis). II The Primary Type of Infection.—*Arch Intern Med* 1938 Nov Vol 62, No 5 pp 853-871 With 7 figs. [14 refs.]

The first communication by the author on this subject has been referred to in this *Bulletin* [1938 Vol. 35 p 459]. In the present one is described the clinical and pathological condition. Infection is by inhalation of chlamydospores and the primary localization is pulmonary. A common locality is the San Joaquin Valley, California, and the disease goes by the name of valley fever or desert fever. In 16 months from 1st January 1938 75 physicians reported 354 cases. The early symptoms are those of a severe cold or influenza, with headache, general pains, pain in the chest or throat, cough and perhaps conjunctivitis. The sputum varies in quantity and may be bloodstained. After a temporary improvement and about 8-15 days from the onset erythematous nodules develop, mostly on the shins, but also on thighs and at times on scalp and arms and upper part of the thorax; they fade in 48-72 hours leaving brownish pigmentation. Diagnosis is rarely made till this rash appears. A ray examination may reveal pulmonary opacities suggestive of tuberculosis and enlargement of the hilar glands. The reaction to coccidioidin, a specific

antigen prepared from the fungus, is positive and may be very marked. A large majority of the patients recover completely but occasionally a coecidioidal granuloma may develop and cause death with symptoms of meningitis.
H H S

DICKSON (Ernest C.) Primary Coecidioidomycosis. The Initial Acute Infection which Results in Coecidioidal Granuloma.—*Amer Rev Tuberculosis* 1938. Dec. Vol. 38. No 6 pp. 722-729 [20 refs.]

A further account of this interesting condition of which the author has made a special study. It is now close on ten years since he reported on the *Misery of Tuberculosis by Coecidioidal Granuloma*. He has shown that the main endemic site is the San Joaquin Valley California. By 1931 of 298 cases, 254 had originated in that State and by 1938 of 450 cases in California 224 had died. It has been observed also in cattle and sheep but no record is known of animal to man, man to man, or man to animal infection. That infection can occur by inhalation of spores was proved in the author's laboratory where a worker inadvertently became infected by inhaling over an open Petri dish culture. Early symptoms are of an "influenzal" type, with fever (100-104°F) and general aching and malaise followed by bronchitic symptoms and sputum mucopurulent and at times blood-streaked. In 8-15 days an erythematous rash like erythema nodosum, and known as "the bumps" appears, commonly on the shins, but it may occur elsewhere. X-rays of the chest reveal hilar shadows. Most patients seem to recover completely but some develop a granulomatous condition of the lungs and of these the fatality is about 50 per cent.

HYMES (Hyman E.) Coecidioidal Granuloma.—*Unders Med* 1939 Jan Vol 38 No 1. pp 19-21 With 4 figs

HARE (K. P.) Preliminary Report on an Experiment in Coolie-Line Sanitation.—*Indian Med. Gaz.* 1938. Oct. Vol. 75 No 10 pp 609-611 With 3 figs.

The three major scourges of the Assam Valley tea estates are malaria dysentery and hookworm disease. The helminth infestation rate is nearly 100 per cent. The installation of tube well water supplies has reduced the incidence of dysentery and some other intestinal infections. Communal latrines of several types have been tried but all were disapproved by the coolies and seldom used. Recently bore hole latrines one for each family have been installed in one coohe line with a total population of 130. The dwellings in this line are semi-detached and the latrines were accordingly built in pairs. Squatting plates set in cement surmount the bore-holes which vary in depth from 14 to 20 feet. The walls of the latrine were built of sundried brick, except for the foundation and two corner pillars which were made of hard brick. Winged walls obviated the necessity for a door and there was no roof. The absence of roof lessened cost, allowed cleansing of the squatting plate by rain and met the coolies' sentiments as to the

impropriety of defaecating in a house. Such latrines can be constructed at a cost of about 10 rupees (15s.) per family. They have been popular and the coolies take a pride in keeping them clean.

WATSON (Malcolm) *Modern Tropical Hygiene*—Reprinted from *Post-Graduate Med J* 1938 Nov 8 pp

This article by laying stress on certain main features on the application of principles and passing over or merely implying details serves a very useful purpose though it does not adduce—it does not pretend to—any fresh evidence or suggest new measures. Sir Malcolm Watson to illustrate his theses takes first malaria the prevention of which in Malaya particularly is so largely due to his work and advice second trypanosomiasis and third plague as examples of infections transmitted by different genera of vectors.

Under the first he speaks of the surprisingly good results in a small town on the Malay Peninsula [? Klang] in the opening years of the present century following properly planned and executed drainage schemes. A few years later in 1909 abolition of breeding sites for mosquitoes was effected by putting in pipes underground all streams and springs within half a mile of inhabited buildings the vector having been found to be a mosquito which selected fast running water for oviposition. In fact on the principle of *autres pays autres mœurs* from the Anopheles view *species sanitation* (a name given by the Dutch) found successful application when scientifically controlled. The author shows what is well known but not always acted upon that large scale research and reclamation need the whole-hearted co-operation of the administrator the medical officer the entomologist the engineer the forest officer the agriculturist, and a point not to be forgotten or minimized, the tribes who own the land.

In 1901 in Klang and Port Swettenham deaths from fever numbered 368 out of a total of 582. Anti-malaria work was then begun and by 1905 fever accounted for only 45 deaths and the benefit as regards other diseases is shown by the fact that total deaths were but 113 or less than one-third of those due to fever alone four years earlier. This work it was which basically made feasible the construction of the Naval Base at Singapore.

The economic effects are best expressed in the words of the Governor in 1926 —

It must be obvious to all who are acquainted with the conditions that prevailed in the Malay Peninsula during the concluding decades of the nineteenth and the opening years of the present century that developments such as the rubber industry which in so short a space of time has spread over so enormous an area would have been totally impossible unless the danger of malarial infection had first been successfully combated. Between 1920 and 1930 the British Empire produced 75 per cent. of the world's rubber and America consumed some 300 000 tons a year.

Similarly speaking of sleeping sickness, the author tells of twenty-one species of tsetse in Africa and of the value of—more the necessity for—species sanitation for exterminating or at least preventing the spread of the fly.

The article is an instructive summary of these aspects of present-day tropical hygiene.

H H S

ACHARD (Ch.) Voyage médical en Afrique noire (Congo belge A.E.F. Cameroun) [Medical Tour in Belgian Congo French Equatorial Africa and Cameroons.]—*Bull Acad. Méd.* 1938. Dec. 6. 102nd Year 3rd Ser Vol. 120 No 36. pp. 381-399

The author compares the staff of doctors in Belgian Congo and in the French African Colonies. With the French, all go through the same medical training during which they acquire *esprit de corps* and make life-long friendships. In the Belgian Congo many of the doctors are foreigners the only criterion is the possession of a diploma equivalent to the Belgian doctorate. Consequently they meet only during the course of instruction at Antwerp in tropical medicine. They do not form a corps subject to a common discipline and they enter the service not as a lifelong career but with a view to returning to Europe. He notes also that many of the doctors in Belgian Congo are in the employ of commercial companies or of religious missions or of private societies. An interesting account of the medical organization of the two French Colonies does not lend itself to summarization. It is particularly noted, however that in French Equatorial Africa there is a serious deficiency in native personnel. Indeed, it is stated that out of 641 *infirmiers* chosen as suitable for stations without doctors 10 were set apart of whom only three passed a test and those proved to be "without medical value." Instruction must be organized from the primary school upwards.

A brief account is given of the diseases met with in the two French colonies.

A G Bagshaw.

MEDICAL AND SANITARY REPORTS

HONG KONG (1937)

Hong Kong is one of a number of islands off the south-east coast of China, at the mouth of the Canton River about 91 miles south of Canton and 40 east of Macao. Hong Kong is 11 miles long and from 2 to 5 miles wide and has an area of about 32 sq miles. It is separated from the mainland of China by the Lyceum Pass. The peninsula of Kowloon on the mainland area 2½ sq miles forms part of the Colony together with the adjacent New Territory. The whole Colony has an area of about 345 sq miles.

Introductory—In previous Summaries attention has been drawn to the fact that so often the text of the Report has remained unchanged year after year (see this *Bulletin* 1936 Supp p 197* 1937 Supp p 203* and 1938 Supp p 214*). It is pleasing to note that the Report for 1937 conspicuously avoids the repetitive methods characterizing its predecessors and strikes an original note by introducing appropriate and informative discussion of the outstanding features of public health experience and discriminating commentaries upon the components of public health organization in the Colony for the year under review. It is of no little significance to note that instead of requiring a considerable extension of printed matter for the presentation of these welcome features space has been economized with such notable success that without sacrificing any feature meriting inclusion by comparison with its immediate predecessor the 1937 Report is a slimmer volume by 60 pages thus representing a saving of about 27 per cent.

Vital Statistics—This section has undergone complete revision. The difficulties attending attempts to make an annual estimate of the Chinese population—difficulties enormously increased for the year under review when a serious refugee problem developed as the result of the Sino-Japanese disturbances—are discussed together with a brief description of the system applied for the registration of births and deaths. As an example of the importance of the part played by local customs or practices in influencing the interpretation of assembled facts and of the value of explanatory text in such connexion a brief note relating to the birth registration among the Chinese population in Hong Kong is of particular interest. It is explained that partly as a result of ignorance or laxness and partly owing to the Chinese custom of postponing the event until the child is in its second year birth registration is still incomplete*. On the other hand, since the outbreak of Sino-Japanese hostilities the tendency has developed amongst the Chinese to secure registration of births in Hong Kong as a preliminary step towards claiming British nationality even when the evidence of local birth is of the most slender.

[But it is to be noted that the Chinese method of reckoning age adds a variable number of months to the true age one year being added at the time of birth and another on the first subsequent Chinese New Year's day so that a child born say in January 1937 is said to be one year old at birth and two years old on the Chinese New Year's day in February 1937 and one born say in March 1937 remains one year old up to New Year's day in February 1938 when it becomes two years old by Chinese reckoning. A formula and tables for converting Chinese ages to their European equivalents are given by STEVENSON and P'AN MINO Tzu in the *Chinese Medical Journal* 1926, Vol 40 pp. 128-130 1207.]

The relevant vital statistical data for 1937 may be summarized as follows —

Estimated Populations

Item	Island of Hong Kong	Kowloon and New Kowloon	New Territories	Maritime	Totals for the Colony
Non-Chinese	9,847	10,887	478	1,572	22,882
Chinese	437,932	339,866	107,052	100,000	984,850
Totals	447,829	350,223	107,828	101,372	1,006,682

Births, Deaths, and Infant Deaths

Item	Births	Birth Rate	Deaths	Death Rate	Infant Deaths	I M R.
Non-Chinese	692	30.6	244	10.8	30	45.9
Chinese	31,611	32.1	34,391	34.9	11,620	378.0
Totals	32,303	22.1	34,635	24.4	11,650	369.4

The registered births include 744 post-registrations after 12 months, viz 705 Chinese and 39 Non-Chinese these have been deducted when calculating the infant mortality rates. As regards registered deaths the monthly average for the first seven months was 2,349 and for the last five months 3,638. The refugee problem and the typhoon were largely responsible for the increase (see also hereafter under *Public Health*).

European Officials resident in the Colony numbered 940 with an average number resident of 918. Seven were invalided and three died.

In an Appendix to the Report under review the Registrar-General supplies the demographic facts for 1937 in considerable detail.

Maternity and Child Welfare Work.—In Hospitals under Government and voluntary control 358 beds were available for maternity cases in 1937 while additional accommodation was also available in a large number of maternity homes of the latter 73 were inspected during the year. At Government Hospitals 4,230 women appear to have been treated for diseases of pregnancy and the puerperal state (with 14 deaths) 3,879 being cases of normal labour. At Chinese Hospitals among 6,439 cases (38 deaths) 6,079 were cases of normal labour. Large numbers of ante natal and other cases are seen in the out-patient departments of the Maternity blocks of the various hospitals and at Government and Chinese Dispensaries.

As from the 1st January 1937 the practice of midwifery habitually and for gain (by unregistered persons) became a punishable offence. "Wan P'os" or handy women who had practised midwifery in Hong Kong for two or more years previously and who enrolled as midwives were exempted from this prohibition. 111 Wan P'os took advantage of the concession and were enrolled. At the examinations of the Midwives Board, 37 candidates were successful at the end of the year the names of 395 women were on the Midwives Register. The

16 midwives employed by the Medical Department provide free services at the homes of poor women and children and when not engaged in maternity and child welfare work assist in first aid work at the dispensaries.

Ante-natal and infant welfare work continues to be carried out at a large number of centres. Personal hygiene and mothercraft are taught to the women attending these centres.

School Hygiene—The *School Hygiene Branch* (comprising one European and two Chinese Health Officers a part time Lady Medical Officer and five Nurses) is responsible for the medical supervision of school-children and the inspection of school premises. With this limited staff responsible for a school population exceeding 86 000 attending over eleven hundred schools it is clear that it is possible to examine only a small proportion of the children. During the year 5,802 medical examinations were carried out in 18 Government schools. [There are 21 Government schools 19 Grant in Aid schools and 1 137 private schools in the Colony.] Dental defects and visual disorders were the conditions most frequently met with. The establishment of a School Dental Department under the charge of a Government Dental Surgeon is recommended. At the various School Clinics attendances of scholars for examination and treatment totalled 2 780 while in addition 76 visits were paid by School Nurses to the homes of scholars.

At the request of the Education Department a large number of premises being used as schools (presumably as private schools) were inspected and many of them found to lack the elementary amenities demanded for the proper accommodation and instruction of young people. It is hoped to amend existing legislation on the subject of school hygiene to ensure that reasonable standards shall be maintained in all schools for as the Report rightly observes. It cannot be emphasized too strongly that by far the best method of teaching hygiene to scholars is by ensuring that the school premises themselves are satisfactory from the public health standpoint.

Public Health Sanitation etc—Dr P S SELWYN-CLARKE the newly appointed Director of Medical Services describes the exceptional difficulties with which the public health authorities had to contend and the unusual factors which combined to influence adversely the health of the community and to give rise to an increased amount of morbidity and mortality during the year under review. The continuance of the Sino-Japanese hostilities and their increasing intensity drove large numbers of refugees to seek a haven in Hong Kong their influx served to aggravate insanitary conditions in the already congested urban areas. Refugees from areas in China where health services had become disorganized brought with them the seeds of dangerous infections—disastrous cholera and smallpox epidemics resulted. In September a typhoon of exceptional severity devastated the Colony and while no accurate estimate of the loss of life is possible it may be noted that the bodies of some 490 persons who had been killed or drowned were picked up along the harbour foreshore. Even the most adequately staffed and wisely organized public health service would have found it difficult to maintain essential services and at the same time successfully cope with a series of calamities of this order but in Hong Kong the anomalous arrangements underlying some of the components of public health administration (see this *Bulletin* 1935 Supp p 191*) must have served to intensify the problems of efficient control. The

whole of the European and Asiatic Sanitary Inspectorate while *theoretically* grouped round the Health Officers in actual *practice* are not controlled by Medical Officers of Health but by a layman the Chairman of the Urban Council of Hong Kong. The present system is unsatisfactory from every point of view—Medical Officers of Health working under these conditions may be likened to Army Officers endeavouring to carry out their complex duties deprived of their N.C.O.s. A more effectively organized and adequately staffed sanitary inspectorate *under the direct control of the Medical Officers of Health* would have been able to deal more successfully with such dangerous infections as smallpox and cholera which during 1937 and in recent years have exacted so heavy a toll of life and suffering. Re-organization of the Health Division with the sanitary inspectorate under the direct supervision and control of the Medical Officers of Health is urgently recommended.

Anti-malarial work continued to be carried out under the auspices of the Malaria Bureau with unabated energy. In the report of the Malaria Bureau these activities are described in detail.

The objectionable bucket system of *sewage disposal*—which continues to function in the majority of tenements and shop-houses—and local methods applied for the collection and removal of night-soil are the subject of description and criticism. The present systems constitute grave sources of danger to the public health and steps are being taken to investigate the possibility of introducing drastic changes which envisage sewer disposal. Methods of *refuse disposal* are discussed and the defects of existing arrangements exposed. The system is capable of improvement and steps are being taken to this end.

The completion of the Shing Mun Jubilee Dam during the year marked a notable stage in the development of public health utilities in the Colony. *Water supplies* are now adequate for the impounding reservoirs (8 on the island and 5 on the mainland) have a combined storage capacity of 5,971 million gallons.

Matters concerned with *housing and town planning* are discussed at some length and various recommendations for future work in this field are outlined. These include new legislation to control town planning etc. and schemes for slum clearance. It may be noted that at present the Sanitary Department (see above) has little or nothing to do with housing other than the removal of obstructions.

During the year special bye-laws were drafted restricting the sale of certain *foods and drinks* with a view to minimizing the risks of infection through their use. Draft legislation which sought to make the pasteurization of milk compulsory met with considerable opposition. The proposals will probably become effective in 1939. Much information of value is expected to be made available following the investigations of the *Nutrition Research Committee*.

The curiousness of organization characterizing the Sanitary Department (see above) are seen in another direction. Health conditions in markets are under the control of the Colonial Veterinary Surgeons instead of under the Health Officers. Until the reorganization of the Health Division has been carried out and the sanitary inspectorate brought under the supervision and control of Medical Officers of Health, the effective *training of sanitary personnel* cannot be provided for.

Port Health Work—Services continued to function as usual. Due to the Sino-Japanese disturbances a decrease in the number of ships

entering the Port is recorded. The principal items of work concerned with shipping during the year may be summarized as follows —

British ocean-going ships entering and clearing	4,322
Foreign	5 202
Other vessels entering and clearing	24 258
Total tonnage dealt with	36 191 724
Emigrants examined	245 488
Emigrants rejected	1 153

Several new *air services* were inaugurated during the year no cases of infectious disease were discovered in passengers or crews of aircraft. The volume of aerial traffic dealt with during 1937 may be gauged from the following data —

	<i>Arrivals</i>	<i>Departures</i>
Aircraft	388	395
Crews	1 150	1 133
Passengers	1 929	1 756

Hospitals Dispensaries etc.—In the words of the Report under review The outstanding event in the year as regards improved hospital facilities was the opening of the Queen Mary Hospital which replaced the old Government Civil Hospital built in 1874 and which was closed on the 30th of June 1937.

The Queen Mary Hospital, which embodies all the latest improvements in hospital construction and equipment has accommodation for 546 beds an Isolation Wing consisting of nine small wards accommodates 22 patients. About a quarter of the beds in the new hospital are allotted to the Medical, Surgical and Gynaecological and Obstetrical clinical units of the Hong Kong University. Private practitioners are privileged to make use of the Maternity Wing for the treatment of their own cases.

The first patients were admitted in May 1937 from the Victoria Hospital by the end of June all the patients had been transferred to the new hospital from the old Government Civil and Victoria Hospitals.

The returns for Government and Chinese Hospitals are presented in *Appendices* to the Annual Report. For present purposes it must suffice to summarize briefly the record of the year's work by stating that to *Government* hospitals during 1937 admissions numbered 17 832, cases treated 18,275 and hospital deaths 1 637. Out patients treated at Government Hospitals exceeded 130 000 these are exclusive of out patients treated at special clinics dispensaries etc. At *Government Dispensaries* alone 59 618 patients were dealt with.

A new and informative account of the origins and subsequent development of the *Chinese Hospitals and Public Dispensaries* is a feature of the Report under review. Dangerous overcrowding characterizes many of the Chinese hospitals and it is observed it is not at all uncommon

to see two patients young and old in the same bed five adult women in two beds pushed close together patients lying all over the ward floors so as to render separation of types of disease and medical attention and nursing matters of extreme difficulty. In one case 61 patients were found in a ward of 12 beds! This distressing state of affairs is in urgent need of reform and it is hoped steps may be taken to improve existing conditions in the near future. To the *Chinese Hospitals* 46,849 patients were admitted, 47,969 were treated and 12 641 died during 1937. The *Chinese Public Dispensaries* dealt with 264,589 new and 238,527 old cases during the year under review.

Mention has already been made of the fact that owing to exceptional circumstances the public health suffered a set-back during 1937 (see *Public Health* above) and that during the late summer a marked increase in morbidity and mortality experience was noted. As regards the principal diseases responsible for disease and death the notes which follow briefly summarize the more extensive commentaries provided in the Report under review.

A serious outbreak of *cholera* occurred. The disease was first recognized in July though it is significantly observed "notifications of dysentery had already shown a marked increase in June." In July 13 cases were reported, in August 1100 and in September 500 thereafter incidence declined rapidly and only one case was notified in December. Altogether 1690 persons were affected and 1,082 died. Undoubtedly the epidemic was one of the legacies of the disturbed conditions in China—the infection was probably introduced by refugees from South China. Extensive preventive measures were instituted and energetically applied. Over a quarter of a million inoculations were carried out at hospitals, public dispensaries, and at centres staffed by the St. John Ambulance Association and Brigade. Having regard to the inadequacy and faulty organization of the sanitary staff, insanitary methods of night-soil disposal, etc. what is surprising is not the sudden development of the epidemic to alarming proportions, but the success which followed the application of control and preventive measures in a dangerous situation.

Cases of *smallpox* were notified in Hong Kong during every month of 1937 with the sole exception of October. The largest monthly total was recorded in April, though a second and, as it proved more serious peak occurred in December. Altogether 129 cases with 94 deaths were notified during the year. Nearly half a million persons were vaccinated, and in this connexion it may be noted that 21,232 (or 75 per cent.) of the infants registered during the year were vaccinated. The exceptionally high case-mortality rate is suggestive of many missed cases—a more effectively organized sanitary inspectorate would prevent concealment of cases and would lead to the discovery of all contacts.

Though during 1937 *typhus* was rife in many parts of China no case of the disease was reported in Hong Kong. Sporadic cases of *cerebro-spinal* fever occurred throughout the year with March and April the months of maximum prevalence. Notified cases numbered 157 and 88 of the patients died. No case of *plague* was recorded—the systematic trapping of rats and other anti-plague measures continued to be carried out as usual.

Diphtheria was responsible for 308 cases with 148 deaths—maximum incidence occurred in the period November–March. Of the total cases notified 241 were treated in hospitals with 112 deaths. Eight non-fatal cases of *scarlet fever* were notified.

Malaria—The anti-malarial work carried out under the direction of the Malaria Bureau since its establishment in 1930 have succeeded in making malaria a relatively unimportant disease in urban areas. The infection rate still remains high in some rural areas where anti-malarial activities continue to receive vigilant attention. The Report of the Malaria Bureau describes the year's work in detail. To Government Hospitals 677 cases were admitted and 695 treated with 23 deaths, while the corresponding figures for Chinese Hospitals were 1,892, 1,931 and 328 respectively. The distribution of types of

infection among the 695 cases in Government and the 1,931 cases in Chinese Hospitals reads as follows —

Government Chinese Hospitals	Benign Tertian	Quartan	Subtertian	Cachexia	Undefined
	208 298	8 7	309 1 033	121 47	51 503

At the Government Bacteriological Institute 8 917 blood films were examined for the presence of malaria parasites and in 3 581 cases positive findings were recorded. In the Report of the Bacteriological Institute a graph is interleaved showing the percentage relation of the different types of malarial parasites to each other month by month throughout the year and also the rainfall in inches (see also this *Bulletin* 1938 Supp p 217*)

July to October were the months of maximum incidence of fevers of the *enterica* group during the year 464 cases with 176 deaths were reported. Government Hospitals dealt with 84 in-patient cases of typhoid and 6 of paratyphoid with 20 deaths and Chinese Hospitals with 211 cases of typhoid with 108 deaths. At the Bacteriological Institute where 1,539 samples of serum were tested for the specific agglutinins of the enteric bacilli 344 were positive with *Bact typhosum* 6 *Bact paratyphosum A* 3 *Bact paratyphosum B* and 62 type undetermined. The investigation into the presence of agglutinins against typhoid organisms in cases showing no clinical signs of the disease was continued (see this *Bulletin* 1938 Supp p 219*)

Preceding the cholera epidemic a significant rise in the reported cases of dysentery was observed (see above *Cholera*). During the year 576 cases were notified (see below) and according to the Report of the Registrar-General 316 deaths were ascribed to the disease. According to the Hospital returns the majority of the cases were bacillary infections viz —

Government Chinese Hospitals	Amoebic	Bacillary	Undefined	Total	Total deaths
	3 165	117 326	4 237	124 728	16 234

At the Bacteriological Institute where 3 758 faecal specimens were cultured for pathogenic organisms 134 were *Bact dysenteriae* Flexner 11 Shiga and 17 Schmutz infections.

Tuberculosis is responsible for one in every eleven deaths due to all causes. Cases treated in hospitals may be summarized as follows —

	Government Hospitals		Chinese Hospitals	
	Cases	Deaths	Cases	Deaths
Pulmonary tuberculosis	193	61	3 653	1 698
Other forms	122	29	753	292

Overcrowded living conditions and under-nourishment coupled with the exceedingly common habit among the Chinese of spitting in public places combine to spread the disease. Hospitalization of any but a very small proportion of the infectious patients is at present not possible. At the Bacteriological Institute 174 out of 687 specimens of sputum examined were positive with *Mycobacterium tuberculosis*.

The number of patients treated in Government and Chinese Hospitals for various helminthic infections was negligible, totalling 317. Among 101 cases in Government Hospitals were 40 cases of ascariasis and 35 of ankylostomiasis while among 216 cases dealt with in Chinese Hospitals 102 were treated for ascariasis and 44 for ankylostomiasis. Thirty-five patients were treated for clonorchiasis (8 in Government Hospitals). Among 2 407 faecal specimens examined at the Bacteriological Institute 170 contained ascariasis, 104 clonorchis, 42 trichurias, 31 ankylostoma, and 89 were multiple infections.

Little is known so far as this disease is concerned in Hong Kong (see this Bulletin 1937 Supp. p. 209*) and until a systematic survey is carried out the situation as far as this disease is concerned must remain conjectural. The question of obtaining the help of the British Empire Leprosy Relief Association to carry out such a survey is under consideration. Out of 154 specimens of nasal and skin smears examined at the Bacteriological Institute, 50 were positive with *Mycobacterium leprae*.

Venereal diseases.—The facilities for free medical advice and treatment remained as previously described. Details of the year's work at six centres may be summarized as follows:—

Centre	New Cases		Attendances	
	M	F	M	F
Queen's Road (Old Govt. Civil Hospital)	1,241	570	5,838	2,821
Violet Pool Health Centre	1,348	657	7,648	2,575
South Kowloon (Dock)	2,228	481	10,452	2,280
Kowloon Hospital	347	634	1,752	3,201
Taiipo Dispensary	28	2	361	18
Un Long Dispensary	31	8	171	28

In-patients treated at Government Hospitals for syphilis numbered 127 for soft chancres 112 and for gonococcal infections 207. At Chinese Hospitals the corresponding figures were 234, 30 and 82 respectively. At the Bacteriological Institute an interesting comparative study was carried out on the recently described *Ida precipitation test* for syphilis. One thousand sera were tested in parallel with the Kahn test, and the following results recorded:—

	Kahn test	Ida test
Strong positive	214	243
Positive	123	141
Doubtful	44	81
Negative	600	585
Total	1 000	1 000

Kahn tests were applied to 16,581 samples of blood serum 4,345 gave positive 723 doubtful, and 11 513 negative reactions. In addition 617 smears were examined for the presence of the gonococcus, but findings do not appear to have been recorded.

Other Diseases—Under this heading mention should be made of the fact that deaths due to *diseases of the respiratory system* occupied the first place in the list of causes of death and were responsible for 10,350 deaths during the year under review *Beriberi* including the infantile variety constitutes a serious problem and no fewer than 1 681 deaths were ascribed to this cause in 1937 In the Table below the cases and deaths recorded in hospitals for certain respiratory affections and for beriberi are summarized —

Disease	Government Hospitals		Chinese Hospitals	
	Cases	Deaths	Cases	Deaths
Brochitis	248	2	3 634	1 050
Broncho-pneumonia	160	103	2 633	1,890
Pneumonia (Lobar and Un- defined)	102	40	940	517
Beriberi	83	13	2 807	915

Scientific.—The four separate Reports discussed under this title are the following —

(a) *The Report of the Bacteriological Institute* records a further increase in the volume of work dealt with during the year when 42 096 specimens of various kinds were examined and reported upon. Under such headings as *malaria enteric fever dysentery etc* in the preceding notes mention has been made of specific examinations and of findings recorded.

(b) *The Annual Report of the Malaria Bureau* confines itself to discussion of new developments during 1937 This work included the collection and identification of anophelines actual methods employed in anti-malarial work the results of precipitin tests on bloods from mosquitoes caught in various localities and dissections made to discover the presence of malarial infection of anophelines

(c) *The Report of the Analytical Laboratory* describes the nature and volume of the year's work under various headings viz. Official (i.e. Government work) semi-official work for the Naval Military and Air Force Authorities and unofficial work which is concerned with analyses carried out for local firms and private individuals in the Colony

(d) *The Report of the University Clinical Units* comprises the separate Reports of the Professors in charge of the Medical, Surgical and Obstetrical and Gynaecological Units respectively the year's work for each of these units is dealt with in detail.

Financial—Total expenditure on Medical Services—which includes such items as water and drainage works Urban Council cleansing services etc —amounted to \$5 193 816 a sum which formed 16.2 per cent. of the revenue of the Colony from all sources during 1937

P. Granville Edge

REVIEWS AND NOTICES

WEYER (Fritz) [Wissenschaftl. Assistent am Tropeninstitut Hamburg]. Die Malaria Überträger. Eine Zusammenstellung der wichtigen Anopheles-Arten mit Angaben über Verbreitung, Brutgewohnheiten, Lebensweise und praktische Bedeutung. [Vectors of Malaria] Mit Geleitworten von Prof. Dr. P. MUEHLEN und Prof. Dr. E. MARTINI.—141 pp. With 15 figs. 1939. Leipzig: Georg Thieme, Verlag. [Unbound Rm. 8.40 Bound Rm. 9.80.]

The purpose of this work is to provide a concise statement of the facts at present known about those mosquitoes which are concerned in the transmission of malaria in all parts of the world. This was last done by Covell (1928 & 1931) and in recent years not only has knowledge been considerably advanced in many regions, but in some respects notably in the increasing importance ascribed to races or "varieties" within a given species, the point of view has been appreciably modified. Its purpose is very competently achieved. The book begins with an essay of some fifteen pages reviewing, in an interesting style with examples from all countries, the various factors that determine whether a given species is important in a given locality. Then follows a table occupying ten pages in which the malarious regions of the world are set out by continents and the carrier species set out under each country with a few words of comment in each case. Chapter 3 forms the kernel of the book and consists of an alphabetical list of the proved malaria carriers, 46 in number, the distribution, breeding places, behaviour of the adult insect and relation to malaria being summarized. These descriptions vary from one to eight pages in length and contain a vast amount of accurate information with reference to original sources. It is particularly useful that the types of water used for breeding in the different localities are described in some detail. Chapter 4 contains brief accounts of 24 additional species which are of less importance or whose relation to malaria is not fully established. There are no keys for the identification of species. Illustrations are given of some fifteen species, each with a very brief description, but apart from lightening the text these serve little purpose. As a work of reference the book should prove of great value to all students in this field. In a foreword Professor Martini commends the continued study of *Anopheles* to "any people which will leave its homeland and achieve colonial successes on the world's stage."

V. B. Wigglesworth

MARSHALL (J. F.) [C.B.E. M.A. F.R.E.S. Director British Mosquito Control Institute, Hayling Island, Hants.] The British Mosquitoes.—pp. xi+341. With 20 plates & 172 figs. 1938. London: Printed by Order of the Trustees of the British Museum. [One Pound.]

W. D. Lang's "Handbook of British Mosquitoes," which was published in 1920 has been for some time out of print. This volume is a revision of Lang's Handbook, but it incorporates so much new material that it is in effect a new book. The subject is covered in great detail. The book begins with an elementary introduction in which the life history of the mosquito is described, together with the external and internal anatomy at all stages, and a detailed account of

those parts which are used for identification. Then follows an exhaustive and advanced systematic account of the 29 species of mosquito that occur in this country, which makes possible their identification as adults, larvae and in some cases as eggs and pupae. The natural history of each species is fully described and the whole is splendidly illustrated with line drawings, photographs and coloured plates. A short chapter of ten pages is devoted to those methods of control which have been found most practicable in dealing with the mosquito pests of this country, and in a final chapter a number of problems in the biology of mosquitoes, particularly the swarming habits of the various species are discussed. This section contains a brief review on malaria in Britain. The book as a whole will be indispensable to any serious student of mosquitoes in England, whether he is concerned with their systematics or with their control. The *special* sections which form the bulk of the book will not of course concern the worker in the tropics, and *general* questions in mosquito bionomics form only a very small part of the whole.

V. B. Wigglesworth

MANSON BAIJR (Philip) [CMG DSO MD FRCP Senior Physician to the Hospital for Tropical Diseases, London etc.] *The Dysenteric Disorders. The Diagnosis and Treatment of Dysentery, Sprue, Colitis and other Diarrhoeas in General Practice*. With an Appendix by W. John MUGGLETON M.S.M. Technical Assistant—pp. xiv+613. With 9 colour and 14 black & white plates and 106 illustrations in the text. 1939. London Toronto Bombay Melbourne & Sydney: Cassell and Company Ltd. [25s.]

This volume embodies the experience of a life-time spent in the investigation and treatment of disease in persons from the tropics and subtropics, and has been written more especially for those engaged in general and in consultant practice who, from time to time, are confronted with conditions frequently inadequately dealt with in the usual standard works on medicine. The book consists of 522 pages of text matter, included in which are many photographic reproductions, charts and diagrams, and numerous excellent drawings in black and white and in colour, by the hand of the artistically-gifted author. A number of these have already appeared in sundry publications. In addition, there are two appendices, occupying some 40 pages; one of these contains an account of the salient features of the morphology and life history of the parasitic intestinal protozoa of man, while in the other is given an account of certain of the laboratory procedures employed in the investigation of such cases as are referred to in the text.

The first four hundred pages of the work, after a general account of diarrhoea and dysentery and the methods employed in their investigation, are concerned with the epidemiology and geographical distribution, pathology and morbid anatomy, symptomatology, complications and sequelae, diagnosis and treatment of the bacillary, protozoal and helminthic dysenteries and of cholera, sprue and hill diarrhoea, conditions which are more particularly associated nowadays with the tropical zones and therefore of which Dr. Manson-Baird's extensive experience well qualifies him to write. The remainder of the volume is concerned with certain forms of colitis, with the steatorrhoeas and

Transmission

Rats—In the Annual Medical Report for Malta for 1936 (p. 205) it is stated that *R. norvegicus* is the principal rat found and was infected in a recent epidemic. Breeding takes place in heaps of refuse collected for composting into manure.

The Eastern Bureau of the League of Nations (p. 746) consider that transmission by rat immigration for instance in carts carrying rice in India, has not been proved.

SOKHEY and CHITRE (p. 204) found that the percentage of deaths in 80 plague rats from different areas and inoculated with standard doses of plague bacilli was inversely proportional to the human mortality in these areas. The cause of this immunity was not apparently due to a benign epizootic or to hereditary transmission and it is probable that different degrees of susceptibility exist in different races of *R. rattus* and that the susceptibles have died out. TAYLOR (p. 203) shows that plague in India is not now so important as it used to be. This may be due to immunity which has been proved experimentally to exist in the rat population. This immunity is roughly proportional to the prevalence of plague in the areas concerned. The transmission of plague is through house epizootics in *R. rattus*.

GIRARD (p. 207) states that the reservoirs of plague in Madagascar are *R. rattus* and *R. alexandrinus* are the concerned. ROMIC (p. 206) adds *Myomys* to this list and states that sylvatic plague probably does not exist in Madagascar. GILLESPIE *et al.* (p. 753) found that *R. alexandrinus* was the most common rat in the Customs jetty and warehouses in Kobe and on board ships, but in the city *R. norvegicus* is the commonest. They therefore conclude that in the Customs sheds 70 per cent. of rats probably come from ships and 30 per cent. from shore.

NARAYAN (p. 756) considers that the musk rat is a carrier of plague fleas and bacilli and is itself susceptible to plague.

Other Rodents—WASSILIEFF (p. 206) states that all Tunisian rodents are susceptible to varying extents. Fleas probably may transmit plague from man to wild rodents though not commonly in country districts. Sylvatic plague may occur in zones near towns if contact is established between wild and urban rodents. FOURIE (p. 751) in South Africa states that human plague was confined to ports and railways until 1914 when an outbreak of pneumonic plague occurred on an isolated farm. Plague is now endemic, and two groups of rodents are responsible, the gerbille (*Tatera* and *Dromodillus*) and the multimammate mouse (*Alomys corbula*). The latter is incriminated. It occupies infested nests of gerbilles when these have died out and also enters human dwellings. Human outbreaks are therefore limited to the range of these mice but the gerbille is the main reservoir of sylvatic plague. In towns the domestic rats are the danger and there is no direct contact between them and the wild rodents. In towns therefore rat harbourages should be eliminated rather than measures taken against wild rodents. The Annual Medical Report for Basutoland for 1936 (p. 748) shows that an epizootic in gerbilles was associated with a small human epidemic.

PHILANG (p. 754) thinks that the considerable mortality found in cats kept in Cambodia to check the invasion of houses by rats was probably due to feline plague.

PUBLIC HEALTH REPORTS Washington (p 210) states that the first positive evidence of plague in wild rodents of Washington State was found by the mass inoculation of fleas and lice from *Citellus townsendi*. Furthermore fleas ticks and lice stored in the icebox produce typical plague when injected into guinea-pigs after 10 months.

MEYER (p 201) in the United States warns against contact with wild rodents especially by handling sick or dead rodents—squirrels marmots, chipmunks and prairie dogs. These Sciuridae and certain mouse and rat species have spontaneous plague. He gives the mode of diagnosis by the large-pool flea method. CUMMINGS (p 753) records 5 human cases of plague in the U.S.A. in 1937 and 105 in the rodents mentioned by MEYER.

The Surgeon General of the United States of America (p 746) reports that seven species of ground squirrels have now been found to harbour plague including *Citellus beecheyi fisheri*, *C. grammurus* and *C. townsendi*. The tree squirrel and the rodents mentioned by MEYER also contract infection.

In the Argentine DE LA BARRERA (p 211) reports that two main types of rodents are concerned in epizootics of sylvatic plague cuis (including the genera *Cavia*, *Galea* and *Microcavia*) and *Graomys griseoflavus*. These are not domestic in their habits their fleas are not of common kinds and little is known about them. A connexion was established between a small epidemic of human plague and a severe epizootic in *Graomys griseoflavus* which had been found in human dwellings under the stress of hunger. It is not however possible to say what is the degree of danger to man.

DE ARAUJO (p 210) states that cats are susceptible to *P. pestis* by scarification or inoculation but not by feeding in the absence of trauma of the mouth or the intestinal mucosa.

Fleas—SAUTET (p 755) discusses the factors determining proliferation or destruction of fleas including seasonal changes humidity nourishment and temperature. Fleas completely blocked die those incompletely blocked may live for a long time and are dangerous, those not blocked are not a source of much danger.

In Malta (p 205) the mouse flea *Leptopsylla musculi* and *X. cheopis* are more common than *Nosopsyllus fasciatus*.

ADVIER (p 210) investigated *Synosternus pallidus*, a common flea of Senegal which however has little opportunity to ingest plague bacilli and even if it does so it does not appear to be very capable of transmitting the disease. FOURIE (p 751) thinks that the primary epizootics in South Africa are apparently spread by *Dinopsyllus hypus*, *X. eridos* and *Chastopsylla rossi*. *X. brasiliensis* found in the multimammate mouse probably spreads plague to man.

GIRARD (p 207) in the Madagascar highlands found that *X. cheopis* remains infective for several weeks after rats have disappeared and thereafter will feed on man. In this way plague may be transmitted for considerable distances by the transport of fleas. Fleas in paddy rice dust of huts may have to obtain their first blood meal from man. If man has the septicaemic form fleas may thus infect local rats and this forms the basis of the reversal of the usual cycle into a cycle man-flea-rat. SOREL (p 206) and ROIC (p 209) state that in Madagascar *X. cheopis* is the important transmitting flea. It is also the principal flea in India, though *X. brasiliensis* according to TAYLOR (p 203) may be

important in the Deccan. *X. asia* is negligible. This author discusses the effect of climatic factors on fleas.

OURTOMO *et al.* (p. 753) found that the flea counts in the Customs sheds at Kobe were 75-82 per cent. *X. cheopis* and 21-07 per cent. *N. fasciatus*. The *cheopis* index of 4.2 deserves serious attention. Counts in Tokyo were only 0-01 *X. cheopis* and in Kobe city 5.73.

ESKOEY (p. 754) in the United States tested the ease with which fleas, rats, and rodents contracted infection and their relative powers of transmission. *X. cheopis* was the most easily infected flea, less so were *N. fasciatus* from rats, *Diomus mordax* and *Hoplopyllus anomalus* from ground squirrels. Transmission by *X. cheopis* was much more effective than by the others. Infected fleas which do not show blockage of the proventriculus do not seem to be infective bite and the bites of most infected fleas are infective for a short time only probably 1 to 2 days, but fleas may be infected and live months, except *X. cheopis* the average life of which was 16 days. Therefore it is possible that infection may be carried through months when the rodents are hibernating. When the plague bacillus is established in the gastro-intestinal tract of the flea it continues to exist until the death of the flea. Parasites concerned in sylvatic epizootics are rather inefficient compared with those of the rat and human infections.

SASSOVICH and TICHOMIROVA (p. 215) found that plague bacilli could be isolated after 6-10 days in larvae and nymphs of the tick *Dermacentor submarginatus* fed on infected guinea-pigs, but that the bacilli could not be transmitted from the larva stage to the nymph stage.

MERTENS (p. 755) found that *Triatoma rubrofasciata* cannot transmit plague by bite directly except immediately after an interrupted meal on an infected animal. As it may harbour plague bacilli for at least a month however it may be dangerous to man if crushed on the skin and the bacilli rubbed into the bite.

Clinical etc

FIMAYER (p. 212) reports a patient with a submaxillary bubo in an epidemic of pulmonary plague. Entrance was probably through the conjunctiva or the upper air passages. MEYER *et al.* (p. 212) report the case of a boy of 10 from a ranch in a sylvatic plague area, with an axillary bubo proved to contain *P. pestis* and meningeal symptoms which relapsed. Plague encephalitis and meningitis were found post mortem. They consider that recent cases of plague from the western States reflect the behaviour of an agent which causes mild infections with a tendency to latency.

In the Annual Report for Baurtoand (p. 748) it is noted that in an outbreak blood culture revealed *P. pestis* although there were no glandular enlargements.

In Madagascar GIRAUD (p. 206) states that 85 per cent of plague cases are only recognised after death, and that diagnosis is by lung and liver puncture. In Java ROSIER (p. 748) uses spleen puncture for post mortem diagnosis.

KAMAL (p. 752) describes the functions of "Health Agents" in Egypt who are responsible for certification of deaths. If acute disease is suspected they are required to puncture heart, apex and base of lungs and liver of cadavers to obtain material for cultures and smear and to fill capillary tubes for despatch to laboratories.

Treatment

NORMAN WALKER (p 213) finds that treatment by serum from human convalescents from plague in whom syphilis tuberculosis and malaria are excluded, in doses of 20 cc. on 3 consecutive days usually brings the temperature to normal. A mortality of 16.7 per cent. was found in 48 patients thus treated against 47.9 per cent. in 48 untreated. Arrangements are being made to store the serum. SOREL (p 207) uses specific treatment by serum and bacteriophage but results with the latter intravenously subcutaneously or into the bubo do not greatly differ from the results obtained by serum alone.

CARMAN (p 757) in East Africa found that 3 of 6 patients recovered with intramuscular prontosil (5 cc. or 2½ cc. twice daily) whereas all the previous nine (who had not been treated with prontosil) had died.

Prevention

In Malta (p 205) a systematic anti-rat campaign is advocated together with a proper service for collection and disposal of all refuse. In Egypt KAMAL (p 752) shows how great are the opportunities for rat nesting in matting roofs of houses. Nothing short of demolition and the building of rat proof houses will keep plague away.

ROSIER (p 748) shows that a reduction in the plague epidemic in Java has taken place along with the continued house improvement campaign. [For the effect of this campaign on the malaria position reference should be made to ROSIER this *Bulletin* 1938 Vol. 35 p 417 and GROOTINGS *ibid* p 902]. Altogether 1 383 363 houses have so far been improved.

TAYLOR (p 204) in India states that the construction of rat proof grain stores in towns is the only permanent measure taken. Temporary measures include (1) vaccination (2) evacuation (3) rat destruction (4) disinfection (5) control of grain traffic. Vaccine has been improved and field trials will be made and evaluated. In rat destruction trapping is of limited value. Poison baiting is easier with pills of 3 grains of barium carbonate in a paste of flour freshly made daily. Cyanide gas fumigation is increasingly popular. The same points are brought out in the Annual Report of the Eastern Bureau of the League of Nations (p 746) which also mentions general sanitation isolation and treatment of patients regular collection and examination of fleas and anti-plague propaganda.

CAMPBELL (p. 750) describes the routine adopted for plague workers on entering infected houses in Mwanza. The workers enter behind an anti-flea barrage of spray and their arms and legs are sprayed. Anti-rat measures are most effective if carried out in the plague off-season because this kills off the rat-cause of carry-over to the next season. The author does not consider carry-over by infected blocked fleas or bacilli in dust or fomites to be important.

GILLES (p 213 and 214) gives the technique of the fumigation of the cargoes of lighters with liquid HCN which is effective and not dangerous if reasonable care is exercised. The abstract cannot be summarized further.

SCOTT (p. 201) states that rodent destruction on the Witwatersrand is carried out by (1) gassing burrows near dwellings and farms (2) poisoned grain in open areas (3) traps on premises where foodstuffs are stored. These measures have been successful. In Basutoland (p 749) the campaign against gerbilles was started by baiting every burrow in an area 150 miles long by 6 to 10 miles wide. This was

successful and the gerbilles were practically wiped out. The work, however needs to be continued.

For pulmonary plague SORZL (p. 207) and ROWIC (p. 209) in Madagascar consider that the only effective method of prevention is to isolate all those exposed to infection. Masks and spectacles must be worn and regular inspection made of these contacts to ensure early diagnosis. GIRARD (p. 208) states that isolation for 10 days is necessary since the incubation period may be up to 9 days. These procedures are efficacious.

ALBEROZ (p. 747) studied the occurrence of plague in Rosario (Argentina) since its introduction in 1899. From 1900 to 1937 there were 703 cases of human plague in Rosario with a mean mortality of 35.27 per cent. Only in the last 8 years have measures been highly satisfactory when disinfection and vaccination gave place to active deratization. From 1930 to 1937 only 14 cases have been reported. FONTENELLE (p. 758) shows that during 1929-1936 plague disappeared completely from Rio de Janeiro with continuation of building improvement and active rat destruction. ALFARO (p. 747) states that anti-plague measures in the Argentine although difficult to carry out have been followed by a noteworthy decrease of plague and the figures of cases have fallen from 1,178 in 1919 to 31 in 1936.

Vaccination—REITANO (p. 215) states that not every avirulent living strain of *P. pestis* possesses immunizing power and found that desiccated *P. pestis* (from which cultures could be obtained up to 30 months) showed no immunizing power and was therefore useless as a vaccine. PIRIE and GRASSET (p. 757) in experimental work show the superiority of living over killed vaccine. Similarly serum prepared from animals inoculated with living vaccine was capable of saving the lives of 2 of 6 infected animals treated with it but six others treated with serum prepared from animals vaccinated with dead bacilli all died. SORZL (p. 207) states that the live vaccine of avirulent E. V. strain used in Madagascar is preferred to a dead vaccine, and GIRARD (p. 208) and ROWIC (p. 209) also mention E. V. and show that the mortality figures have fallen since its introduction. OTTEN (p. 757) is convinced that the only successful vaccine must be a living one prepared from avirulent strains of high antigenic potency and quotes figures of an alternate-case field trial he made the results of which show the value of his vaccine in a striking manner. In the preparation of a vaccine it is essential that antigenic potency must be preserved, and he advises deep-stab culture at 4-6°C. for producing variants which lose virulence without impairing immunizing properties. ROSTER (p. 748) reports that this live avirulent vaccine of OTTEN has been used in the affected areas of Java on 2,363,642 individuals. Excellent results were obtained, and the present decline of the epidemic is attributed chiefly to this prophylactic measure.

CAMPBELL (p. 750) found that mass inoculation [presumably with dead vaccines] did not seem to have any effect in stopping the Mwanza outbreak, modifying the illness or reducing the chances of acquiring infection. It did, however allay panic.

On the other hand the report of the Haffkine Institute (p. 200) discusses vaccines of dead bacilli with the following conclusions: (1) Broth vaccines incubated at 27°C. are more potent than those incubated at 37°C. (2) The reverse is the case with agar grown vaccines probably owing to the larger organisms produced at 37°C. (3) Broth-grown heat-killed vaccines from virulent cultures at 27°C.

are superior to live avirulent vaccines grown at either 27°C or 37°C. (4) In broth vaccines heat-killed vaccine incubated at 27°C. is the most potent live avirulent vaccine grown at 37°C. the least potent. In agar vaccine from the same strains live avirulent vaccines incubated at 37°C. were the most potent and heat killed vaccines incubated at 27°C. the least. (5) The method of killing the vaccine grown at 37°C. does not seem to matter but in those grown at 27°C killing at 55°C. for 15 minutes gives a much more potent vaccine than at 60°C. for one hour (6) Stored at 4°C. heat killed vaccines show no measurable loss of potency for months Live avirulent vaccines on the other hand deteriorate so rapidly that it would be impossible to issue them from a central laboratory for effective use in so large a country as India.

C II

LEPROSY

PRÉCIS OF ABSTRACTS IN THIS SECTION

MUIR (p 531) advises the appointment of a whole time leprosy expert for East Africa and commends the voluntary system to attract patients without compulsion

TOLENTINO (p 531) considers resistance to be a dominant and susceptibility a recessive character and that they are transmitted in Mendelian fashion HAYASHI (p 531) thinks that a shift of incidence to the later years of life is an indication of a decline of the disease, as in Norway

JOSEPH (p. 532) finds that hot humid climates are favourable and high altitudes with low vapour tension unfavourable to the spread of leprosy in India. Poverty and various customs play a part. OBERDORFFER (p 532) shows that the highest incidence in Ceylon is round Colombo and other towns of the south west and east.

PIÑERO GARCIA (p 532) states that incidence in Rosario has risen from 1 to 2.5 per 10 000 in the decade 1927-37

MACNAUGHTON (p 532) describes leprosy in Fiji Intramuscular iodized chaulmoogra oil is the usual treatment

STRACHAN (p 533) states that 61 per cent. of early untreated NI cases appear to have undergone spontaneous arrest in Basutoland.

DOULL (p 533) shows that the maximum attack rate (of 4.1 per 1 000) occurs between the ages of 10 and 14 at Cebu in the Philippines and that the annual risk of contracting infection is about 5 times as high in persons with house contact as in the ordinary population. At Cullon LARA (p 533) observed that in child contacts areas of skin which are most frequently in contact with parents—arms legs and buttocks—are usually first found to be infected In some instances the first lesions were small weal like or papular spots usually bacteriologically positive

LOWE and CHATTERJI (p 534) think that leprosy lesions arising at the site of scarification or tattooing may originate from contamination of the instruments but that more commonly a leprosy infection is latent at the time of the injury

LEITNER (p 534) discusses the bone lesions in leprosy

CASSIANO (p 535) shows that the leprosy reaction though occasionally closely simulating true erysipelas differs from it in that it occurs only

where there are cutaneous lesions of leprosy and is mild not infective and not associated with a streptococcus. GUILLAUMOU (p 535) reports the leprosy reaction following Jennerian vaccination in 11 patients.

DEGOTTE (p. 535) and DUBOTS and DEGOTTE (p 535) found that if Tr. Iodi is applied to lesions, allowed to dry and then covered with starch powder sweating either from muscular exercise or pilocarpine injection will produce a blue colour. This test they found to be valuable in suspected cases, lack of power to sweat being shown in 42.26 per cent.

RADMA (p. 536) states that gland puncture showed acid fast bacilli in 24.5 per cent. of a series of lepers and in 4.6 per cent. of non-lepers, but in 2 of the latter 5 positives the bacilli were atypical and easily distinguished from *Mycob. leprae*. VAN BREUSEGHEM (p 536) found leprosy bacilli in 20 per cent. of treated and 40 per cent. of untreated cases by examining mucus from both nostrils. NAIR and PANDALAI (p. 536) found acid-fast bacilli in the lesions of 57.27 per cent. of 147 neural cases. [See also DES ESSARTS below.]

RADMA (p 536) shows that blood lipase is low in severe leprosy and increases as patients improve under treatment. SPEIGHT (p 537) found the blood sedimentation rate to be a good index of prognosis if the influence of intercurrent disease is excluded.

GREVAL *et al* (p 537) found the complement fixation test with the Witebsky-Klingenstein and Kuhn antigen, to be sensitive in the nodular type but less so in the nerve type. The test is not specific. ROW (p 537) obtained a strong reaction in all cutaneous cases with a complement fixation reaction employing a preparation made by prolonged autolysis of tubercle bacilli. FICKER (p. 537) uses an antigen prepared from cultures of acid fast bacilli in a flocculation reaction which he reports to be positive in a larger proportion of nerve cases than is usual with similar tests and (p. 538) uses Calmetestrol for strengthening weak complement fixation reactions.

CAPPELLI (p 538) found that the Pallida reaction is negative with the sera of non-syphilitic lepers.

BURNET (p 538) finds the leprolin reaction to be positive in nerve cases and a large proportion of contacts but negative in cutaneous leprosy and infancy. Its significance is not understood.

ROUSSEAU and GAUGEAT (p 539) claim to have cultivated *Mycob. leprae* from a leproma in a fluid *Aspergillus* medium. MANALANG (p 539) reports increase in the proportion of non-acid fast forms of leprosy bacilli (believed to be degenerated) in lesions treated with *H. erythraea* preparations. He also (p 539) found the Cullon Mercado preparation to be the most effective in causing the disappearance of *Mycob. leprae* from gland tissue kept in test tubes, but *erythraea* oil and others the most effective in removing acid-fastness.

BURNET (p 539) records the successful infection of one of a series of hamsters with human leprosy. The spleen had not been removed.

MARCHOUX and CHORINEZ (p 540) consider that the smallest lesions of the skin permit the entry of leprosy bacilli, which can also penetrate healthy mucous membranes. The bacilli are spread by leucocytes. DES ESSARTS (p 540) believes that leprosy bacilli may be eliminated from the skin of patients with so-called closed leprosy and that these patients may therefore be a danger to others. JEREMIAH and BARTHOLOMEWS (p 540) also consider that patients with neural leprosy are potentially infective and should be segregated. C II

LEPROSY REVIEW 1939 Jan Vol 10 No. 1 pp 1-102. With numerous illustrations.—*East African Number*

This important issue contains reports by Dr E. Muir on his 1938 tour in East Africa. The recommendations based on the conditions found necessarily contain much repetition but the following points are of especial importance although most of the information is of local interest.

He confirms the high incidence of leprosy in the north-east of the Belgian Congo and extending to Uganda and the Equatorial Province of the Sudan. In the Kenya uplands it is less prevalent than on the coast and in Tanganyika. The severity however does not correspond with the incidence, this he attributes to the widespread infection involving even those with higher degrees of natural resistance who develop a mild form. In the Congo extensive surveys are being made by the Belgian Croix Rouge and in British Territories much anti-leprosy work is carried out by missionary bodies with funds chiefly supplied by Government or Native Administrations.

His main recommendations are firstly the supply of a whole-time expert to tour round the leprosy institutions giving advice on the best preventive measures and on treatment. Next he supports the voluntary system to attract the patients and he notes that compulsion is nearly everywhere being done away with in our possessions. Out-patients clinics may be of value where the patients are well-nourished and when the patients can be followed up to their homes and contacts examined. The abandonment of compulsion in Zanzibar resulted in an improved morale and no diminution of numbers. As usual occupation therapy is stressed as well as education of the patients. In addition to East Africa Malta and Aden are reported on.

L. Rogers

TOLENTINO (Jose G.) The Role of Heredity in the Transmission of Leprosy.—*Monthly Bull. Bureau of Health* Manila. 1938. June. Vol 18. No 6 pp 261-272. [12 refs.]

This paper discusses the rôle of heredity in the transmission of leprosy on the lines of Mendel's law. The author considers that resistance and susceptibility may be transmitted to the offspring to a great extent according to that law. Resistance appears to be the dominant and susceptibility the recessive characteristic. The resistant persons are immune under any conditions of exposure to infection but a slight amount may infect a susceptible one. Not all the children of lepers are susceptible and adult infections are possible. He concludes that susceptibility and resistance to leprosy are very likely hereditary.

L. R.

HAYASHI (Fumio) The Age Distribution Curve in Leprosy.—*Internal J. Leprosy* Manila. 1938. Oct.-Dec. Vol. 6. No 4 pp 491-496. With 9 figs.

The data for four censuses in Japan are analysed. In leprosaria cases the age distribution is low and approaches the curve of the age of onset. A shifting of the age curve to a later period indicates a late stage or a decline of the disease as illustrated by Norway. The

fact that the number of lepers found at the censuses does not decrease proportionately to those among military conscripts is partly explained by a rise in the age of the curve for the whole country

L. R.

JOSEPH (J. J.) Factors influencing the Incidence of Leprosy in the Madras Presidency—*Leprosy in India* 1939 Jan. Vol. 11 No 1 pp 3-13. With 1 map

The author discusses the incidence of leprosy on the basis of records of over 400 leprosy clinics at which within nine years some 200 000 cases have been recorded. The census returns from 1871 to 1921 showed almost stationary figures among an increasing population, but in the decade to 1931 the population increased 10 per cent. and the leprosy figures 100 per cent. due to increased interest in the disease. A map shows the chief foci of infection in the north-east coastal and the southern central areas. This confirms the higher incidence in hot humid climates. High altitude and low vapour tension are unfavourable to the spread of leprosy. Caste and marriage customs help to spread the disease. In schools and colleges the highest incidence is among those below the age of 12 years. The poor depressed classes who live under bad sanitary conditions, have a high incidence.

L. R.

OBERDORFFER (Manfred) Moderne Leprabekämpfung in Ceylon. [Leprosy in Ceylon.]—*Arch f Schiff- u Trop Hyg* 1938. Dec Vol. 42. No 12 pp 550-552 With 1 fig (map)

This brief paper illustrates by a map the incidence of leprosy in Ceylon. It brings out the high incidence in the south-western part of island and a smaller area on the east coast. The highest rates run 5 to over 10 per 10 000 population were met with around the cities of Colombo and Galle and those of the east coast.

L. R.

REO GARCIA (Pedro P.) Endemiografía de la lepra en Rosario [Leprosy in Rosario.]—*Revista Méd Argentina* 1938 Nov 30 Vol 25 No 48 pp 2233-2247 With 6 diagrams [16 refs.]

There are many Rosarios but the one referred to here seems to be Córdoba, Argentine Republic.] The article gives a good deal of information but mainly of local interest and to a great extent dealing with the history of the disease and its spread during the past decade. In 1927 there were 1 111 known lepers in the Argentine, when the population was 10 639,338 or 1 per 10 000. Since then the rise has been unchecked till in 1937 the number was 3,288 among a population of 12,781 611 or 2.5 per 10 000. Details of the 1928-29 census of lepers are given, stating the nationality, age, sex, place of residence and type of disease. The mortality during the decade is presented in a series of graphs. Doubtless there are other patients who have escaped notification.

H. H. S.

MACNAUGHTON (W. G.) Report on Central Leper Hospital, Makogai. —*Fiji Ann Med & Health Rep for Year 1937* pp 41-44

At the end of 1937 577 patients were accommodated in the Fiji leper institution, of which this is the annual report. Cases are being

received in an earlier stage than formerly especially in Fijians and the majority are cutaneous ones chiefly among the Indians. Iodized chaulmoogra oil intramuscularly is the usual and the most painless treatment. Methylene blue on the whole has not been followed by marked improvement. Among 560 treated patients 161 became arrested or quiescent for from six months to two years and 233 more were improved. Of the 161 the neural type formed 70 per cent. About four and a half gallons of chaulmoogra oil were produced from trees grown on the island. Work is provided and about \$1 000 worth of produce was purchased from the patients. The settlement is a credit to Fiji.

STRACHAN (P D) Statistical Evidence Indicating the Predominance of Abortive or Stationary Leprosy in Basutoland.—*Internat. Jl Leprosy* Manila 1938 Oct-Dec Vol 6 No 4 pp 497-499

This paper reports the results of further surveys in Basutoland and shows the existence of a large number of abortive cases. Statistics are given to indicate that a large number of early neural cases tend either to remain stationary or to abort. During ten years 61 per cent of early untreated NI cases appeared to undergo spontaneous arrest.

L. R

DOLL (James A) The Importance of Field Studies of Leprosy with Especial Reference to the Risk of Household Exposure.—*Amer. Jl Hyg* 1939 Jan. Vol. 29 No 1 Sect A pp 27-33

This is an interesting account of field studies of leprosy at Cebu in the Philippines. The results are most clearly expressed as attack rates per unit (usually 1 000) of person-years of experience—that is, the number of cases per 1 000 persons observed for one year. The records deal with 8 007 individuals of 1 051 families. Living in a house with a leper for one month constitutes exposure to infection. The attack rates averaged 1.3 per 1 000 person years with a maximum of 4.1 between 10 and 14 years of age and falling to 0.2 at over 50 years. The annual risk of contracting the disease is about five times as high with as without house exposure the figures being 5.1 to 0.9. The highest rate of 14.8 to 2.1 was again from 10 to 14 years of age. The rate among exposed persons was 5.0 in males and 4.1 in females. No account was taken of the duration of house contact with a leprosy patient or of the type of the cases.

L. R

LARA (C B) Early Leprosy in Children of Lepers, Further Observations on the Early, Definitely Identifiable Leprotic Lesions.—*Monthly Bull. Bureau of Health* Manila 1938 July, Vol. 18 No 7 pp 325-355 With 5 figs.

This paper deals with further work in watching for the earliest stages of leprosy in children of lepers under close observation at the

advocates the application to the lesions of a coating of Tr Iodil and after it has dried starch is sprinkled over it. On provoking sweating by muscular exercise (or according to Dubois by the injection of pilocarpine) the starch is turned blue only in the areas where sweating occurs. Its absence indicates the positive reaction of loss of the power to perspire. Positive results were obtained in 60-67 per cent of 196 definite but not very advanced, cases of leprosy. In suspected cases the rate was 42.28 per cent and in slightly suspicious ones 21.05 per cent. These figures are in agreement with VAN BREUSEGHEM's 71 per cent of reactions with the test. He therefore considers this test of JURGENSEN and MILNOR to be of some value in suspected cases of leprosy.

11 This paper records very similar results with the use of pilocarpine in place of muscular exercise to produce sweating. The author obtained 72 per cent of reactions in simple neural lesions, 88 per cent in tuberculous ones, and 79 per cent in 100 total cases. [See also *il. Bulletin* 1934 Vol. 31 p 554] L. R.

RADWA (R) La ponction ganglionnaire de sujets sains en pays d'endémie lépreuse. [Gland Puncture in Healthy Persons in Endemic Leprosy Areas.]—*Ann. Soc. Belge de Méd. Trop.* 1938, Sept. 30 Vol. 18, No. 3 pp. 497-500.

The author reports on examinations of 135 lepers and 102 non-lepers for lepra bacilli by means of gland puncture. The former yielded 24.5 per cent of positive results. The latter only 4.8 per cent, but in two of the five positive ones the acid-fast bacilli were atypical and easily distinguished from that of Hansen. L. R.

VAN BREUSEGHEM (R) Contribution au diagnostic de la lèpre. L'examen du mucus nasal [Diagnosis by Examination of Nasal Mucus.]—*Ann. Soc. Belge de Méd. Trop.* 1938, June 30 Vol. 18, No. 2 pp. 291-292.

The author records that he found lepra bacilli by examination of the nasal mucus from both nostrils in 20 per cent. of treated cases of leprosy but in 40 per cent of untreated cases. They were found on both sides in 30 per cent only of the positive cases, so both should be examined. L. R.

NAIR (V. Govindan) & PANDALAI (N. G.) A Note on the Importance of a Thorough Bacteriological Examination of All Cases of Clinical Leprosy.—*Jl. Indian Med. Assoc.* 1938, Nov. Vol. 8, No. 2, pp. 86-90 [12 refs.]

These authors report finding acid fast bacilli in the lesions of 57.27 per cent of 147 neural cases of leprosy. They stress the importance of such examinations in all forms of the disease. L. R.

RADWA (R) Sur la lipase du sérum des lépreux. [Lipase of Serum in Leprosy.]—*Ann. Soc. Belge de Méd. Trop.* 1938, June 30 Vol. 18, No. 2 pp. 233-236. [11 refs.]

The author refers to the work of ROGERS, confirmed by MUIR, showing a decrease in blood lipase in severe cases of leprosy and an increase

in cases improving under chaulmoogra treatment. He goes on to record his own observations confirming the earlier work. Details of repeated estimations in fourteen cases show a serious decrease in lipase in severe cases as compared with that in cases doing well. In those improving under alepol treatment a notable increase in the lipase in the blood was observed. L. R.

SPEIGHT (A.) Erythrocyte Sedimentation Test and Prognosis in Leprosy.—*Trans Roy Soc Trop Med & Hyg* 1939 Jan 28 Vol 32. No 4 pp 505-509 With 3 graphs.

The author has made regular monthly estimates of the erythrocyte sedimentation curve in cases of leprosy as advised by MURR, and divides them into three types. The prognosis is favourable when the index remains at a low point throughout not exceeding 25 and also when a high initial rate shows a progressive fall under the influence of treatment. On the other hand the outlook is unfavourable when a high index does not decline with treatment. Intercurrent disease and other depressing influences may increase the rate and should also be taken into account in making a prognosis. L. R.

GREVAL (S. D. S.) LOWE (John) & BOST (R.) Complement-Fixation in Leprosy with Witebsky, Klingenstein and Kuhn (W.K.K.) Antigen a New Technique.—*Indian J Med Res* 1939 Jan Vol 26. No 3. pp 843-849

Complement fixation tests have been carried out on leprosy cases with the Witebsky Klingenstein and Kuhn antigen with the technique of the Wassermann test. A high order of sensitiveness was found in the lepromatous type but a low order in the nerve type. The specificity of the test is not of a very high order and positive reactions have been obtained in kala azar and doubtful ones in malaria, syphilis and tuberculosis. The diagnostic value is only considerable in the lepromatous type. L. R.

ROW (R.) Some Experimental Observations on Human and Rat Leprosy and their Significance in the Pathogenesis and Treatment of the Disease.—*Trans Roy Soc Trop Med & Hyg* 1939 Jan. 28. Vol 32. No 4 pp 497-504 With 2 plates. [12 refs.]

Complement fixation tests were carried out in over one hundred leprosy cases with a preparation made by prolonged autolysis of tubercle bacilli. A strong reaction was obtained in all cutaneous cases and negative ones in nerve cases showing no lepra bacilli. In tuberculoid cases the reaction was doubtful. L. R.

FICKER (Martin) Eine neue Flockungsreaktion bei Lepra [A New Flocculation Reaction in Leprosy].—*Ztschr f Immunitätsf u Experim Therap* 1938. Nov 8 Vol 94 No 3/4 pp 357-362.

The author describes yet another form of antigen for a flocculation reaction in leprosy. It is prepared from cultures of the acid fast bacillus 1225 or L3 Troc by an elaborate method for which the original paper should be consulted. Flocculation with it is reported to give negative reactions in syphilis, but positive ones in leprosy. It is also said to give a larger proportion of positive results in cases of nerve

leprosy than are obtainable by any previous such test, and in a series of cases it gave positive reactions when examinations of the nasal mucus were negative.

L. R.

FICKER (Martin) Ueber Verstärkung von Antigenen für die Komplementbindung bei Lepra. [Antigens for Leprosy Complement Fixation Tests.]—*Zucker f. Immunitätsf u. Experim. Therap* 1938 Nov 8. Vol. 94 No. 3/4 pp. 363-368.

In this brief note the author reports that weak and doubtful complement fixation reactions in leprosy may be strengthened by the addition of Bayer's Calmestrol.

L. R.

CAPPELLI (E.) La "Pallidareazione" di Gaehtgens sui sieri lebbrosi. Contributo allo studio dell'essenza della R. Wassermann. [The "Pallida Reaction" in Sera of Lepers.]—*Giorn. di Batteriol e Immunol* 1939 Mar Vol. 22, No 3 pp. 425-436. [18 refs.] English summary [Summary appears also in *Bulletin of Hygiene*]

The pallidareaction practised on leprosy sera with the technic suggested by Gaehtgens and with the spirochaetic antigen created by him allows us to conclude —

(1) that the specificity of the reaction is confirmed by the total absence of positive results (+++) on the sera of non-leptic lepers

" (2) that, as the Pallidareaction was positive (+++) only in one case, which concerned the one leper shown to be affected with lues, this fact, if proved by further researches, offers the possibility of revealing positive specific reactions for lues in lepers

(3) that the humoral reactions which can be observed in sera of lepers by means of antigens consisting of extracts of sound organs and of organs of hereditary leptic individuals (positive Wassermann reaction)—even

VAN BREUSEGHEM (R.) showing the existence of specific leprosy apart from the possibility of aspecific reactions — antitoxins—may be compared to those of leptic sera only in the aspecific component with regard to the fact that this reaction remains negative toward an antigen formed only by *Treponema pallidum*.

BURKET (Et.) La réaction à la Léproline chez un groupe lépreux en Tunisie. [Leprolin Reactions.]—*Arch. Inst. Pasteur de Tunis* 1938 Dec. Vol. 27 No. 4 pp. 341-359

Leprolin reactions in cases in Tunis are recorded which are in close agreement with those of previous observers. The reaction is negative in infancy and in cutaneous cases of leprosy. It is positive in nerve cases, and in large proportion of contacts, especially those of the later ages. It is not certain if the reaction is a measure of immunity or an allergic phenomenon.

ROUSSEAU (Paul) & GAUGEAT (M) Culture du bacille de Hansen—a partir du léproma—(suivant la méthode de VAUDREMER et Mlle BRUN) [Cultivation of Hansen's Bacillus].—*Rev Méd et Hyg Trop* 1938 Sept.-Oct. Vol. 30 No 5 pp 268-270

These authors claim to have cultivated Hansen's bacillus by immersing portions of lepromata free from skin in a fluid *Aspergillus* medium. They describe a cycle of development commencing with a granular cyanophile stage and reaching an acid-fast condition. L. R.

MANALANG (J) Non-Acid-Fast Forms of *M. leprae* in Leprotic Lesions. Second Report.—*Jl Philippine Islands Med Assoc* 1938 Oct Vol. 18, No 10 pp 617-626. With 4 charts.

Four lepromatous patients with symmetrical lesions on the back were injected on one side intradermally with *H. wrightiana* preparations for from fourteen to seventeen weeks and the effect on the lepra bacilli noted from time to time. In three there was a definite increase in the proportion of non-acid fast organisms. In the fourth case abscesses and ulcerations explained the absence of such changes. One patient with repeated mild lepra reactions during the experiment also showed markedly increased non acid fasts in the untreated control lesions. The author considers the non-acid fast forms to be bacilli degenerating as the result of the action of the drugs. L. R.

MANALANG (J) Comparative Effects of Different Chaulmoogra Preparations on *M. leprae* in vitro.—*Monthly Bull Bureau of Health Manila* 1938, Sept Vol. 18 No 9 pp 451-460

Experiments to ascertain the effects of the prolonged action of chaulmoogra preparations on acid fast bacilli in glands removed at autopsies and kept in test tubes are recorded. The numerical diminution or staining alterations of the bacilli were noted each month. The Cullion Mercado preparation was most effective in causing the disappearance of the *M. leprae* from the glands and *wrightiana* oil and esters in removing acid fastness. These observations seem to agree with DE VERA's clinical trials of similar preparations. L. R.

BURNET (Et) Inoculation positive de la lèpre humaine au hamster inoculation négative à divers autres rongeurs. [Successful Inoculation of Human Leprosy Material in the Hamster Failure in Other Rodents].—*Arch Inst Pasteur de Tunis* 1938, Dec Vol 27 No 4 pp 327-340 With 8 coloured figs. on 1 plate.

This paper records the successful infection of a hamster by the insertion under the skin of a small piece of a human leproma. In less than a year a subcutaneous lesion, containing numerous acid fast bacilli developed as shown by coloured illustrations. This confirms ADLER's success in 1933 [this *Bulletin* 1933 Vol. 35 p 293 and 1939 Vol. 36 p 240]. The infected hamster did not have its spleen previously removed and others in which that was done before inoculation proved negative, so that operation is not essential to success. Even if the result is regarded as grafting it still has value. Five similar experiments with hamsters some of which had their spleens previously

PELLAGRA.

PRECIS OF ABSTRACTS IN THIS SECTION

The effect of sunlight in producing symptoms of pellagra is discussed by BICKEL (p 543) and VILLARET *et al* (p 543). These authors report two alcoholic patients who had both suffered from general disabilities but exposure to the sun brought out the exanthem. Similarly KIELLAND (p 544) shows that the initial attack and relapses were connected with exposure to sunlight in a patient in Norway who had been feeling unwell for some time. His diet had been deficient in the PP factor. [See also this *Bulletin* 1937 Vol. 34 p 182.]

That there may be an endogenous factor in the aetiology of pellagra is suggested by the occurrence of that disease in uniovular twins reported by MAINZER (p 544). Although living far apart these twins developed pellagra at the same time but other members of the family did not.

DE LANGEN *et al* (p 545) remark on the possibility of pellagra occurring as a conditional deficiency as a result of various lesions or intoxications. Smoking may have a preventive effect but endocrine disturbances in women probably contribute to conditional deficiency. They think pellagra is not a pure vitamin B₃ deficiency but is more complex. Similarly SLATINEANU *et al* (p 545) consider that pellagra develops as a result of unbalanced diet in conjunction with organic insufficiencies. These are interdependent and may depend primarily on intoxication or infection. CLAUDIAN and GHERMANI (p 546) have found deficiency of vitamin C in pellagrins and non-pellagrous persons suffering from other diseases. Deficient supply and deficient assimilation probably occur. MAASSEN (p 546) reports a case of pellagra due to gastroenterostomy.

PAULY and DEPRECO (p 546) found marked changes in the cells of the anterior horns of the spinal cord in a case of pellagra. There was no subacute combined degeneration nor peripheral neuritis.

WATSON (p 547) considers that the estimation of porphyrin in pellagra by the B.E.S. test is unreliable and not specific and gives values too high when compared with those obtained by a modification of the Fikentscher method. DOBRINER *et al* (p 547) investigated the excretion of porphyrin in pellagra. The total amount and the amount in the urine fell during treatment. Porphyrinuria is not a constant feature of the disease and may be simply an indication of hepatic dysfunction.

IONESCO and CONSTANTINESCO (p 548) found that the serum carotin in a number of patients with pellagra was low. Creatinin and creatin were also low but increased under treatment by diet probably due to the excess of meat given. VILTER *et al* (p 548) found that the blood of pellagrins was relatively deficient in codehydrogenase as shown by the inability of *H. influenzae* to grow in high dilutions of blood in peptone water. Under treatment with nicotinic acid the codehydrogenase content was raised to normal. Pellagrins maintained on a pellagra-producing diet and treated with nicotinic acid and vitamin B₃ recover but may relapse. The administration of riboflavine cures these relapses. The authors advise a treatment which ensures adequate mixed vitamins. SLATINEANU and POTOP (p 549-50) find the polypeptides in the serum and C.S.F. of pellagrins to be

Tropical Diseases Bulletin

increased but not proportionally. Sodium and potassium are decreased irregularly. In general these changes appear to be related to the mental symptoms.

Atrophy of the gastric mucosa with increased secretion and accelerated emptying was found in most of the patients examined radiologically by TYRDEL and TAMLER (p. 550).

Treatment by nicotinic acid and its derivatives is reported on favourably by a number of workers. The dosage required [see pp. 550 to 556] appears to vary considerably and daily amounts, usually in divided doses, of 150 mgm. in slight cases to 1000 mgm. in severe attacks have been given by the month. Doses administered by injection are 100 to 150 mgm. daily. For prevention the requirements also vary considerably. SCHMIDT & SYDENSTRICKER (p. 555) found 100 mgm. twice weekly to be insufficient. SPIES *et al.* (p. 553) and VILNER *et al.* (p. 554) found some improvement to follow the administration of give 2 to 5 cc. of coramine *per os* daily to a total of 50 cc. and VILNER *et al.* (p. 554) found some improvement to follow the administration of diminotinic acid and one of its derivatives. The usefulness of nicotinic acid-amine in skin lesions is shown by KUENAU (p. 556).

MAWSON BAKER and RANSFORD (p. 550) draw attention to the importance of the recognition of pre-pellagrous conditions, and SPIES *et al.* (p. 553) describe the nervous symptoms of pellagra which are not always recognized as such.

SYDENSTRICKER *et al.* (p. 551) show how the symptoms clear up under nicotinic acid and have examined its physiological effect in controls. SPIES *et al.* (p. 554) use vitamin B₃ to relieve the pain and numbness of peripheral neuritis in pellagra, and record the reactions of normal persons to the administration of nicotinic acid.

GRECOU *et al.* (p. 552) have not obtained such good results with nicotinic acid as have been reported from America, but the dosage used has been much smaller. ALROST *et al.* (p. 555) while recognizing the good effects of nicotinic acid in Egypt have not been able to reproduce the brilliant results obtained in America.

HARRIS (p. 556) describes three experimentally produced conditions in animals which are analogous to human pellagra—canine black tongue, monkey and pig pellagra. Nicotinic acid produces dramatic improvement.

AZARY (p. 557) used larostidine and found that the rash in 3 patients disappeared in three weeks. Some anti pellagra effect was observed after the use of various pyridine compounds by SPIES *et al.* (p. 557), and LEWIS (p. 557) obtained apparently good results with intravenous sodium thiosulphate, 10 cc. of a 10 per cent solution twice weekly in one patient.

NAPIER (L. Everard) Pellagra.—*Indian Med. Gaz.* 1939 Mar Vol 74 No 3 pp 137-142. With 5 figs. [10 refs.]

The author's intention is to draw attention to pellagra in India where he thinks, more cases would be diagnosed if the signs and symptoms were more widely recognized. He gives a long quotation from a Paris journal of 1755 and follows this with a systematic description in which the theories of causation are discussed and the pathological symptomatology and treatment adequately detailed.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES 1938 July Vol 196 No 1 pp 122-138 [80 refs. —Pellagra.

BICKEL (Georges). Alcoolisme chronique et pellagre révélée par une insolation accidentelle. [Chronic Alcoholism and Pellagra disclosed by the Effects of Sun Bathing].—*Schweiz. Med. Woch.* 1938 Oct 15 Vol. 68. No 42. pp 1159-1160 [16 refs.]

Writing from Geneva the author states that he has seen two cases of pellagra in three months and believes that the disease is commoner than is usually recognized. He reports the case of a man who had drunk half a bottle of whisky a day for the past 10 years and seen twenty-four hours after taking a sun-bath. Severe sunburn developed on the arms and legs, hands and feet there was burning of the tongue and gums, diarrhoea with twenty stools a day, mild delirium, coproporphyrinuria and general asthenia.

The previous history showed that each spring for five years he had had stomatitis and glossitis, mild dermatitis, irregular bowel action and some change in character. Five doses of 0.1 gm. a day nicotinic acid caused immediate benefit—in four days all symptoms had cleared except the weeping lesions on the hands which took five weeks to heal.

H S S

VILLARET (Maurice) JUSTIN BESANÇON (L.) KLOTZ (H. Pierre) & SIKORAY. Pellagre chez un alcoolique révélée par un essai d'hélio-thérapie d'une polymérite. [Pellagra in an Alcoholic Subject revealed after Exposure to Sunlight].—*Bull. et Mém. Soc. Méd. Hôp. de Paris* 1939 Mar 13 53th Year 3rd Ser No 8 pp. 367-371

An account of a 48-year-old male alcoholic in whom the diagnosis of pellagra was revealed by the appearance of a typical skin rash on the lower parts of the legs and dorsa of feet following upon an exposure to the June sunshine of Paris in an attempt on the part of the patient to treat the loss of power in the lower limbs. The symptoms which were antecedent to the exanthem, consisted in a general asthenia, progressive anorexia to complete loss of appetite associated with vomiting and wasting. The muscles of the legs were markedly affected and walking was almost impossible. Knee jerks were feeble, Achilles jerks absent with hypo-excitability to the Faradic and Galvanic currents. There were also noted amblyopia with central scotoma for green and pallor of the optic discs.

Treatment consisted in giving vitamin B₁, yeast and liver extract. The skin lesions improved in a few days and on discharge from hospital a month later the patient had gained 5 kilos. in weight. H S S

KIRLLAND (J) Et tilfelle av pellagra med opblussing av symptomene efter soiling [Pellagra and the Effect of Sunlight in producing Symptoms.]—*Nordisk Med* 1939 Vol. 1 No. 10 pp. 663-696
English summary

Eight cases have been recorded in Norway since pellagra was first seen in that country in 1934. The present case is of more than ordinary interest because the initial attack and relapses were distinctly and intimately connected with exposure to sunlight.

A man of 49 years who had been feeling "below par" for some time seized the opportunity of the first brilliantly sunny day of the year in May 1937 to sun-bathe. Within two days he had attacks of diarrhoea and his hands became very red and he felt greatly depressed. The backs of the hands were red, dry and scaly, the tongue was red. A test-meal revealed achlorhydria. He improved much with dietetic treatment but twice afterwards the glossitis and dermatitis recurred after exposure to the sun. He was then given a course of dieting rich in the PP factor and recovered and on taking such diet was able to subject himself to the sun's rays without showing the above symptoms. His diet prior to his illness had been deficient in the PP factor.

The author quotes SMITH & RAFFIN who kept 35 pellagrins in bed on a diet poor in PP factor till the symptoms disappeared and then exposed them and a number of controls to small doses of sunshine. None of the controls showed any symptoms, but 20 of the 35 others showed dermatitis and aggravation of their pellagra symptoms.

MAINZER (Fritz) Ueber Pellagra. I. Mitteilung Pellagra bei einigen Zwillingsschwwestern. [Pellagra in Uniovular Twins.]—*Acta Med Scandinavica* 1939 Vol. 99 No 2-3 pp 292-296
With 6 figs [31 refs.]

That there may be an endogenous as well as an exogenous factor concerned in the aetiology of pellagra is a matter of considerable interest. The question was discussed for the first time by the reviewer [this *Bulletin* 1937 Vol. 34 p 183]. In this article by Dr Mainzer, Director of the Jewish Hospital Alexandria, the point receives further confirmation by the occurrence of pellagra in uniovular twin sisters aged 23 years. These two young women after living apart from each other the one in France and the other in Alexandria, for 3 years developed pellagra on four occasions at the same times. A sister and two brothers who partook of the same diet showed no evidence of the affection, the diet itself did not appear to have been qualitatively deficient. All members of the family ate a moderate amount of maize.

The dermal lesions, mental symptoms and blood pictures in both were identical. In both the same degree of diminution of basal metabolism was found. Gastric acidity was only determined in one—achlorhydria was discovered. Other points noted in both were the same marked degree of myopia, identical electrocardiograms, the same low normal values for fasting blood sugar with the same blood sugar curves after insulin. Serum nitrogen, chloride, uric acid and cholesterol identical values, etc. The blood pressure was higher in one sister than in the other.

MAINZER (F) Die Aetiologie der Pellagra. Uebersichtsreferat ueber die Entwicklung und den gegenwärtigen Stand der Frage (1914-1938). [The Aetiology of Pellagra. A Review of Modern Work and Opinions.]—*Ztschr f Vitaminf* Berne 1938/39 Vol. 8. No 4 pp 347-365 With 2 figs. [91 refs]

DE LANGEN (C D), BOSWIJK (J C.) & VAN NIEUWENHUIZEN (C L C.) Een endemie van pellagra genezen met nicotinezuur [An Endemie of Pellagra cured with Nicotinic Acid.]—*Nederl Tijdschr v Geneesk* 1938. Oct. 8 Vol. 82. No 41 pp 4970-4976 With 2 plates. [19 refs.] English summary

Ten patients were found in a mental asylum suffering from pellagra. Nine of these were treated with nicotinic acid and were completely cured of pellagra the tenth was not treated and died. There was no difficulty in the diagnosis as the patients had a typical syndrome. All were females four of them were housed in the same pavilion and three in neighbouring pavilions. Six of these patients were "negativistic" and had to be fed. In one ill-nourished patient pellagra developed during treatment with cardiazol injections. Some of these accompanying conditions suggest the possibility of secondary pellagra a conditional deficiency such as may be seen in gastric cancer ulcerative colitis chronic alcoholism as a sequel to gastroenterostomy in syphilis of the stomach and benign stricture of the oesophagus. It is remarkable that all the pellagra sufferers in this institution were women and in view of the instant effect of treatment with nicotinic acid there seems reason to believe that the smoking habits of the men had a preventive effect. It is the opinion of the authors however, that that is not the whole explanation and that endocrine disturbances in women can be contributory to conditional deficiency. They think it probable also that pellagra may be of complex pathogenesis and just as beriberi is not a pure B_1 avitaminosis so is pellagra not a pure B_3 avitaminosis. Dosage in treatment still awaits exact definition. It seems possible to give more than 1 gm. daily. In the present cases 50 mgm. were administered 3 to 4 times daily in milk with little indication of toxic effect. Some patients developed an erythema over the whole body which usually lasted no more than 15 minutes but might do so for some hours. W F Harvey

SLĂTINEANU (AL) BALTEANU (I) SIBI (M) NITULESCU (I) & LEVIT (V) Contribution à l'étude du chimisme intestinal dans la pellagre. [Chemical Changes in the Intestine in Pellagra.]—*Bull Acad Méd Roumanie* 1938 3rd Year Vol. 5 No 4 pp 489-503 [38 refs.]

— — — NITULESCU (I) & LEVIT (V) Contribution à l'étude du chimisme intestinal dans la pellagre — *Bull Office Internat d'Hyg Publique* 1938 Oct Vol. 30 No 10 pp 2265-2274 [32 refs]

The authors views upon the aetiology of pellagra may be thus translated —

Pellagra develops as the result of an unbalanced and one-sided diet reacting upon an organism suffering from organic insufficiencies—gastric intestinal hepatic and renal these are interdependent and may depend primarily upon an intoxication (alcohol) or an infection (malaria, syphilis, etc.)

They hold that it is essential to treat the chronic gastritis, the liver insufficiency, the intestinal disorders, etc. as these conditions may not only cause lack of absorption of essential food principles but allow of the absorption of poison and disallow detoxication.

In support of their beliefs they find that pellagrous diets lead to acid production: the faeces are acid with increase in organic acids, the pH commonly being about 6. This indicates fermentative bowel flora.

The salicylate reaction points to a loss of detoxication power by the liver. Albumin is lost into the bowel and undergoes putrefaction with the formation of amino-acids and enormously increased ammonia. Histamine-like substances—cadaverine, guanidine, putrescine—are present, also sulphur compounds porphyrin, indol, skatol, phenols, etc. are all increased. Vitamins produce a transitory beneficial effect but vitamin deficiency is not the real cause of pellagra.

CLAUDIAN (I.) & GHERMANI (A.) Recherches sur la carence de vitamine C chez les pellagriques, par le test de saturation. [Vitamin C Deficiency in Pellagrics, gauged by the Saturation Test.]—*C. R. Soc. Biol.* 1938. Vol. 129. No. 33. pp. 999-1003.

Clinically pellagra often suggests a plurivitaminic deficiency state. Some observers have believed that a vitamin C deficiency occurs in some cases and good results have been noted following the administration of this factor.

Using the saturation test of HARRIS and RAY and the intravenous method of administration of ascorbic acid, the work being carried out in the winter and early spring, the authors have found a retention of considerable degree not only in pellagrics but also in non-pellagrous inhabitants living under the same conditions in Rumania. Among patients admitted to hospital for other conditions, including cirrhosis of the liver, gastric carcinoma, Graves' disease and pernicious anaemia similar figures were obtained, but in normal healthy well-fed individuals there was no evidence of deficiency of vitamin C. They suggest that states of deficiency may arise both from a deficiency in food supply and from a defect in assimilation.

PAULY (R.) & DEFRECO (M.) Pellagre et troubles nerveux. [Pellagra and Changes in the Nervous System.]—*Jl. Méd. de Bordeaux* 1939. Feb. 11-16 & 23. Vol. 116. Nos. 6-7 & 8. pp. 145-156. 163-164. With 6 figs. [84 refs.]

The substance of this long article deals with a single case of pellagra, clinical notes, post mortem findings and histo-pathological examination.

with special reference to the nervous system a second almost identical case is noted but not detailed

The authors point out how very few cases of pellagra have been published in France since the War and that in consequence ignorance concerning pellagra and especially of the nervous lesions of the disease has come to be widespread. The case described was that of a woman a chronic alcoholic aged 34 seen at Bordeaux in 1934 in third relapse. Both patients died. No treatment is mentioned as having been given. The lengthy anatomic-pathological descriptions it would be difficult to summarize here but it is remarked in regard to the C.N.S. that while degeneration of hyalin sheaths was absent cell changes were marked especially in the anterior horns of the cord. The changes of a subacute neuritis wanting. Some general discussion on the neurological and psychical symptoms in pellagra is followed by a discussion upon anatomic-pathological findings and then a section upon aetiology in which the authors appear to incline towards a theory which would include vitamin deficiency toxic agents or virus infection

H S S

WATSON (C J) The Urinary Pigments in Four Cases of Alcoholic Pellagra.—*Proc Soc Experim Biol & Med* 1933. Dec Vol. 39 No 3 pp 514-518 With 1 fig

Writing from the University of Minnesota the author points out that the method of estimating porphyrin in the urine in pellagra adopted by BECKH ELLINGER and SPIES (B.E.S. test) is far from reliable the results compared with those obtained by a modification of the Fikentscher method (red fluorescence in U.V. light with the Zeiss stufenphotometer) are far too high. Beckh and his colleagues obtained figures as high as 100 mgm. per litre whereas with the newer test the figures never exceeded 0.6 mgm. per day. The higher figures correspond very much with those obtaining in idiopathic porphyrinuria but red urine has never been described in pellagra. The fact is that the B.E.S. test is not specific for porphyrin. Other pigment bodies possibly having a common origin with porphyrin give positive reactions such bodies might originate by esterification or conjugation. On the other hand it is suggested they might be indigo derivatives—indirubin indirupurin.

[The B.E.S. method consists of the extraction of acidified urine with ether after which the ether is extracted with a small amount of 25 per cent. HCl. Red or red violet colour is considered to be due to porphyrin and is estimated colorimetrically with a standard porphyrin solution. See *Quart J Med* 1937 Vol. 6 p 305]

H S S

DOBRINER (Konrad) STRAIN (W H) & LOCALIO (S A.) The Excretion of Porphyrin in Pellagra.—*Proc Soc Experim Biol & Med* 1933. June Vol. 38 No 5 pp 748-752. With 1 fig [11 refs]

A case of pellagra has been studied in order to determine whether the increased output of porphyrin in the urine is due to a normal total output with an increased proportion excreted by the liver through the urine or not also whether the porphyria represents a simple increase of a normal process due to increased haematopoiesis or a pathological metabolism of pigments marked by the excretion of coproporphyrin Type III

The case was a typical alcoholic case with dermatitis stomatitis, vulvitis and diarrhoea. Free hydrochloric acid was present in the gastric juice. Treatment was by yeast and liver extracts. During a 6-day observation control period the total coproporphyrin excretion averaged 897 mgm. per day of this 254 mgm. were excreted in the urine. In the first nine days of therapy coincidentally with clinical improvement, the total excretion fell to a daily average 458 mgm., of which 157 were found in the urine. Large amounts of protoporphyrin and δ-tertoporphyrin were also found in the faeces possibly due to bleeding into the bowel.

The excreted coproporphyrin was a mixture of Types I and III the first determined by melting point the second in only small amounts, insufficient for final determination. This mixed porphyrin excretion is similar to that reported in pigment cirrhosis of the liver and lead poisoning and differs from that of pernicious anaemia haemolytic jaundice, etc., in which only Type I is produced and excreted.

The porphyria in pellagra must be interpreted with care. It is not a constant feature of the disease. It may be simply an indication of hepatic dysfunction.

LOVINESCO (N Grila) & CONSTANTINESCO (P) Recherches de laboratoire dans la pellagre. [Laboratory Research in Pellagra.]—*Bull et Mém Soc Méd. Hôp. de Bucarest* 1938. Nov-Dec. Vol. 20. No. 8-10 pp 305-315

(a) Using the method of HALDEN and UNGER with the aid of Pulfrich's photometer estimations of the serum carotin in 21 pellagrins were made. In 7 cases it was below normal limits (0.02 to 0.11 mgm. per litre) in the remainder there was a tendency towards the lower limit. In 18 cases the average figures obtained before and after treatment were 0.0263 mgm. and 0.0338².

In 7 of the 21 cases palmo-plantar xantho-chromia was noted but no corresponding increase in serum carotin was found. It is suggested that either this colouration in cases of pellagra is not due to carotin or that in this disease carotin may become fixed in the tissues with consequent reduction in the blood.

(b) In the same series of cases using the technique described by RAPPAPOORT and GEIGER, fibrinogen was found to be present in normal amounts. Accompanying successful treatment a slight increase was noted.

(c) In 28 cases of pellagra determinations of creatinin and creatin were made using the method of LIEB and ZACHAR. Totals tended to be at the region of the lower limits of normal (or actually diminished according to French standards) but while the creatinin values are much increased, those for creatin are proportionately diminished.

As the patient improves under treatment by diet the figures tend to become readjusted (probably due to the excess of meat given) H S S

VILTER (Richard W) VILTER (Sue Potter) & SPIES (Tom D) Relationship between Nicotinic Acid and a Coenzyme (Cozymase) in Blood of Pellagrins and Normal Persons.—*J Amer Med Assoc* 1939 Feb 4 Vol. 112. No. 5 pp 420-422. [11 refs.]

Using the knowledge made available by the LEWIS, namely that bacilli of the influenza group will not grow in culture devoid of what

was called growth factor V now identified as coenzyme (coferment of WARBURG) and that the organisms cannot synthesize it from its components—nicotinic acid amide, adenylic acid, ribose and phosphoric acid. The authors decided to test the coenzyme blood content in pellagrins. The actual method employed will not be detailed here but the results are expressed in blood dilutions which would support growth. With four normal controls dilutions in peptone up to 1:12,000 supported growth of *Haem influenzae* the blood of three pellagrins in dilutions of only 1:2,000.

Maintained on a pellagra producing diet but treated with nicotinic acid growth promoting activity of the blood of the pellagrins was raised to normal.

It is argued that coenzyme (coferment) is significantly raised by nicotinic acid therapy and the hypothesis is suggested that the value of nicotinic acid in pellagra depends on the synthesis of nicotinic acid nucleotide and finally of coenzyme in the body.

Supplementary observations showed that in one case of pellagra with mental symptoms the blood contained no growth promoting factor V at all. After 2 days treatment with 500 mgm. nicotinic acid the symptoms cleared and growth occurred in a 1:4,000 dilution.

In 3 cases of diabetes mellitus with severe acidosis the coenzyme content was found to be markedly lowered but return to normal occurred with correct diet or insulin or nicotinic acid.

In 2 cases of lymphatic leukaemia which had been treated by X rays growth supported only in 1:1,000 dilution and no improvement occurred after nicotinic acid therapy. Three cases of malignant disease and one of Hodgkin's disease supported better growth than normal. One case of pernicious anaemia at a dilution of 1:8,000. The V factor may also be demonstrated in the urine.

The other part of the paper deals with the probability of another factor being concerned in pellagra.

It has been shown that pellagrins maintained on a pellagra-producing diet with supplements of nicotinic acid and vitamin B₁ lose their symptoms but that some of them relapse. A further study was made on four cases of endemic pellagra from Birmingham, Ala. were maintained on a pellagra-producing diet plus 100–400 mgm. synthetic nicotinic acid and 10 mgm. synthetic vitamin B₁ each day. Within 1 to 2 months the patients began to lose appetite and weight and a mild dermatitis appeared and this clinical picture persisted unchanged for the next 10 months. Fifty mgm. riboflavin on two successive days were then administered. Within 48 hours improvement occurred with increased vigour and sense of well-being and the skin changes were less marked.

The authors believe that riboflavin is useful in human nutrition and in pellagra in relapse and that as diseases due to deficiency of water soluble vitamins are of complex origin treatment should include the administration of mixed vitamins.

I. SLATINEANU (AL) & POTOP (I) Recherches sur le taux des polypeptides dans le sang et dans le liquide céphalo-rachidien chez les pellagriques [The Polypeptide Content of the Blood and Cerebrospinal Fluid in Pellagrins.]—C R Soc Biol 1938 Vol. 129 No 30 pp 713–715

ii. SLATINEAXU (Al.) & PUTOP (I) Le sodium et le potassium du sérum et du liquide céphalo-rachidien dans la pellagre. [The Sodium and Potassium Content of the Blood and Cerebrospinal Fluid in Pellagra.]—*Ibid* pp. 718-720

i. Estimations were made among several groups of pellagrins numbering 50 in all. The authors found that the polypeptides in serum and in cerebrospinal fluid are in general augmented in quantity but great variations occur. The polypeptides in blood and C.S.F. are not proportional. The variations of the polypeptides of the C.S.F. are independent of the variations in non-protein N and of albumin in the C.S.F. In the majority of cases the variations in the polypeptides of C.S.F. appeared to be related with changes in mental conditions.

ii. Considerable variations of total sodium and potassium occur in serum and C.S.F. of pellagrins (58 cases). The totals for each do not run parallel in the serum nor in the C.S.F.

Blood potassium tends to be diminished in psychotic cases, in C.S.F. there is great variability. Blood sodium tends also to be diminished and in the C.S.F. variations occur as seen in the blood.

TRYDEL (M.) & TAMLER (A.) Röntgenuntersuchungen des Magens bei Pellagra [X-ray Examinations of the Stomach in Pellagra.]—*Med Klin* 1938 Aug 19 Vol. 34 No. 33 (1756) pp 1090-1091

Thirteen cases of pellagra were submitted to careful X-ray examination of the stomach. In eleven a complete atrophy of the folds of the mucous membrane was demonstrated. In all marked increase in gas retention was shown throughout the gastro-intestinal tract and in most signs of increased secretion and accelerated emptying while the great proportion showed pathological alteration in form of the stomach either elongation or dilation.

H S S

MANLON BARR (Philip) & RANSFORD (O. V.) Stomatitis of Vitamin-B₂ Deficiency treated with Nicotinic Acid.—*Lancet* 1938 Aug 20 pp 428-429 12 refs.]

The authors report an interesting example of the condition which they refer to as the pre-pellagrous state and the result of treatment with nicotinic acid.

A married woman aged 62 gave a history of 5 years morning diarrhoea raw sore tongue and soreness at the angles of the mouth. Later tingling sensations and numbness down the outer side of one leg were complained of. Examination revealed little beyond a distended abdomen, exaggerated deep reflexes a mild microcytic anaemia and a considerable hyperchlorhydria. The patient complained of malaise and depression.

Treatment consisted of an alkaline mixture and 150 mgm. nicotinic acid daily. The diarrhoea ceased immediately in 48 hours the lips had healed and the tongue was clearing up. At the end of 10 days the patient was practically well.

[This case serves to illustrate the importance of recognizing these conditions of pre-pellagra or sub-pellagra. They may be more frequent in temperate climates than is usually believed. At the same

tune the authors statement In temperate climates the skin lesions of pellagra do not appear needs modifying cases of this disease with typical dermatitis occur in England as everywhere else.]

SYDENSTRICKER (V P) SCHMIDT (H L) JR FULTON (M C.) NEW (J S) & GEESLIN (L E.) Treatment of Pellagra with Nicotinic Acid. Observations in Forty-five Cases.—*Southern Med J* 1938 Nov Vol. 31 No 11 pp 1155-1163 [17 refs.]

Forty-five cases of pellagra (40 endemic 2 alcoholic 3 secondary) were treated in the University Hospital Augusta Georgia with nicotinic acid. The physiological effect of the drug was also essayed in controls 10 whites and 7 negroes It was found that 75 to 100 mgm. produced flushing tingling and tachycardia and lowering of blood pressure occurred with bigger doses—250 to 1 000 mgm. There was also an increased gastric acidity in most cases comparable with that produced by histamine

Full case notes are given of the 45 individuals 30 of whom had suffered previous attack They were all typical and need not be further detailed here

The authors appear to consider the most beneficial dosage to be 600 mgm. daily for 3 days followed by a daily maintenance dose of 100 mgm. in four fractions at 4-hourly intervals

Glossitis stomatitis and diarrhoea cleared up in 24 hours the dementia in 3 to 5 days and the dermatitis in a week With this treatment previously diminished gastric hydrochloric acid increases or reappears if previously absent in most cases porphyrimuria disappears.

GRECOU (Aurel) IONESCOU (N. Grub) & CONSTANTINESCOU (P.). L'acide nicotinique dans le traitement de la pellagre. [Nicotinic Acid in Pellagra].—*Bull et Mém Soc. Méd Hôpôt de Bucarest* 1938 Nov-Dec. Vol. 20 No 9-10. pp 283-299 [34 refs.]

After referring to the observations of others upon the subject the authors report in short eighteen cases of pellagra treated at Pancepti and Ploesti with nicotinic acid. While admitting that this substance is not without some use in the treatment of the disease their results fall far short of those published in America. It is suggested that the disease as seen in America and as seen in Rumania possesses a rather different clinical picture and that this in turn depends upon some difference in the grouping of deficient factors, so that while in America nicotinic acid yields brilliant results in Rumania they are less satisfactory.

[Another possible explanation may be that the dosage of the drug was much smaller than that now commonly used in America. The Rumanian observers at the same time do not appear to have appreciated the fact upon which American writers have laid stress, namely that the amount of nicotinic acid required in individual cases varies very widely.]

RACHMILEWITZ (M.) & GLUECK (Helen L.) Treatment of Pellagra with Nicotinic Acid.—*Brit Med J* 1938. Aug 13 pp 348-349 [10 refs.]

BRITISH MEDICAL JOURNAL 1938. Aug 13 pp. 353-354—
Nicotinic Acid for Pellagra.

In this article is given an account of two very typical cases of pellagra treated at the Rothschild Hadassah Hospital, Jerusalem, by nicotinic acid. All signs and symptoms (except disordered patellar reflex) cleared up including skin lesion diarrhoea mental disturbance, etc. The glossitis which was present in one of the cases was the first condition to improve. [It is, however noteworthy that in the second case the much more severe of the two there was no glossitis. This absence of glossitis may occur in any series of cases as has been pointed out elsewhere. But the cure of the glossitis has been used by a number of observers as the index of an antipellagrous substance, including nicotinic acid. How then is explained the absence of glossitis in cases presumably suffering a nicotinic acid deficiency? As has been suggested by the reviewer elsewhere a study of the exceptional cases may throw considerable light on the subject their explanation is urgently needed.]

In the leading article a short account is given of the history of the introduction of nicotinic acid in the treatment of pellagra. H S S

BERNTH (O.) & STURUP (G. E.) Nikotinsyrebehandling af pellagra. [The Treatment of Pellagra with Nicotinic Acid].—*Ugeskr f Læger* 1938. Vol. 100 pp. 1137-1140 [13 refs.]

RAVX (J.) Et tilfælde af pellagra behandlet med nikotinsyre. [A Case of Pellagra treated with Nicotinic Acid].—*Ibid* pp 1140-1141

The case recorded by Bernth and Stürup was that of a woman, aged 41 with gastric achylia, anaemia depression, lassitude anorexia,

glossitis skin and mucous membrane changes characteristic of pellagra and violent diarrhoea. The administration of nicotinic acid stopped the diarrhoea at once. The cutaneous manifestations disappeared in a fortnight and the mental condition improved.

Ravn's patient was a 30-year-old woman suffering from schizophrenia and typical pellagra. The administration of nicotinic acid was followed by rapid improvement the stomatitis and diarrhoea disappearing first, and the changes in the skin somewhat later

SPIES (Tom Douglas) ARING (Charles Dair) GELPERIN (Jules) & BEAN (William Bennett) The Mental Symptoms of Pellagra. Their Relief with Nicotinic Acid.—*Amer Jl Med Sci* 1938. Oct. Vol. 196. No 4 pp 461-475 [21 refs]

A paper read at Atlantic City reciting the many nervous symptoms which may be witnessed in pellagra. These symptoms are well known to pellagrolgists but in practice not always recognized for what they are. Many are neurasthenic in type—fatigueability insomnia anorexia vertigo palpitation headache nervousness unrest apprehension anxiety forgetfulness and paraesthesiae

There may be also loss of memory disorientation confabulation and confusion or further excitement delirium mania or depression. There may be a trend towards a paranoid reaction with fears of relatives and delusions of persecution. [That such symptoms may occur when the more ordinarily recognized signs of pellagra are mild or wanting should never be lost to mind.]

Sixty acute cases with mental manifestations were submitted to treatment by nicotinic acid or coramine after a period of observation without any other supplement to a control diet. Recovery took place in all cases in from 10 hours to 6 days and no recurrence occurred if a maintenance dose of nicotinic acid was kept up. If the dosage was stopped relapse occurred in a third of the cases. Nicotinic acid also was shown to prevent the development of mental symptoms in cases of subclinical pellagra. It will be noted that only acute cases were treated. Some 26 other cases—Korsakow's psychosis manic depressive states involutional insanity schizophrenia etc. received no benefit from similar treatment.

The dosage of nicotinic acid used was 500 to 1,000 mgm. daily by mouth or 5 doses of 20 mgm. daily intravenously that of coramine, the diethylamide of nicotinic acid was 2 to 5 cc daily by mouth to a total of 20 to 50 cc.

[July 1939]

SPIES (Tom Douglas) BEAN (William Bennett) & STONE (Robert E.)
 The Treatment of Subclinical and Classic Pellagra. Use of
 Nicotinic Acid, Nicotinic Acid Amide and Sodium Nicotinate,
 with Special Reference to the Vasodilator Action and the Effect on
 Mental Symptoms.—*Jl Amer Med Assoc* 1938. Aug 13
 Vol. 111 No. 7 pp 594-599 With 2 figs. [11 refs.]

The authors in treating 79 cases of pellagra in hospital found that within 72 hours of the administration of large doses of nicotinic acid amide [coramine] fading of the mucous membrane lesions and blanching of the cutaneous lesions when present regularly occurred at the same time the functions of the gastro-intestinal tract tended to return to normal, there was remission in mental symptoms and porphyrinuria decreased. The peripheral neuritis was not relieved but pain and numbness disappeared 48 hours after the injection of 50 mgm. vitamin B₁ twice daily. Subsequently 98 relapsing cases of pellagra were treated at their own homes without any change of conditions. Within three days these pellagrins volunteered they felt much better and that dizziness depression burning sensations, confusion and upset head had disappeared. This improvement after several weeks was however not maintained though good effect was observed on increasing the dosage. This experiment is still being carried on.

It was noted that in pellagrins each individual varied very greatly in response to the same dosage and very differently to different dosage. The same was true of normal persons treated with nicotinic acid—the amount which will produce a reaction varies very greatly in different individuals and in the same individual at different times. In pellagrins there is an increased need for nicotinic acid with infection fever or exercise. The reactions to nicotinic acid were studied in normal individuals.

The flushing, tingling increased warmth etc are most marked on the ears and over the malar regions and neck, the flush is blotchy over the trunk and less marked over the abdomen and extremities. Circumoral pallor may be noticed. The perineal region and axillae may be affected—increased warmth sweating and itching. No changes in the tongue or mucous membranes have been noted. Nausea vomiting and abdominal cramps may occur but there is no constant deviation of pulse-rate blood-pressure respiration or electro-cardiogram. The reaction appears to differ from that produced by acetylcholine or histamine.

VILTER (Sue Potter) BEAN (William Bennett) & SPIES (Tom Douglas)
 Further Observations on the Effect of 2, 6-Dimethyl Dimicotinic
 Acid and Dimicotinic Acid on Pellagrins in Relapse and on Normal
 Persons.—*Southern Med Jl* 1938 Nov Vol 31 No 11
 pp 1163-1164

Experiments were made concerning the value of 2, 6-dimethyl pyridine-3, 5-dicarboxylic acid and 3, 5-pyridine dicarboxylic acid in the treatment of 9 pellagrins given in doses of 500 to 1,000 mgm per chem. Some improvement was observed in 5 cases these substances are of little use in the treatment of pellagra. It was also found that the physiological response as witnessed in the pellagrins and 2 controls differed from that of nicotinic acid in that there were no vasomotor reactions.

H S S

SPIES (Tom D) GRANT (Jean M) STONE (Robert E.) & McLESTER (James B) Recent Observations on the Treatment of Six Hundred Pellagrins with Special Emphasis on the Use of Nicotinic Acid in Prophylaxis.—*Southern Med J* 1938 Dec. Vol. 31 No 12. pp 1231-1237 {13 refs.}

Much has already been written upon the treatment of pellagra by nicotinic acid. The present article deals with the evaluation of the pellagra-preventive properties of this substance in persons who having had pellagra with relapse had remained in their usual surroundings on their usually grossly inadequate diet and in whom recurrence appeared imminent.

In 173 so selected persons treated with nicotinic acid no relapse occurred whereas the relapse rate in control groups was between 85 and 100 per cent.

The necessary dosage was found to vary very greatly. Three persons remained free of pellagra symptoms on 50 mgm daily two required 1 000 mgm. daily to keep them free. As the relapse season advanced so the dose had to be increased. The study was carried out in Birmingham and Jefferson City Alabama between 15th February and 1st September 1938.

In a few cases treatment was discontinued for 1-2 weeks with the prompt appearance of symptoms of subclinical pellagra.

A number of cases developed the polyneuritis of pellagra while under treatment which in turn responded to exhibition of vitamin B₁.

H S S

SCHMIDT (H. L.) Jr & SYDENSTRICKER (V. P.) Nicotinic Acid in the Prevention of Pellagra. A Preliminary Note.—*J Amer Med Assoc* 1938 June 18 Vol 110 No 25 pp 2065-2066

The authors thought it would be of interest to find out whether nicotinic acid is a potent substance in preventing relapse in pellagra. To this end were selected from a pellagra outpatient clinic 33 subjects who had had pellagra, and were showing signs of relapse on 9th March, 1938.

To sixteen, 100 mgm nicotinic acid were given twice a week. to the other seventeen, 90 gm. yeast daily were given as controls. The patients remained on their own home diet. Treatment was carried on for the period 16th March to 27th April. The control (yeast) group showed good general improvement though in most cases some glossitis persisted. Among those treated with nicotinic acid, with one exception though there was a rather dramatic improvement in the first two weeks, retrogression soon set in and their condition at the end of the experiment was as bad as at the beginning. The authors point out that the yeast besides containing specific factors also affords a considerable amount of nutriment.

1. ALPORT (A. Cecil) GHALIOUNGUI (P) & HANNA (G) Treatment of Pellagra with Nicotinamide.—*Lancet* 1938 Dec 24 pp 1460-1463

II. LANCET 1938 Dec. 24 pp 1473-1474 {13 refs.}—Treatment of Pellagra.

I. Fifteen cases of typical pellagra as it occurs among the Egyptian fellahen were treated with nicotinamide in ten, with nicotinic acid in

five while remaining on an ordinary diet. Great improvement was effected in the acute mucous membrane lesions and a slower improvement in the acute skin conditions was noted. Chronic skin lesions in friction areas and chronic atrophic changes in the tongue were only slightly affected. The appetite, mental condition and general physical health of all the patients were improved by the treatment, but gastric acidity never reappeared. Despite the excellent results obtained in the small series of cases the authors say —

While we feel satisfied that it is the most effective treatment we have yet tried, we could not confirm the brilliant results obtained after only 24-48 hours by some observers.

11 In the leading article a résumé of some of the papers on the subject which have appeared in the last two years [all of which have been summarized in this *Bulletin*] is given.

[The writer of the article unfortunately appears to lay stress on the pellagra producing action of maize which is a pity in view of the fact that maize *per se* is not the cause of pellagra. It is of course true as is pointed out that SWAMINATHAN (*Nature* 1938 Vol. 141 p. 830) has shown that while wheat contains 5.33 mgm per 100 gm of nicotinic acid and rice 2.4 to 2.8 mgm, white maize only yields 1.5 mgm.]

HARRIS (Leslie Juhus) The Vitamin B₃ Complex. VIII. Further Notes on "Monkey Pellagra" and its Cure with Nicotinic Acid.—*Biochem Jl* 1938 Sept. Vol. 32 No. 9 pp. 1479-1481 With 1 fig. [11 refs.]

Three experimentally produced conditions in animals have been considered as analogous to pellagra in the human being—canine "black tongue" so called "monkey pellagra" and what has been designated pellagra in pigs.

The present article supplements the author's preliminary paper of last year on "monkey pellagra." Monkeys kept on a basal diet resembling Goldberger's "black tongue" diet containing adequate

amounts of vitamins A B C and D develop deficiency symptoms consisting of loss of appetite diarrhoea vomiting loss of weight a pallor of the skin some loss of fur "jumpiness" and more marked emaciation ending fatally—symptoms which are referred to as 'monkey pellagra'. The exhibition of nicotinic acid produces dramatic improvement within two or three days in doses daily of 5 mgm for a monkey weighing 2 kgm. H S S

AZMY (Solman) The Treatment of Pellagra by Amino Acids. Report of Six Cases from the Post-Graduate Section Faculty of Medicine, Egyptian University—*Jl Trop Med & Hyg* 1938. Nov 15 Vol. 41 No 22. pp 357-362. With 14 figs.

To three patients with pellagra 1 ampoule of larostidine (Roche) was given intramuscularly daily for 22 days to 3 other patients histophan 2 ampoules daily for 22 days. It is stated that in all the rash had disappeared by the 21st day of treatment. In one case in which there was also diarrhoea that was also benefited. All or nearly all were suffering from urinary bilharziasis and ankylostomiasis.

It is suggested that in pellagra there is a deficiency of amino-acids and that in the present series cure was effected by the administration of two of them.

[It would obviously be unwise to make any deductions from the results now reported—the series is so small disappearance of the rash was the only criterion used in evaluating treatment after results are not mentioned and there were apparently no controls.] H S S

SPIES (Tom Douglas) GRANT (Helen M.) & HUFF (Nelwyn E.) The Antipellagric Effect of Certain Pyridine Compounds.—*Southern Med Jl* 1938. Aug Vol. 31 No 8 pp 901-902. [11 refs.]

An article reporting preliminary trials of some seven pyridine derivatives in pellagra from the University of Cincinnati and the Hillman Hospital Birmingham, Alabama.

The following substances were used Picolinic acid alpha and beta picoline trigonelline beta amino pyridine 2-6 dimethyl pyridine and di-nicotinic acid. The fifth and seventh substances had previously been isolated from liver extract by others.

The number of cases submitted to trial were very few and the period of trial very short. The authors however suggest that a number of pyridine derivatives may have a beneficial effect upon pellagrins in relapse. The 3rd 6th and 7th mentioned substances appearing to have some antipellagra effect. H S S

LEWIS (D R.) A Case of Pellagra Successfully Treated with Intravenous Injections of Sodium Thiosulphate.—*Indian Med Gaz* 1938 Oct. Vol. 73 No 10 p 616

The patient a Hindu male 20 years of age came under the author's observation presenting typical symptoms of pellagra rash and discoloration of arms and legs (starting on wrists and ankles two months before) and on the neck, and leukoplakia at the angles of the mouth. His diet was rice and dal. On admission to hospital the diet was left unchanged and the only treatment was injection twice weekly intravenously with 10 cc. of a 10 per cent solution of sodium thiosulphate.

Changes were soon observable—the blackened patches became brown and the brown erythematous and a few days later the pigmentation and erythema disappeared, though the parts first affected—feet ankles and elbows—remained rough. Appetite improved together with a general sense of well-being and “during treatment the patient gained 9 lb in weight. [Nothing is said as to the duration of the treatment.]

BERIBERI

PRÉCIS OF ABSTRACTS IN THIS SECTION

MEYERS (p. 558) describes two tests for the diagnosis of beriberi. The first is the development of or increase in, an audible sound in the cubital fossa after subcutaneous injection of adrenalin. The second and more important is the estimation of diuresis after the fasting patient has drunk 1 litre of water. Both tests should return normal results after the administration of aneurine. He shows (p. 559) that these tests are normal in simple polyneuritis and that the second test may be normal in that form of beriberi which is accompanied by transient oedema. This oedema is due to lowering of the tone of the walls of the arterioles and increased tension in the capillaries. Aneurine cures both oedema and nervous lesions in beriberi and oedema therefore probably has an intrinsic rather than an extrinsic origin.

GARRETT (p. 560) reports a child suffering from polyneuritis and fever who was cured after being given a vitamin B₁ preparation.

TOULLEC (p. 560) recommends the use in the East of rice so decorticated that it retains vitamin B₁ as in the parboiled rice of England and America. A diet for Indo-China containing the necessary 300 I.U. of B₁ is suggested. KIMURA (p. 560) also advises the use of rice from which part of the bran is removed but which retains the embryo. This rice is known as Hलगमल. C II

MEYERS (F M). Clinische onderzoekingen in verband met beriberi. [Clinical Tests for Beriberi].—*Geschied. Tijdschr v Nederl-Indië* 1938 June 28 Vol. 78. No. 26 pp 1537-1550 With 3 figs. [30 refs.] English summary

The heading of this first communication is “Two criteria for the diagnosis of beriberi. They are dependent on insufficiency of the circulatory apparatus and insufficiency of the water metabolism. The first of these criteria is the development of an audible sound in the cubital fossa with subcutaneous inoculation of adrenalin. If, as is frequent in pronounced beriberi, this phenomenon is already present over the large arteries, with in some cases “pistol-shot”

character the adrenalin test is superfluous. In any case adrenal injection should emphasize the phenomenon. The author however considers the second criterion named Volhard's diuresis proof the more important. This test consists in the fasting patient drinking 1 litre of water and a careful record of the diuresis every half hour for 4 hours. By this time or sooner a healthy person should have excreted all the water. Consideration of course must be given to the possibility of loss of water by sweating especially in the tropics. In both tests it is not sufficient simply to have a positive result. The tests must be completed by observing the restoration to normality with administration of aneurine (vitamin B₁). Many conditions with polyneuritis are at the present time regarded as allied to beriberi. It is possible therefore that the differential diagnosis between beriberi polyneuritis and polyneuritis of other—infecting toxic—sorts the question of the primary dry beriberi the question of neuritis or neuralgia and beriberi present popular between types of neuritis or neuralgia and beriberi the existence of a *beriberi sine beriberi* that is of the existence of the positive vascular test and the positive diuresis test in an individual having no symptoms of beriberi may be cleared up by the application of the method of testing here presented

H. F. Harvey

MEYERS (F. M.) *Clinische onderzoekingen in verband met beri-beri. [Clinical Investigations in Connexion with Beriberi.]—Geneesk. Tijdschr. v. Nederl. Indië 1939 Jan 3 Vol. 79 No 1 pp 3-16 [17 refs.] English summary*

The starting point of the above mentioned research is the opinion that an aneurine (vitamin B₁)-deficiency appears specifically under two distinct clinical syndromes: first, as a simple polyneuritis and secondly as a complex syndrome with polyneuritis, edema and disturbances in the function of (the heart and) blood vessels (beriberi). From this point of view investigations have been undertaken, concerning the significance of the edema in beriberi.

In most cases of simple polyneuritis complicating factors precede the nervous lesions—mostly infections. The same is not true for beriberi. Polyneuritis as a rule does not appear to be an early case of beriberi. With a purely anamnestic information it was not possible to discover any difference in dietary insufficiency between the two groups. Thus the distinction between polyneuritis and beriberi seems to be essential, rather than accidental.

In about half of the cases of polyneuritis without edema, heart trouble is also absent and in 92 per cent. of the cases of polyneuritis with edema heart trouble is present (DE LANGEN). Yet it is hardly possible to consider the edema in beriberi as of cardiac origin only.

The vascular syndrome after an injection of adrenaline that is typical for beriberi (AALLENKER) is absent in the majority of polyneuritis cases and VOLHARD'S diuresis test has a normal course in these cases. Meanwhile the last named test may have the same result in beriberi, in which the edema is of a pronounced transient character. These transient edemas represent probably the simplest and purest picture of the beriberi edema. They are of a hydrostatic nature and seem to be caused by a lowering of the tonus of the arteriolar walls and thus by an increased tension in the capillary system.

Thus the problem of the beriberi edema must be concerted into the question of this circulatory failure. It is unknown why this failure appears in only a certain group of cases with aneurine deficiency. But, since

treatment with aneurine cures the edema as well as the nervous lesions, it seems probable that the first has an intrinsic, rather than an extrinsic origin.

[See also WENTKEBACH this *Bulletin* 1935 Vol. 32, p. 79.]

GARRETT (E. B.) Polynuritis with Oedema simulating Beriberi. [Memoranda.]—*Brit Med J* 1938, Aug. 6, p. 287.

The case of a child of 4 years exhibiting polynuritis with fever. The cause was not ascertained, and the child a diet was a normal mixed diet with no indications of vitamin B₁ deficiency. Improvement followed the parenteral administration of Betanin (vitamin B₁), otherwise there is no obvious reason for regarding it as a case of beriberi, and the author clearly recognizes this in the title of his record.

H H S

TOULLEC La prévention du bérubéri. [The Prevention of Beriberi.]—*Rev Méd Française d'Extrême-Orient*, 1938, Feb. Vol. 16, No. 2, pp. 108-119 [Summary appears also in *Bulletin of Hygiene*].

This is a discussion of the conditions leading to the prevalence of beriberi in the East. The chief factors are the very high proportion of carbohydrates in the diet and the low vitamin B₁ intake. It appears to be impossible to persuade the native to use unpolished rice as he objects to the taste and states that it does not satisfy hunger. The author recommends the use of rice decorticated in such a way that the vitamin B₁ is left in the rice. This is done in what is called in America and England "parboiled rice." The increased production and use of vegetables would help to increase the B₁ supply. The daily requirement of B₁ is believed to be about 300 International Units. 100 I U are contained in 200 gm. spinach, white cabbage, carrots, peas, cress, leeks and salads and in 400 gm. potatoes, 160 gm. meat, and in 400 gm. of milk. A diet is suggested which would meet the body's needs and, though difficult to attain, would not be actually impossible in Indo-China.

KIMURA (T.) The Problem of abolishing the Use of Highly-milled Rice with Reference to the Merit of "Halgamai" (Rice so milled as to retain Embryo-Bud).—*Jl. Public Health Assoc. Japan* 1938, Aug. Vol. 14, No. 8, pp. 1-8.

The author strongly advises the wider consumption of "Halgamai," i.e., rice which has been milled so that some of the bran which is digested with difficulty is removed but in which the embryo which contains large amounts of vitamin B₁ is left. This rice is more easily digestible and more pleasant to the taste than unpolished or half-milled rice. Because of the prevalence of beriberi and latent B₁ avitaminosis he recommends abolition of consumption of polished rice by legislation, education of rice dealers, urging of authorities responsible for feeding the army and navy etc., to use Halgamai as a means of increasing the B₁ consumption of the people.

VENOMS AND ANTIVENENES

PRECIS OF ABSTRACTS IN THIS SECTION

Snakes —JOHNSON (p 563) describes a method for stripping snakes by the application of an electric current which causes contraction of the muscles surrounding the glands.

DURAN REYNALS (p 563) shows that spreading factor is markedly present in venom and that the strength of the factor and the toxicity of the venom are closely correlated.

FELDBERG and KELLAWAY (p 564) record experiments on the action of alcoholic extract of envenomed liver lysocithin and cobra venom which cannot be further abstracted. FELDBERG HOLDEN and KELLAWAY (p 565) show that the close similarity between the effects of lysocithin and those of venoms is explained if the venom causes the formation of lysocithin in certain tissues. Lysocithin is haemolytic its other effects are given in full in the original abstract.

ROY and CHOPRA (p 566) compare the properties of cobra and Russell's viper venoms and ROY (p 566) has investigated their lipolytic actions. There is a close parallelism between the lecithinase activity and haemolysin formation in the presence of lecithin.

VON KLOBUSITZKY and KÖNIG (p 566) regard as haptens the coagulating constituents of the venom of *B jararaca* after separation from their natural binding substances.

CASTELLANI (p 567) from experiments with snakes whose poison glands had been extirpated, and whose blood thereafter showed increasing venom content concludes that venom is a product of tissue metabolism and that one function of the glands is to extract it from the blood.

FABBRI (p 567) obtained good results from the use of cobra venom as an analgesic in 20 patients with various diseases. KELLY (p 568) successfully treated patients with herpes simplex by intradermal injections of the venom of *Ancistrodon piscivorus*.

DE AZEVEDO and TELXEIRA (p 568) regard the diffuse glomerulonephritis with proliferative endarteritis found in a child who died 26 days after being bitten by *B jararaca* as the result of the slow action of the venom, which is excreted by the kidneys.

KELLAWAY (p 568) gives the properties of the venoms of the principal Australian snakes, with symptoms of poisoning and methods of treatment. SCORTECCI (p 570) records the case of a man in Ethiopia who died 7 hours after being bitten by *Dendraspis angusticeps* in spite of immediate ligation of the limb scarification, the introduction of potassium permanganate and, later suction.

Spiders—DOXONOFF (p. 570) shows that an increase in the number of Black Widow spiders found in the raisin vineyards of the San Joaquin Valley has taken place since the introduction of paper trays for the drying of the grapes. The spiders prefer these to the old wooden trays as shelter.

D'AMOUR *et al* (p. 571) found that adult *L. mactans* contain about one lethal dose of venom for immature rats. The venom is probably an albumin and produces a potent antiserum in sheep after continued injection of sublethal doses. In the *Journal of the American Medical Association* (p. 571) emphasis is laid on the late effects of poisoning by *L. mactans*. Paraesthesiae and muscular spasms are not infrequent, but may be in part due to autosuggestion.

Scorpions—SHULOV (p. 571) shows that a scorpion can give six effective stings in a short time. There is a difference between the amount of poison of satiated and hungry scorpions. Various factors of age, nutrition, etc., which influence the power of a sting should be considered in evaluating findings.

WATERMAN (p. 572) records a death rate of 4.7 per cent. in scorpion poisoning, the mortality reaching 25 per cent. in children under 5 years. Death may occur in from 1½ to 42 hours. The symptoms are described and treatment discussed.

MEDULLA (p. 573) gives a list of scorpions of Cirenaica. The symptoms of poisoning by *Buthus bicolor* which persisted for more than three months in one patient, are described. SERGEANT (p. 573) shows that the sting of *Priocnemis australis* in North Africa may be fatal to children and old people. The preparation of antivenene is described and its value demonstrated by records of treated patients.

MONY (p. 574) attributes a syndrome of hemiplegia observed in a child to the sting of a scorpion. BARROS (p. 574) describes the symptoms caused by the sting of the scorpion *T. serrulatus*. In serious cases serum should be given early in 40 cc. dose for adults and 80 cc. dose for children, repeated if necessary.

FLECKER (p. 575) records scorpion sting in five patients in Australia. It appears to be probable that the venom of Australian scorpions is less toxic than that found in other countries, as all these had only slight symptoms.

Tick paralysis—BARRETT (p. 575) describes the symptoms of tick paralysis. The ticks responsible are *D. andersoni* in America and *I. holocyclus* in Australia. Symptoms are those of ataxia and muscular weakness leading to respiratory paralysis, and suggest a lesion of the anterior cornu, but recovery usually takes place rapidly on removing the tick. It is suggested that the tick produces excessive egg venom and excretes it by the over-active salivary glands. GIBBS (p. 576) describes a case and arrives at similar conclusions. MAIL (p. 577) shows that over 150 cases have been recorded and that sheep, cattle and horses are attacked. He agrees that *D. andersoni* is chiefly responsible. ROBINSON and CARROLL (p. 577) show that *D. variabilis* is also capable of causing the disease and describe a case from Georgia, U.S.A.

Ants—WEBER (p. 578) records the intense local reaction he experienced as a result of being stung by the ant *Paraponera clavata* Fabr. Vesiculation occurred with intense pain and temporary paralysis of the limb. It is said that multiple stings may prove fatal to man.

SABINO (Santos Carrasquel) Notas sobre ophidismo [Notes on Herpetology]—*Brasil Medico* 1938. Oct. 22. Vol. 52 No 43 pp 962-971 With 5 figs & 8 photos. [15 refs.]

This is a brief sketch of snakes pointing out some of the distinctions in the skull and teeth formation between poisonous and non poisonous snakes, and describing some of the latter and methods of catching them for obtaining venom together with a few remarks on indications for treatment.
H H S

BOURRET (René) Les serpents venimeux en Indochine. [Venomous Snakes of Indo-China.]—*Rec Méd Française d'Extrême-Orient* 1938. May Vol. 18 No 5 pp 485-487 With 12 figs.

This is a brief account of the common venomous snakes of Indo-China. The snakes are described and shown in illustrations and mention is made of the action of the venoms and of the treatments usually adopted. No new work is recorded and the article cannot satisfactorily be abstracted but is a useful guide to the subject.
C IV

PASQUAL (J R. H.) Field Guide to the Commoner Colubridae and Viperidae—*West African Med J* 1938. Oct. Vol. 10 No 1 pp 38-39

JOHNSON (Carl M.) A New Method for stripping Venomous Snakes.—*Amer J Trop Med* 1938. July Vol. 18 No 4 pp 385-396

The usual method of manual manipulation for the evacuation of the venom glands is often accompanied by injury which interferes with subsequent function. Contraction of the muscles surrounding the glands can be obtained by the application of the active electrode of a five to ten volt induced current to the side of the head behind the eye and of the indifferent electrode to any part of the body. The exact position of the active electrode must be determined by experiment but in certain snakes a point about midway between the eye and the back of the head at the upper limit of the upper labials is the best. The active electrode is a wooden handle into which is inserted a piece of glass tubing carrying a copper wire which is looped at the end and covered with several thicknesses of gauze. The indifferent electrode consists of coiled wire inserted into a sponge.

The interval between such venom extractions should be not less than two weeks.
C IV

DURAN REYNALS (F.) Content in Spreading Factor and Toxins in Organs and Poisonous Secretions of Snakes.—*Proc Soc Exper Biol & Med* 1938. June Vol. 38. No 5 pp 763-766

The spreading factor though it exists in practically all mammalian tissues as well as in those from other zoological groups is most active in cell secretions. Therefore the living cells may only be potential sources of the factor the activity of which does not become manifest until the secretion itself has undergone some change.

The potency of the spreading factor in venom, blood serum and tissue extracts was determined in four poisonous and two non poisonous species of snakes. In three of the experiments with poisonous snakes

the venom gland was cut and thoroughly washed before extraction to remove all traces of the secreted venom. The venoma, sera and tissue extracts were mixed with India ink a control of saline and India ink was used, and a mixture of the venom, etc. with saline in place of the ink served to show the severity of the lesions uncomplicated by the ink. The table of results shows that the factor is only present in the washed glands in the same proportion as in the other tissues. It is markedly present in the venom and there is a close correlation between the strength of the factor and the toxicity of the venom. Both the factor and the venom are therefore products rather than components of the gland cells. The serum of snakes shows some activity while that of mammals is practically inactive [See also CASTELLANI below]

FELDBERG (W) & KELLAWAY (C H) Liberation of Histamine and Formation of Lysocithin-like Substances by Cobra Venom.—*Jl Physiology* 1938, Nov 14 Vol 94 No. 2, pp 187-226. With 30 figs. [22 refs.]

Cobra venom contains a lecithinase which splits off oleic acid from lecithin. The remaining portion, lysocithin, is powerfully haemolytic. Crude lysocithin was prepared by the action of cobra venom on egg lecithin and this, without any attempt to prepare pure lysocithin was used in the experiments, of which full details are given. The conclusions cannot be better expressed than in the authors own words —

"1 The injection of cobra venom (3-20 mg) into perfused organs (lung, liver) of dogs and monkeys causes the appearance in the venous perfusate of histamine or protein and of a substance or substances which cause slow contraction and transient changes in the excitability of the guinea pig's gut. In the case of the liver pigments are also set free. No histamine appears in the perfusate of envenomed monkey's liver since this organ has a very low histamine content. The changes in the venous perfusate from the liver of dogs poisoned by intravenous injections of cobra venom are similar to those observed when the venom is injected into the isolated organ.

2 Histamine protein and liver pigments are *liberated* from the cells of perfused organs, but the substance (or substances) which causes slow contraction of the gut and subsequent changes in its reactivity is *formed* in the organs by the action of the venom.

3 This substance is present in large amounts in extracts of envenomed organs. It is soluble in absolute methyl alcohol and heat stable. Pharmacological actions of alcoholic extract of envenomed monkey's liver ('envenomed liver') have been compared with those of cobra venom and of extract of lecithin treated with venom ('lysocithin').

4 Envenomed liver and lysocithin cause slow delayed contraction of the guinea pig's jejunum and characteristic after-changes in reactivity to histamine and to acetylcholine. The effects of cobra venom are similar but in this case the muscle is readily desensitized.

5 Envenomed liver, lysocithin and cobra venom contract the rat's jejunum, the normal guinea pig's uterus and the uterus poisoned by histamine. In the case of cobra venom the preparations are readily desensitized.

"6. On the isolated cat's heart, lysocithin causes changes in coronary circulation and strong reduction in the force of the beat. rapid failure occurs and the heart ceases to beat in diastole or in mid-position. Extracts of normal monkey's liver which by themselves have no action, protect

from the action of lysocithin and if the protection is not complete a gradual failure occurs similar to that caused by envenomed liver. Cobra venom (2-4 mg) causes rapid failure and systolic contracture of the heart.

7 Injected into the anterior chamber of the rabbit's eye envenomed liver lysocithin and cobra venom cause opacity of the cornea and irregular alterations of its curvature. Extracts of normal monkey's liver are without effect.

8 Injected intravenously into guinea pigs envenomed liver and lysocithin cause symptoms resembling acute anaphylactic shock with the addition of haemorrhagic oedema of the lungs.

9 Washed sheep's red corpuscles are immediately haemolysed by envenomed liver and lysocithin but not by cobra venom nor by extract of normal monkey's liver. The latter has a protective action against haemolysis by lysocithin.

10 Envenomed liver and lysocithin injected into the perfused dog's liver cause output of protein, histamine and pigments. With repeated injections the output of histamine increases. These effects are closely similar to those produced by repeated injections of small doses of cobra venom.

C H

FELDBERG (W) HOLDEV (H F) & KELLAWAY (C H) The Formation of Lysocithin and of a Muscle-stimulating Substance by Snake Venoms.—*Jl Physiology* 1938 Vol 14 Vol 94 No 2. pp 232-248. With 11 figs.

In this paper the authors record investigations on the pharmacological activity of purified lysocithin. The previous paper (see above) dealt with the crude substance.

Lysocithin is haemolytic in concentrations up to 1 in 6400 but has no action on guinea pig's gut. It

causes decreased excitability of the isolated jejunum and contraction of the uterus of the guinea pig, opacity of the cornea if injected into the anterior chamber of the rabbit's eye and haemorrhagic oedema of the lung when injected intravenously into the intact guinea pig. It causes the liberation of protein pigments and histamine from the perfused liver of the dog and of protein and pigments from the perfused liver of the monkey. In the cat and dog it causes a steep fall of systemic blood pressure which in the former is associated with a rise of pressure in the pulmonary artery and haemorrhagic oedema of the lung and in the latter with a rise of pressure in the portal vein. Injected into the femoral artery of the dog it causes evanescent vasodilatation. These effects resemble those produced by venoms.

Lysocithin and a gut stimulating substance are formed by the action of venom on lymph egg yolk or lecithin *in vitro* and also in the tissues by the action of venom on perfused organs. The mode of formation of the gut stimulating substance is unknown.

The close similarity between the effects of lysocithin and those of venoms is easily explained if the venom causes the formation of lysocithin which in some instances acts not only alone but also by the liberation of histamine. No desensitization occurs against the action of lysocithin. Desensitization against venom therefore must be accounted for by failure to produce further lysocithin in response to a second dose of venom.

No investigation was made as to whether or not lysocithin plays a part in producing neurotoxic manifestations.

C H

ROY (A. C.) & CHOPRA (R. N.) Some Biochemical Characteristics of Snake Venom.—*Indian Jl Med Res.* 1938. July Vol. 26 No 1 pp 241-248.

A comparative examination of cobra and Russell's viper venoms showed that the former contains less albumin and more pseudoglobulin than the latter but has no englobulin which is present in the viper venom. Neither shows diastatic action or the capability of inverting saccharose. Both digest fibrin, liquefy gelatine, clot milk and digest casein, but the viper venom appears to be more active than the cobra venom in proteolytic action. Lipolytic action could not be determined on account of the faulty technique employed. Cobra venom is haemolytic in varying degrees for the susceptible species of erythrocytes but viper venom is non-haemolytic in the large majority of cases.

C IV

ROY (A. C.) Lipolytic Activity of the Venoms (Cobra and Russell's Viper).—*Indian Jl Med Res.* 1938. July Vol. 26. No 1 pp 249-257 11 refs.]

The lipolytic action of cobra and viper venom which was not determined in the work of ROY and CHOPRA above is reported in this paper. Neither venom has any action on an emulsion of olive oil, but cobra venom acts energetically on ethyl butyrate. The esterase and haemolytic activities, however are not parallel since the former is destroyed by heating the venom to 58°C. for half an hour while the latter is not appreciably affected. Both venoms act on lecithin by splitting up fatty acids, but the viper venom appears to have the stronger action. The venom lecithinase is very stable even to boiling for 15 to 20 minutes, but autoclaving entirely destroys it.

There is a close parallelism between the lecithinase activity and haemolysin formation in the presence of lecithin. With an emulsion of cholesteryl oleate, cobra venom showed appreciable lysis of the emulsion, and viper venom a flocculation but neither could split up the emulsion.

C IV

VON KLOBISITZKY (D.) & KÖNIG (P.) Novos estudos immunologicos sobre a substancia coagulante do veneno de *Bothrops jararaca*. [New Immunological Studies on the Coagulating Substance of the Venom of *Bothrops jararaca*].—*Mem Inst Butantan* 1937 Vol. 11 pp 149-181 English summary

Two sera obtained from goats immunized with a solution of *Bothrops jararaca* venom previously purified by means of fractionation and adsorption with $\text{Cr}(\text{OH})_3$, showed a certain capacity of fixation although the purified antigen used possessed a higher coagulating power and a lower neurotoxic activity than the original poison.—

1. They neutralized more completely both the neurotoxic constituents of the natural poison (*Bothrops jararaca*) and the coagulating fraction extracted from it than its original coagulating activity.

2. They failed to neutralize the original coagulating activity of the rattlesnake poison (*Crotalus terrificus*).

In the light of these findings it seems that the coagulating constituents of those snake poisons, after separation from their natural binding substances, should be considered as haptens.

CASTELLANI (Giovanni Tarabini) II Nota sullo studio dei rapporti fra la tossicità del sangue in toto di *Vipera aspis* e quella della secrezione ghiandolare del veleno [The Resemblance between the Toxicity of Whole Blood and Poison Gland Secretion in *Vipera aspis*].—*Arch Ital Sci Med Colon e Parassit* 1938 Apr Vol. 19 No 4 pp 223-228

The author quotes the findings of PRISALIN and BERTRAND who considered that the venom of *Vipera aspis* is formed by some kind of internal secretory mechanism, and who found that the toxicity of the whole blood after extirpation of the poison glands was diminished for a period of one to two months after which it slowly returned to normal. With this finding the author's present work does not agree.

Using for his experiments specimens of *V. aspis* which were (unavoidably) in bad condition he extirpated the poison glands of a number of which 8 lived long enough to be of use (10 to 18 days). Eight others with glands left intact were used as controls. Whole blood was withdrawn from all these and dilutions with 0.9 per cent NaCl were made as follows —

	I	II	III	IV	V	VI
0.9 per cent. NaCl	0	0.167	0.278	0.348	0.393	0.433
Whole blood	0.5	0.333	0.222	0.152	0.107	0.067

Mice of 18 gm weight were inoculated intraperitoneally with 0.5 cc. of these dilutions. All the mice inoculated with I and II from both gland-extirpated and control snakes died within 16 hours but whereas all mice in the extirpated group inoculated with III died only 2 of the controls died (within 25 hours). Signs of intoxication were found with IV and V and in the extirpated group in 13 cases but only in 8 cases in the control group. The remaining mice were unharmed.

It was also seen that the blood of snakes whose glands had been extirpated 18 days before the experiment was more toxic than that of the 12 day snake. A longer period than 18 days was impossible on account of the bad condition of the snakes.

The author therefore concludes that after extirpation of the glands an increase in the toxicity of the blood is evident on the 12th day and more evident still on the 18th day. He concludes that venom is a product of tissue metabolism and that one function of the poison glands is to extract it from the blood. He does not claim this experiment to be a final proof but thinks the results might be even more striking in a warm climate using snakes which are in good condition. C W

FABRI (Giuseppe) Azione terapeutica del veleno di cobra. [Therapeutic Uses of Cobra Venom].—*Polisimico Sez. Med.* 1938 May 1 Vol 45 No 5 pp 256-268

Snake venom has been employed for haemophilia for haemorrhage after dental extraction and for epistaxis and also for neuralgias and other painful conditions such as cancer tabetic crises leprosy rheumatism and for epilepsy. Good reports have been issued under each of these headings but the venom used has generally been that of Daboia (*Vipera russellii*).

The author of this article has employed cobra venom [he does not mention the species] a colubrine and gives brief details of twenty patients six of nerve-root affection five of carcinoma (three of stomach and one each of uterus and rectum) two of sciatica, two of trigeminal neuralgia, and one each of five other conditions four neuralgias and one tabes. He started by injecting 1/25 mgm. and after three or four doses in the course of 10-14 days, increased to 1/10 mgm. In nearly every case much relief was obtained from 7-8 injections and in some even earlier. There were no indications of the toxin being cumulative and in the author's hands it proved a very serviceable analgesic. [The method of employment the site of injection etc. are not stated.] H H S

KELLY (Richard J.) Treatment of Herpes Simplex with Moccasin Venom.—*Arch Dermat & Syph* 1938. Oct. Vol 38. No 4 pp 599-602.

Fifteen patients with herpes simplex were treated, when possible in the incipient stage with moccasin [*Anacardion parvum*] venom by intradermal doses of 0.2 cc. of a 1 in 3 000 dilution. In some cases one injection was enough but one patient was given two injections on successive days. The symptoms were usually relieved and the course of the eruption materially shortened and the number of recurrences appears to have been decreased. Three patients with herpes zoster reported relief of symptoms following this treatment but the course of the disease appeared to be unaltered.

Attempts to influence the virus directly by the use of moccasin venom 1 in 3 000 dilution in experiments on rabbits were unsuccessful. [See also this *Bulletin* 1936 Vol 33 p 394.] C II

DE AZEVEDO (A. Penna) & TEIXEIRA (J. de Castro) Intoxicação por veneno de cobra. Necrose symetrica da cortex renal. Uremia. [Poisoning by Cobra Venom. Symmetrical Necrosis of the Renal Cortex.]—*Mem Inst Oswaldo Cruz* 1938 Vol 33. No 1 pp 23-37 With 8 plates [10 refs.] English summary

A child of 15 was bitten by *Bothrops jararaca* on the leg and died 28 days later. The principal pathological changes were found in the kidneys and consisted of diffuse glomerulo-nephritis and symmetrical cortical necrosis. Proliferative endarteritis was present and probably accounted for the necrosis. The endarteritis was progressive but was not accompanied by thromboses.

The authors consider that the renal changes were the result of the slow and prolonged action of the venom which is eliminated by the kidneys. The blood showed haemoglobin down to 11 per cent. and red cells to 960 000. Renal insufficiency was shown by increase in the blood nitrogen, creatinin, inorganic phosphorus and indican, but the patient did not present the clinical evidence of azotaemic nephritis. C II

KELLAWAY (C. H.) The Symptomatology and Treatment of the Bites of Australian Snakes.—*Med J Australia* 1938 Oct. 8 25th Year Vol 2. No 15. pp 585-589

From the descriptions given by the author the pharmacological properties of the venoms of Australian snakes may be shown in general terms as a table [constructed from the text by the reviewer] —

	Neurotoxic	Haemolytic and cytolytic	Coagulant
<i>Notechis scutatus</i> (Tiger snake)	+++	+	+++
<i>Acanthophis antarcticus</i> (Death adder)	+++	+	0
<i>Demisonia superba</i> (Copperhead)	+++	+++	0
<i>Demansia textilis</i> (Common brown snake)	+++		+++
<i>Pseudechis porphyriacus</i>	+	+++	+++
<i>Oxyuranus scutellatus</i>	+++	+	++
Snakes of genus <i>Hoplocephalus</i>	+++	+	

Neurotoxic action is a paralysis of both sensory and motor nerve endings but there is also a possible central action. The haemolytic and cytolytic action results in the liberation of histamine and causes symptoms of cardio-vascular failure. The coagulant action causes intravascular clotting and if in large doses may do so in the inferior vena cava and the portal and mesenteric veins with death in a few minutes.

The symptoms of onset may occur in 15 minutes to 2 hours and are usually nausea vomiting faintness and drowsiness. Symptoms of neurotoxic origin are incoordination blunted sensation paresis of various muscles including the tongue and diaphragm, and coma. General features may include albuminuria and haemorrhages the latter due to coagulant venom.

Symptoms may appear relatively slowly so that death usually takes place at about 48 hours after the bite but if the venom is injected into a vein or if a large amount is injected death may occur in a few minutes. A feature of bites by brown snakes is that sometimes there is a long period of freedom from symptoms after the first 24 hours with death from respiratory failure 36 or 48 hours or more after the bite.

Treatment, If a limb is bitten consists of immediate ligature proximal to the bite to stop arterial flow of that portion of the limb which contains only one bone. The bite should be washed immediately with saliva or urine if necessary. Excision or cutting should be performed but are only valuable in the first few minutes. The flow of blood can be assisted by suction and should be encouraged by occasional release of the arterial ligature after a venous ligature has been applied in addition to prevent entry of venom into the general circulation. Local venesection may be performed, using the two ligatures but is only valuable if an efficient arterial ligature was applied at once.

Monovalent tiger snake antivenene is useful but has no action in brown snake or death adder bites. The dose is 60-100 cc. intravenously. It is wise to perform an intradermal test with 0.1 cc. and if there is any reaction desensitization should be performed as follows: 0.025 cc. subcutaneously one hour later 0.1 cc. subcutaneously one hour later 1.0 cc. subcutaneously one hour later 0.1 cc. intravenously. If the last does not cause allergic symptoms the full dose diluted to 1 in 5 should be given slowly at body temperature into a vein. Treatment of allergic symptoms is by immediate cessation of the serum injection and the administration of atropine or adrenalin.

The patient should be kept at rest and given black coffee or possibly strychnine. C W

SCORTECCI (Giuseppe) I "Mamba" dell'Africa Orientale Italiana [The "Mamba" in Italian East Africa.]—*Riv di Biol Colon* Rome. 1938. Apr. Vol. 1 No. 2. pp 81-90 With 2 fig English summary (6 lines)

The author gives a brief account of the "mamba" *Dendraspis*, a deadly snake met with in Ethiopia (and elsewhere in Africa). There are two species at least, the green and the black, but both are here called *Dendraspis angusticeps*. An instance is detailed which illustrates the potency of its venom. One of a hunting party, a man (21 years of fine physique and unusually robust) was bitten on the foot by a mamba at 3 p.m. Assisted by one of his companions ligatures were applied immediately, one above and one below the site of the bite [the actual location of the wound is not stated, hence we do not know how a ligature was applied below a wound of the foot], the wound was scarified and crystals of potassium permanganate introduced. A little later another ligature was applied above the knee and a fourth to the thigh. On arrival at camp the man was put to bed, suction applied to the wound and stimulants given. For a time his condition appeared to be satisfactory, then diarrhoea set in with spasmodic contractions of the muscles of the throat. By 9 p.m. he was unable to speak and at 10 p.m. died from respiratory paralysis "the poison reaching the respiratory centre." In spite of prompt application of tourniquets and local treatment, a healthy robust adult was killed in 7 hours. A plea is made for inclusion of antivenene for *Dendraspis* in the sera for Naja, Bitis, Echis and other local snakes. H H S

PHISALEX L'immunité naturelle des espèces venimeuses et ses mécanismes [Natural Immunity of Venomous Species and its Mechanism.]—*Bull Acad Afric* 1938 May 3 102nd Year 3rd Ser No 119 No 17 pp 464-474

DONOHUE (Heber C) Notes on the Black Widow Spider in the San Joaquin Valley [Research Notes.]—*Jl Parasitology* 1937 Aug Vol 23 No 4 p 424

This is an interesting explanation of the recent increase, apparently certainly and actual probably of *Latrodectus mactans* in the San Joaquin Valley, California, especially in and about farm buildings in raisin vineyards. The grapes used to be dried on wooden trays, stacked in piles, but of late these have been replaced by folded paper trays left on the ground. These are a favoured shelter for the Black Widow spider which thrives on the larvae of the raisin moth *Ephestia figulidella* which enters the trays in numbers for egg-laying, and the trays of folded paper offer better concealment for the spider than do the wooden trays. In 1933 no spiders were found in 200 wooden trays in two places but 29 in 1 100 paper trays from ten different crops. Some 36 million papers were used altogether so that it is estimated that there were about 836 000 of these spiders and in many trays webs were found but no spiders, these having probably escaped during the handling of the trays. Further raisins from wooden trays are found in the vineyards, whereas a large proportion of the paper

trays are hauled to the farmyards for boxing and the spiders enter outbuildings wood piles and other shelters and so are found in increasing numbers in and about the farm buildings H H S

D AMOUR (Fred E.) BECKER (Frances E.) & VAN RIVER (Walker)
The Black Widow Spider—*Quart Rev Biol* 1937 Vol. 11
No 2. pp 123-160 With 5 figs. [Summarized in *Biol Abstracts* 1937 Aug-Oct Vol. 11 No 7 p 1872.]

Numerous observations on the natural history of the black widow spider (*Latrodectus mactans*) including distribution habitat, temperament, reproduction development, and means of dispersal. Plates show the sex differences and several stages in the development of the ♀. The second part of the paper is devoted to a study of the venom, its toxicity and chemistry and of the development of immunity toward it. Similar studies were made of the toxic substance of the eggs. Finally assays of the hyper immune sheep serum produced by the E. R. Squibb and Sons Company are recorded. The more important experimental results are summarized. The average lethal dose for immature rats is 0.32 mg. of dried venom which is about $\frac{1}{4}$ the amount present in an adult ♀ spider. Chemical evidence indicates that the venom is a protein, probably an albumen. Injection of sub-lethal doses over a period of time into rats or sheep gives a potent anti-serum, about 25 A.L.D. of venom being neutralized per c.c. None of the antidotes studied was effective. No pathologic abnormalities in rats kept chronically intoxicated could be discovered. About 6500 spiders and 500 rats were used in this investigation.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION 1937 July 31
Vol. 109 No 5 p 331—Black Widow Spider Bite [Queries
& Minor Notes.]

The symptoms of poisoning from the bite of the Black Widow spider *Latrodectus mactans* may be very severe [see this *Bulletin* 1936 Vol. 33 pp 401-403]. The question of late effects however has not often come under discussion. The author of this note mentions the case of a man of 35 years who was bitten and presented the usual symptoms but was not recovered sufficiently to cease treatment by his physician for four weeks. Although six months had elapsed since the bite was inflicted the patient still complains of cramps in the arms and abdominal muscles and of a degree of weakness which prevents him working. Paraesthesiae numbness tingling and transient muscle spasms are not infrequent sequelae of spider-bite but recovery is usually complete and the severity of these after effects appears to depend not a little upon the autosuggestibility of the subject.

SHULOV (A.) On the Poison of Scorpions in Palestine.—*Harefuah*
1938 July-Aug Vol. 15 No 1-2. [In Hebrew English
summary pp 1-2.]

Experiments with scorpions and with extracts of their stings led to the following conclusions —

1. Of the five species experimented with, *Buthus 5-striatus* is the most poisonous. The degree of venom of the other species falls gradually in the following order: *Prionurus bicolor* Nebo *Buthus judaicus*, *Scorpio maurus*.

* 2. Of the five ages of *Buthus 5-striatus* which were experimented with, the three older ones are the most poisonous. The degree of venom of the two younger ages, up to the length of about 2.5 cm. reaches, according to its influence, half of that of the older ones. The analysis of the contents of the gland showed that the amount of venom of the youngest ages is $\frac{1}{3}$ of that of the older ones.

3. Comparative experiments made as to the variability of the influence of the venom during the various hours of the day in different temperatures and seasons showed that there are no differences in the degree of influence in a temperature of 10°C . and above neither in the different hours of the day nor in the various seasons. It was established that under the conditions of this country there is no interruption of activity in the winter and the multiplication of the scorpions is not connected with any season in particular.

4. The estimation of the effective amount of poison excreted from the gland at the same time of the day and season showed that the scorpion, be it even the youngest, can give 6 effective stings, following which the poison becomes weaker, probably due to reduction taking place in the concentration of the excreted poison. There is quite a difference in the amount of poison, both in the gland and as estimated from the bites, of satiated and hungry scorpions.

* 5. The factors effecting a change in the degree of venom depending on the scorpion are very numerous and the following were established with certainty: the species of the scorpion, its age, its state of nutrition, the number of stings it has stung a short time preceding the experiment, the state of the tip of the sting.

"The conditions depending on the animal experimented with are the toughness of the skin at the spot it was stung, whether the body is hairy or not, the proximity of blood vessels to the bitten spot, the general health conditions (perhaps also a special constitution).

"All the above named factors are bound to make the influence of the sting very manifold and also give rise to contradictory opinions originating from unlike individual experiments.

WATERMAN (James A.) Some Notes on Scorpion Poisoning in Trinidad.—*Trans Roy Soc Trop Med & Hyg* 1933. Apr 20 Vol. 31 No 6 pp 607-624 [14 refs.]

The incidence of poisoning by scorpions in Trinidad is uncertain because only severe cases come under medical observation. Most occur between Couva and Siparia in the cane-fields of the south or the cocoa plantations of the north-east: they often lurk in shoes and clothing. In the five years, 1929-33 there were at one hospital in a cane-growing district 698 cases admitted, 189 in the last year and 33 deaths or 4.7 per cent. 13 of them in the last year. The fatality rate as one would expect is greatest in the very young: of 16 under one year six died, and up to the age of 5 years (83 cases, 22 deaths) the rate was 25 per cent. between 6 and 10 years (96 cases, 5 deaths) 5.2 per cent. in the second decade 5 fatal among 190 cases or 2.6 per cent. of 324 over 21 years of age only one died. Death might take place at any interval from $1\frac{1}{2}$ to 42 hours.

The symptoms are burning pain, usually lessening in 15 minutes; the patient feels sick and presents salivation, nausea and vomiting with profuse sweating. The vomit may be dark coffee-ground in colour. Respirations may be as rapid as the pulse, but though there is dyspnoea there is never cyanosis. Reflexes are increased. In infants and children convulsions are common and in such cases the prognosis is bad. In half the cases there is glycosuria.

Excretion may occur in poisonous amount in the milk and the author refers to the case of a woman being stung shortly before nursing her child. The latter showed symptoms of scorpion poisoning and died. A similar condition has been recorded after snake-bite.

At autopsy all the viscera are congested the lungs are oedematous (due probably to cardiac failure) and small subserous and submucous haemorrhages are visible. The pancreas may show haemorrhages and pancreatic cyst has been found at intervals of varied length afterwards.

Treatment used to be by potassium permanganate intravenously but this has been given up. Some now give 2 cc of 0.25 per cent. colloidal manganese intramuscularly repeated if necessary and have reported good effects. Others give glucose 10 per cent rectally or 3 per cent subcutaneously followed by insulin. Treatment otherwise is symptomatic. Brief details of eight cases are recorded.

MEDULLA (Candido) Sugli avvelenamenti da puntura di scorpione in Cirenaica [Scorpion Poisoning in Cirenaica.]—*Arch Ital Sci Med Colon e Parassiti* 1937 Aug Vol 18 No 8, pp 483-493 With 2 figs.

The chief value of this article is the list of scorpions found in Cirenaica. Introductory to this is an account of a soldier aged 48—from the clinical history an "old soldier"—who was stung on the back of the right hand and the arm. He first felt a slight prick on the hand and soon after a more severe one on the arm and taking off his coat he found in the sleeve two scorpions a dark-coloured one 4 cm. in length and a light grey one 3 cm. both proved to be *Buthus bicolor*. He suffered from pain and inflammation in the arm and the larger joints and had fever between 38.5 and 39°C. he remained in bed for about a month. The inflammatory signs disappeared with the fall of temperature to normal but the pains in the muscles and joints persisted and after 96 days more or less confined to bed he was transferred to another hospital where after a few days of atophan by mouth with daily massage the pains disappeared.

The scorpions listed by ZAVATTARI as found in Cirenaica and Tripolitania are 17 in number viz —

BUTHIDAE *B. occitanus tunetanus* *B. bageux* *B. quinqueserialis* *B. aculeocarinatus klaproxi* *B. australis australis* *B. a. amorenxi* *B. a. lybicus* *B. a. priamus* *B. bicolor bicolor* *B. b. arneus* *B. b. longecarinatus* *B. syriacus* and *B. leptochelys*

SCORPIONIDAE *S. manus tunetanus* *S. m. palmatus*

CHACTIDAE *Euscorpius carpathicus* and *Orthochirus innesi*

H H S

SERGEANT (Etienne) Sérum antiscorpionique. (Note préliminaire.) [Scorpion Antivenene.]—*Bull Acad Méd* 1938, Mar 1 102nd Year 3rd Ser Vol. 119 No 9 pp 254-257

Priornus australis is the dangerous species of scorpion in Northern Africa and during the hot season its sting has proved fatal to children and the aged. The symptoms produced are severe pain at first localized, later extending vomiting, vertigo sweating, dyspnoea cardiac disturbance coma and death when it occurs in 2-24 hours.

The antivenene is prepared by injecting the poison from 100 mixed glands as the toxin content varies in different scorpions. The fatal dose for a mouse of 20 gm is 1/40 of a gland or half a drop of an emulsion of 100 glands in 100 cc. physiological saline. For injection of horses cholesterin 12.5 gm. per 100 cc. is added and just before injection $HgCl_2$ 1 in 1,000 1 cc. for each 10 cc. of the emulsion. The initial dose is 1 cc. increasing at first weekly later fortnightly to 30 glands (a maximum of 60 has been attained). To the final antivenene 1 cc. commercial formalin is added to 3 litres serum ampoules are heated to 55°C. for 45 minutes.

A good antivenene will protect 75 per cent of mice injected with a lethal dose and then elsewhere with 10 drops of the serum. *P. australis* antivenene protects also against *Buthus occiduus* and *Pr. Liouvillei* (the black scorpion) both North African scorpions.

The antivenene was used in 33 patients (19 children 1 old man and 13 adults) seriously ill and thought to be dying. 28 recovered and 7 died (6 children and 1 adult). In the case of 8 others (7 children 1 old man) seriously ill, but in whom a fatal issue might be expected from the species of scorpion and the age of the patient all recovered that is, out of 41 cases 34 ended in recovery 82.9 per cent. Sixty-six who showed symptoms—pain vomiting, sweats and chills—but not dangerous, all recovered.

H H S

MODY (S H.) Aphasia and Complete Right Hemiplegia after Scorpion Bite.—*Indian Med Gaz* 1938 May Vol 73 No 5 p 285

The author records a case of aphasia with supranuclear right facial paralysis and right hemiplegia in a boy aged 11 at Poona. The condition originated five days after the patient had been struck by a scorpion and no other lesion could be found which would account for it. The author therefore attributes the paralysis to the action of the venom, perhaps through the formation of an embolus of agglutinated red blood corpuscles.

C IV

BARROS (Evandro F.) O quadro clinico da intoxicação escorpionica [Symptoms of Scorpion Sting].—*Hospital* Rio de Janeiro 1938. Aug & Sept Vol 14 Nos 2 & 3 pp 317-330 581-593 [24 refs.]

The species of scorpion dealt with in this long article is *T. serrulatus*. The author divides cases into mild and severe. The former present symptoms of local pain and numbness, hyperaemia and oedema and systemic disturbance with sweating agitation headache vertigo and tachycardia. In severe cases these are all present but aggravated, with vomiting and passage of urine and faeces, and disordered respiration. Each of these symptoms is described fully and discussed in detail as to its pathogeny in the present article. The systemic and distally produced symptoms come on in severe cases within two hours. Mild cases do not need serum but in the more serious, if the toxic symptoms are marked and two hours or more have elapsed at least 40 cc. of antivenene should be injected intravenously and this should be repeated if there is no definite improvement in another hour. After a further hour if the amelioration is not marked, 20-30 cc. should be given intramuscularly or intravenously and so on from hour to hour. If the patient is a child under ten years of age the initial doses are doubled 80 cc. intravenously for the first and, if needed,

the second and subsequently 20-30 cc. Even after there is apparent recovery the patient should be kept under observation for at least twelve hours in case there should be any relapse or return of symptoms. Though the symptoms may be so serious as to threaten the life of the patient the fatality rate if the poison is ever fatal to man is not stated. The antivenene referred to is that prepared at the Ezequiel Dias Biological Institute the potency being such that each cc contains 4-6 m.l.d. for the camandongo (Brazilian house-rat)

DE MAGALHÃES (Otávio) Escorpionismo [Scorpion Poisoning].—*Hospital Rio de Janeiro*. 1938 Mar Vol 13 No 3 pp 421-426 With 2 figs.

FLECKER (H) Injuries caused by Australian Scorpions.—*Med J Australia* 1937 June 5 24th Year Vol 1 No 23 pp 875-876

Three genera of scorpions occur in Australia namely *Urodacus* of a size up to 120 mm. *Buthidae* and *Bothriuridae* under 45 mm. *Lychas marmoratus* and *Isometrus maculatus* are species of the last. Practitioners in Tropical Queensland have been asked to report all cases of injury by scorpions trivial as well as severe to the Registrar Cairns.

Five cases are reported in this paper (1) A child of 5 years stung on the sole of her foot by *Urodacus spinatus* suffered from a sharp stinging feeling lasting for two hours the parents were more upset than the child. Reference is made to a case reported in 1924 of a sting by *U. novae-hollandiae* producing a very bad swollen finger (2) A man of 38 years stung on the foot by *Lychas marmoratus* the result was swelling and induration for 12 hours, with a feeling of nausea and a pulse rate of 100 per minute but no other indications of systemic disturbance. Three cases of sting by *Isometrus maculatus* (3) man of 28 years stung on the foot. There was severe pain lasting about a minute followed by a burning sensation not very severe for at least another half hour and a swelling 15 mm. in diameter (4) A man of 25 years stung on the calf pain severe for 15 minutes over the whole calf but passing off in two hours. (5) A woman of 49 years stung on the right index finger pain spread to the shoulder and lasted for at least three hours. In none of these last three patients were there any constitutional symptoms. Unless only a small amount of venom happened to be injected and that is hardly likely in all these cases the toxicity of scorpion venom in these Australian species would appear to be less than in other countries e.g. in Brazil where the sting of *Tityus serrulatus* may be fatal [see this *Bulletin* 1936 Vol. 33 p 399 and J. A. WATERMAN above]

H H S

BARNETT (E. J.) Wood Tick Paralysis in Children.—*Jl Amer Med Assoc* 1937 Sept. 11 Vol. 109 No 11 pp 846-848

Wood tick paralysis in children though acute, is usually afebrile. The child awakens in the morning feeling quite well but collapses on attempting to stand the gait is ataxic when efforts at walking are made and in a few hours walking and even standing are impossible owing to progressive muscular weakness of the legs, and self feeding

owing to ataxia of the arms. The offending tick has usually been feeding for 5 or 6 days and is found engorged on any part of the body. If not found and removed death may occur from respiratory paralysis; if removed recovery is rapid and usually complete in 48 hours. The condition has been reported from Montana, Oregon, Wyoming, Idaho and Washington States, and also from British Columbia and Australia. Although the disease is recorded in five States only the tick is found over a range of thirteen States. In the Rocky Mountain area the wood tick is *Dermacentor andersoni* concerned in Rocky Mountain spotted fever, tularemia, tick paralysis and Colorado tick fever. In Australia the cause seems to be the common scrub tick, *Ixodes holocyclus*.

Attempts to reproduce the disease in animals by the *D. andersoni* have been unsuccessful, even when the same tick from an actual patient has been applied. It must be noted, however, that the engorged female usually refuses to feed. Though the dog tick, *Rhipicephalus sanguineus* has never been reported as causing the disease in nature experimentally the eggs have been found capable of doing so.

In nature, man is an accidental host, the tick being primarily a parasite of small rodents. The adult female lays about 300 eggs daily and a total of about 6 000. The evidence so far available points to the eggs or the egg-laying as responsible for the symptoms. For infection of emulsion of eggs in saline subcutaneously or intraperitoneally into dogs sets up the train of symptoms. There was no effect when they were administered per os.

Details are given of the case of a girl, 6 years of age, who complained of itching and burning pain in fingers and toes, soon followed by ataxia, increasing muscular weakness, loss of deep reflexes—in fact symptoms typical of lower motor neuron lesion not of the peripheral nerves, but of the anterior cornual cells—a mild irritative lesion of the posterior sensory roots and a severe irritative lesion of the anterior horn cells of the cord. There was no involvement of the cranial nerves in this case. Examination revealed an engorged tick on the scalp. Recovery was complete in 48 hours after its removal, though it is probable that had it not been found, death would have resulted from respiratory paralysis. The suggestion is made that the tick produces excessive egg venom early in the egg formation stage and excretes it by the enlarged over-active salivary glands. (An instructive article which should be read in the original. Knowledge of the condition should be disseminated in areas where it is liable to occur for many physicians may not be aware of it. Recovery soon follows removal of the tick but death may result from failure to recognize the train of symptoms.)

H. H. S.

GIBBS (J. Heyward). Tick Paralysis in South Carolina.—*Jl Amer Med Assoc* 1938. Sept. 10. Vol 111. No 11. pp 1008-1009. With 3 figs.

Tick paralysis, an ascending paralysis of the Landry type, has been recognized in some mid-western States for a number of years. The case now reported from South Carolina is the first to be recognized in the eastern States. The patient was admitted to hospital with weakness and incoordination of the legs, absent knee jerks but normal sensation responses. The weakness and ataxia spread rapidly to the arms, and speech became thick but there was no difficulty in swallowing. At this point, while the condition was becoming worse a distended

wood tick was found attached to the right occiput. It was removed and the patient rapidly and completely recovered. The patient was afebrile except for a temperature of 100°F on the evening of the first day in hospital.

It is supposed that this condition is due to a toxin from the salivary glands of the tick. *D. andersoni* was responsible for a similar case in the State of Washington. As Rocky Mountain spotted fever has been reported from South Carolina it is possible that this case of tick paralysis (a totally different condition but caused by the same tick) may be a precursor of other cases which can be handled effectively only if promptly recognized. It is thought that ticks of the genus *Ixodes* may also cause the condition. C IV

MAIL (G. Allen) Tick Paralysis in British Columbia.—*Bull. Brit. Columbia Board of Health* 1938 Oct Vol 8 No 15 pp 185-197

A fatal case of tick paralysis in a girl aged 3 is recorded. Two ticks, one a large fully engorged female, were found over the occipital protuberance and removed, but as the respiratory muscles were affected when this was done the child died within a few hours. More than 150 cases of this disease, many of which were fatal, are recorded in the files of the Division of Entomology at Kamloops and every year sheep, cattle and, more rarely, horses succumb to it. It is therefore important that it should be recognized.

Symptoms are detailed and it is pointed out that the ticks may be attached to any part of the body. From the first appearance of symptoms to complete paralysis and death may be as short a period as 2 days, but is more usually 3 to 5. Complete and early removal of the ticks and mouth parts by excision if necessary is essential.

The tick chiefly incriminated is the common wood tick, *Dermacentor andersoni* Stiles. *Ixodes ricinus* Linn., the coast tick, though not known to produce paralysis, may give rise to troublesome ulcers.

ROBINOW (Meinhard) & CARROLL (T. B.) Tick Paralysis due to the Bite of the American Dog Tick. Report of a Case observed in Georgia.—*Jl Amer Med Assoc* 1938 Sept 17 Vol 111 No 12 pp 1093-1094 With 1 map

The onset of tick paralysis is sudden and its progress rapid. Flaccid paralysis begins in the legs and spreads to the arms and neck. Speech and deglutition become difficult, the pupils dilate and death may supervene from respiratory paralysis. Early removal of the tick is followed by rapid recovery, but delay may be dangerous. Paralysis seems to occur only after the impregnated female tick has fed for several days on a patient and is probably not due to a living virus but to a venom elaborated in the developing ova. *Dermacentor andersoni*, which is also a vector of Rocky Mountain spotted fever, tularemia, relapsing fever and probably Colorado tick fever, has been responsible for all human cases so far reported in the United States and Canada.

The case here reported is the first from Georgia and the tick was unlike the others, *Dermacentor variabilis*. The patient was a girl of 9 years who was acutely ill, and showed a temperature of 100.6°F on admission to hospital. There was flaccid paralysis of the legs

Incoordination of the arms thickness of speech and nystagmus with normally reacting pupils. Examinations of the cerebrospinal fluid, blood urine and faeces were negative. Two ticks were first found one engorged female and one male, attached to the scalp. Recovery promptly followed the removal of these. Later a second female showing no signs of engorgement was found and removed.

WEBER (Neal A) The Sting of an Ant.—*Amer J Trop Med* 1937 Sept Vol 17 No 5 pp 765-768 With 1 fig.

The Ponerae subfamily of ants possess a well-developed sting and a virulent poison. In Central and South America a widespread species is *Paraponera clavata* Fabr. about an inch in length, blackish-brown in colour with large mandibles. It is known in Venezuela as the Cumanagato and as the viento cuatro horniga or "24-hour ant" because it is believed to kill a man in 24 hours, in British Guiana as the Mumun, and in Brazil as the Tucandera. If a nest is disturbed they emerge in large numbers and attack and may climb trees and drop on the intruder. If stung by many a man might die in 24 hours, for the author's account of being bitten by a single specimen shows that the sting is severe. He was stung through heavy khaki on the knee and in eight minutes there was a "white welt" with inflamed periphery and a burning sensation. The site was bathed with ammonia, on the idea that the poison was formic acid, and a wet ammonia pack applied. For the next two hours the burning sensation was intense and the limb seemed paralysed. These sensations then gradually

Blister caused by sting of *Paraponera clavata* Fabr.
(Reproduced from the *American Journal of Tropical Medicine*)

disappeared but $4\frac{1}{2}$ hours after the stinging there was a blister 53 mm long 20-29 wide and 7 mm. in height with a reddened base with vesicles. The knee felt stiff and 24 hours later there was an inflamed area 60×70 mm and the blister which had been opened had re-formed and the rest was covered with small vesicles. Four days after the injury the area was still red and the large blister discharged pus the redness remained for another week and the wound did not heal completely till 19 days after its being inflicted. [Since some of the poison was probably absorbed by the clothing and the patient did not therefore receive the full dose it is obvious that multiple stings might be very serious. The nature of the venom should be investigated.]

MALARIA

PRECIS OF ABSTRACTS IN THIS SECTION

TCHITCHIRABINE and HOFFMANN (p 580) use a test in which HIO_4 is the reagent for detecting plasmoquine in urine. One tenth mgm per litre can be identified.

In the paper by FARINAUD (p 581) is given an account of the prophylactic measures necessary during military operations in Indo-China. SHUPIZINA (p 581) shows that mixtures of larvicides with large volumes of talc such as 1 in 50 or 1 in 100 are inefficient and costly. The resistance of larvae to the action of arsenical poisons increases with age. DAVEY and GORDON (p 582) recommend that the maximum size of aperture for screening against mosquitoes in West Africa must not exceed 0.047 inch. This is provided in a screen of 16 meshes to the linear inch composed of wire of 28 S W G.

MILAM and COGGESHALL (p 583) infected 30 white and 12 negro patients with *P. knowlesi* by inoculation. The negroes were less susceptible than the whites and reinoculations were failures. SINTOV *et al* (p 583) failed in an attempt to infect two patients with *P. cynomolgi*.

DAS GUPTA and CHOPRA (p 583) consider that in monkey malaria prontosil soluble is less satisfactory than atebuin.

The paper by MANWELL (p 584) is concerned with the identification of those species of bird malarial parasites which are well established.

HEGNER and WOLFSON (p 584) found exo-erythrocytic schizonts (which they call *Toxoplasma*-like parasites) in association with *P. calhemerium*, *P. relictum* and *P. nucleophilum*. Attempts to separate *P. calhemerium* from the schizonts failed but the authors still hold that it is not proved that the schizonts belong to the plasmodium. WENYON disagrees with this and contends that toxoplasmas reproduce by binary fission and cannot be likened to the schizonts in question.

HEWITT (p 585) discovered that in *P. calhemerium* infections the ring forms prefer young red cells. Multiple infections occur early in the cycle but diminish later owing to destruction of the multiple-infected cells. The proportion of multiple infections varies inversely as the proportion of young red cells.

HEGNER and ESKRIDGE (p. 535) found that the serum of birds in the acute phase of infection with *P. calhamerium* is able to ward off the ill effects of this infection if injected into others, but cannot suppress the infection since the parasites are as numerous in them as in controls.

BLOOM and TALLAFERRO (p. 588) describe the common infarcts in the spleens of canaries infected with *P. calhamerium* which result from thrombosis of the splenic veins. These regenerate completely the process being initiated by macrophages followed by infiltration of lymphocytes. DECOURT and SCHREIDER (p. 586) found evidence to suggest that malarial parasites in fowls infected with *P. gallinaceum* are stored in masses of lymphoid tissue when they cannot be found in the spleen. No recognizable parasites can be seen but they may exist as certain granules found within lymphoid cells.

BISHOP *et al.* (p. 587) show that *P. relictum* infection may persist in canaries for more than 8 years. BASU (p. 587) describes a parasite of herons in India for which he proposes the name *P. heroni*. Development was observed up to the oocyst stage in *Culex fatigans*. MAXWELL and HARTIG (p. 588) show that *P. rugosus* and others of the *P. rouxi* type in birds are highly susceptible to both atabrin and plasmoquine.

C IV

TCHITCHIBABINE (A) & HOFFMANN (Ch) Méthode d'identification des gamétocoides synthétiques dans l'urine par une réaction colorée. (Method of Identification of Synthetic Gametocoides in the Urine by a Colour Reaction.—*Bull Soc Path Exot* 1938, Oct. 12, Vol 31 No 8 pp 740-742)

The authors report that iodic acid HIO_3 is a much more sensitive reagent for the detection of plasmoquine in the urine than is chloranil (tetrachloroquinone) which was recommended by SCHULMANN, WEINBOEFER & WILGIER. The test is carried out as follows —

200 cc. of urine are made alkaline by the addition of 50 cc. of a 30 per cent solution of caustic soda. This is then extracted thrice in a separating funnel with ether 25 cc. each time. The ethereal solution, 75 cc., is shaken with a few grammes of anhydrous potassium carbonate and then filtered into a 250 cc separating funnel. Five cc. of 10 per cent sulphuric acid are added after shaking, the lower layer is decanted into an ordinary test tube. The contents of the tube are gently boiled for 30 seconds to drive off the ether. After complete cooling under running water 2 cc. of a 10 per cent watery solution of iodic acid are added the tube is then shaken and left to settle.

If plasmoquine is present in the urine a violet colour develops in 2 or 3 minutes this darkens somewhat and lasts for nearly half an hour. By this method it is possible to identify plasmoquine in quantity as small as a tenth of a milligramme per litre of urine. Rhodoquine and plasmocid also give colour reactions with this test. With plasmocid the colour only appears after a delay of 15 to 20 minutes, as compared with 2 or 3 minutes with plasmoquine. If appreciable quantities are present plasmoquine gives a violet blue colour plasmocid violet red. With plasmoquine the colour persists for about half an hour with plasmocid it begins to fade after a quarter of an hour.

Norman White

FARINAUD (M. E.) La prophylaxie du paludisme dans les troupes en campagne. [Malaria Prophylaxis among Troops on Service].—*Ann de Méd et de Pharm Colon* 1938 July-Aug-Sept. Vol. 36 No 3 pp 583-608 With 4 charts.

Three examples are given from the military history of French Indo-China of the havoc caused by malaria during military operations in the hilly interior of that country. There follows an excellent account of the prophylactic measures that could and should be taken to prevent or mitigate such catastrophes. The recommendations contain nothing new or original. Examples are given of the results obtained by drug prophylaxis in malarious posts. The paper is designed primarily for the benefit of the military medical officer. V 14

SHIPIZINA (N. K.) A propos de l'action des poudres insecticides sur la larve d'anopheles en relation avec le degré de dispersion des toxiques et de la concentration des substances ajoutées. [Action of Insecticide Powders on Anopheline Larvae in Relation to the Degree of Dispersion of Toxic Substance and the Concentration of Added Substances].—*Méd Parasit & Parasitic Dis* Moscow 1938. Vol. 7 No 3 [In Russian pp 346-370 With 13 figs [18 refs.] French summary pp 371-372.]

Increase in the concentration of substances such as talc added to toxic powder larvicides prolongs the death time of larvae. Thus mixtures of 1 in 50 or 1 in 100 are much slower in action than a mixture of 1 in 10 and the percentage of larvae destroyed is less. The presence of detritus in suspension protozoa etc. in natural breeding places explains why the action of larvicides is sometimes slower there than in the laboratory other conditions being equal. The solid pellicule formed by diluents in excess results in a slowing down of the filtration in the larva. This is most marked in young larvae whose filtering apparatus overcomes with difficulty the force of adhesion of the particles of talc. Another result is that the concentration of the toxic substance in the intestine of the larva is considerably diminished. Experiments have shown that the mixture of the larvicide with a large volume of talc such as 1 in 50 1 in 100 is irrational from the point of view of the alimentary physiology of larvae and is unnecessarily costly.

The resistance of larvae to the action of arsenical poisons increases with age. For young larvae arsenic is more toxic than Paris green. It is a finer powder with a higher degree of dispersion. Its arsenic content is not sufficiently high for fourth stage larvae. Relative to the size of their bodies young larvae have a stronger capacity of filtration than fourth stage larvae. In natural conditions the food of a larva takes from 30 to 60 minutes to pass from the anterior end of the oesophagus to the anterior end of the posterior intestine at a temperature of 25°. When poison is taken the intensity of filtration, and consequently the rate at which food passes through the alimentary canal, depends on the dose. If more than a lethal dose is taken filtration and the passage of food stops in from 10 to 20 minutes. In such cases the poison does not pass beyond the anterior end of the stomach. With lesser doses this action is delayed but there is no possibility of the expulsion of the poison before the commencement of such action.

DAVEY (T. H.) & GORDON (R. M.) The Size of Aperture Necessary in Screencloth Intended for the Protection of Dwellings in West Africa. — *Ann Trop Med & Parasit* 1938, Dec. 21 Vol. 32, No. 4 pp. 413-424 With 3 figs. [10 refs.]

In July 1937 it was reported from the Gambia (and confirmed by the authors) that mosquitoes were getting through the screens at the Government Hospital. These screens were composed of wire of No. 30 Standard Gauge with 14 meshes to the linear inch giving apertures of 0.059 of an inch. Consequently BLACKLOCK [this *Bulletin* 1939 Vol. 35 p. 259] stated that screencloth of this type was clearly unsafe for West African conditions. The authors then commenced experiments in order to select a screencloth which, while admitting the maximum amount of air and light, would be capable of excluding mosquitoes from dwellings.

Screencloths chosen for the experiment were —

(a)	14 mesh	30 S W G	aperture 0.059 inch (1.5 mm.)
(b)	16 "	30 "	0.050 " (1.3 mm.)
(c)	16 "	28 "	0.047 " (1.2 mm.)
(d)	18 "	30 "	0.043 " (1.1 mm.)

16 000 mosquitoes were used, chiefly "wild" *Anopheles gambiae* and *A. funestus*; other species included *Aedes tritaenatus* and *A. simpsoni*. Specially designed cages were employed but as mosquitoes which passed through the screens were not actually seen doing so a separate cell was constructed of glass in which the movements of the insects could be observed under a magnifying glass. The apparatus and the attitudes of mosquitoes passing through the mesh are illustrated in text figures.

The experiments showed that *Anopheles gambiae* and *A. funestus* were able to pass through the apertures of 0.059 of an inch in screen (a). *A. funestus* could pass through the apertures of 0.050 of an inch in screen (b) and that neither species passed through apertures of 0.047 and 0.043 of an inch in screens (c) and (d) respectively. The two species of *A. tr.* were able to pass through the apertures in screen (a) but were not tested with the other screens.

The authors recommend that the maximum size of aperture for screencloth against mosquitoes in West Africa must not exceed 0.047 of an inch (1.2 mm.) this aperture is provided in a screen having 16 meshes to the linear inch composed of wire of 28 Standard Wire Gauge.

The requisite aperture could be obtained by using the thinner stronger and more durable stainless steel. The greater number of meshes to the linear inch would admit more air and light while affording the same protection. Objections that the steel is not always stainless and that the initial cost is high have been made but as the production of really stainless steel becomes perfected and the demand increases it should soon be possible to supply a screencloth of great durability at a reasonable price.

There is some confusion in the literature about the formula for designating different types of screencloth. The important point, however, is the size of the aperture so the formulae of previous investigators are converted into sizes of apertures in inches and the results of their experiments tabulated. From this table it is seen that there are no published records of mosquitoes passing through apertures

less than 0.048 of an inch (1.2 mm.) and that very little work has been done on *Culicines*.

Observations made on the movements of mosquitoes while penetrating the screens show that the thorax enters the aperture diagonally. The legs of a mosquito do not prohibit its passage inability to pass depends upon the dorso-ventral diameter of its thorax. [There will be many to whom this work is of considerable practical interest though some readers may not understand that the two names *A. gambiae* and *A. costalis* refer to the same mosquito] H S Leeson

MILAN (D. F.) & COGGESHALL (L. T.) Duration of *Plasmodium knowlesi* Infections in Man.—*Amer J Trop Med* 1938 July Vol. 18 No 4 pp 331-338

The paper reports that 30 white and 12 negro patients with general paresis were infected by inoculation with *Plasmodium knowlesi* as a therapeutic measure. In the white patients the parasites first appeared in the blood as early as the third day and as late as the eighteenth day and they persisted for three to fourteen days. As tested by injection into susceptible monkeys the blood was negative on the 18th to 131st day after the original inoculation. Of the patients found negative by monkey inoculations 18 were re-inoculated with intervals of 30 to 491 days and all proved refractory. The negro patients were less susceptible than the white and the duration of visible infections varied from 2 to 11 days. The blood was infectious to monkeys as late as the 36th day and non-infectious as early as the 28th day. Re-inoculations proved unsuccessful. It is noted that in the case of one negro the blood was infective to monkeys from the 2nd to 18th day though parasites were never detected in the blood smears. It seems that similar invisible infections may occur with human malaria and the failure to recognize them is due to the want of a sufficiently sensitive host. C M Weyson

SINTOV (J. A.) HUTTON (E. L.) & SHUTE (P. G.) Failure to transmit an Infection of *Plasmodium cynomolgi* to Man by Blood Inoculation and by Mosquito Bites.—*J Trop Med & Hyg* 1938 Aug 1 Vol 41 No 15 pp 245-246 [16 refs.]

The paper describes unsuccessful attempts to infect two human beings with *Plasmodium cynomolgi*. In one case the patient received infected monkey blood intramuscularly and sporozoites intravenously while in the second case infected mosquitoes were allowed to bite the patient who also received an intravenous injection of sporozoites. It is of interest to note that the strain of parasite had been sent by air mail from India in defibrinated monkey blood to which 0.2 cc. of 50 per cent. dextrose solution was added per 10 cc. of blood. Though the blood had been exposed to the ordinary climatic conditions on the journey of seven days a monkey was successfully infected in London. Of a number of *Anopheles maculipennis* var. *atroparvus* fed on an infected monkey 36 per cent. became infected. C M W

DAS GUPTA (B. M.) & CHOPRA (R. N.) Studies on the Action of Synthetic Drugs on Simian Malaria. Sulphonamide Derivatives.—*Indian Med Gaz* 1938 Nov Vol. 73 No 11 pp 665-667

The authors have treated monkeys inoculated with *P. knowlesi* with prontosil soluble administered intravenously. They have found

that daily doses of 0.5 and 1 cc. are insufficient to check the infection. Larger doses (3 cc. daily for three days) are sufficient to bring about a cure but these are quite out of proportion to the human doses. In its action the drug resembles quinine but for the cure of an infection it is less satisfactory than atabrin. C M H

MANWELL (Reginald D.) The Identification of the Avian Malariae.—*Amer J Trop Med* 1938, Sept. Vol. 18, No. 5, pp 545-575 [28 refs.]

The increased interest which has been taken in bird malaria during recent years has resulted in the establishment of a number of new species of bird malarial parasite. Some of these are undoubtedly good species while others are doubtful. In this paper the author discusses the differentiation of about a dozen species which appear to him to be well established. He gives a useful key which will enable observers to separate the species on morphological grounds, while in a table is set forth a comparison of the infections which are produced in canaries by a number of species inoculable to these birds.

The paper is one which must be consulted by those engaged in the identification of bird malarial parasites. C M H

HEGNER (Robert) & WOLFE (Fruma) Association of *Plasmodium* and *Toxoplasma*-like Parasites in Birds.—*Amer J Hyg* 1938, Nov Vol. 28, No. 3 pp. 437-454. With 11 figs. [20 refs.]

The authors revert [this *Bulletin* 1938, Vol. 35 p. 730] to the subject of the exo-erythrocytic schizonts which have been assumed to be stages of development of certain bird malarial parasites and the possible relationship of these to the common toxoplasms of birds. Twelve strains of bird malarial parasites belonging to eight species have been examined in various birds chiefly canaries and the schizonts in question have been found in association with *P. cathemerium*, *P. redicium* and *P. multophilum*. The general account is somewhat obscured by the use of the expression *Toxoplasma*-like parasite for the exo-erythrocytic or endothelial schizonts which most observers have assumed to be stages of development of the malarial parasites with which they appear to be always associated.

The histories of a number of transmissions of strains are given and the presence or absence of the schizonts is discussed. Attempts to separate *Plasmodium cathemerium* from the exo-erythrocytic schizonts (*Toxoplasma*-like parasites) failed, though the experiments involved sub-inoculations, passage through mosquitoes, treatment with quinine, differential viability, inoculation into chicks and centrifugation. In spite of this it is still held that it has not yet been proved that the schizonts belong to the plasmodium.

[To the reviewer it seems that such a discussion is hardly likely to solve the problem, if indeed there is a problem, for no observer has yet shown that a bird toxoplasma, which is only known as the small rounded parasite in the nuclear notch of a blood leucocyte ever reproduces by schizogony in endothelial or other cells or gives rise to schizonts of the type under discussion. The expression *Toxoplasma* like would bring to mind the fairly characteristic intra-leucocytic forms just referred to and would not suggest large multinucleate schizonts, which are not known as stages of development of toxoplasma. In all recent work that has been carried out there has been a complete

failure to demonstrate for the toxoplasms any other type of reproduction than binary fission. Recent observations by the reviewer of a strain which was inoculable to both birds and mammals are in support of this while he is of the opinion that the toxoplasms are not protozoa at all but that they are vegetable organisms related to *Histoplasma capsulatum* or similar yeast like parasites.] C M W

HEWITT (Redginal) Multiple-Infected Red Cells in Avian Malaria.—*Amer J Hyg* 1938 Nov Vol 28. No 3 pp 321-344 With 3 figs. & 1 plate [20 refs.]

A study of *Plasmodium cathemerium* infections in canaries has shown that at the beginning of the 24-hour cycle of the parasite as many as 100 per cent of the ring forms of the parasite are in young red cells. Of these infected cells 66 per cent contained a single parasite the rest harbouring two three four or five. As the cycle progressed the percentage of multiple infections diminished till finally no cells with more than two parasites could be found. It was evident that with the growth of the parasite the cells were unable to withstand more than two parasites and those with three or more had been destroyed.

Generally speaking the number of multiple infections bore a relationship to the percentage of young red cells present at the time of sporulation. Where 100 per cent of the red cells were young no multiple infections occurred. With reduction in the percentage of young red cells in the blood there was an increasing number of multiple infections a state of affairs which seems to indicate a preference on the part of the merozoites for young cells even when this entails producing multiple infections. When all the red cells are young the merozoites have little difficulty in finding suitable cells. Similarly by increasing the percentage of young red cells in the blood by treating the birds with phenylhydrazine the number of multiple infections became reduced. Generally the distribution of the parasites in the young red cells was found to be such as would have occurred if no mature cells had been present. C M W

HEGNER (Robert) & ESKRIDGE (Lydia) Passive Immunity in Avian Malaria.—*Amer J Hyg* 1938 Nov Vol. 28. No 3 pp 367-376 With 2 figs.

In an experiment to discover if the blood of birds infected with *Plasmodium cathemerium* contains substances capable of protecting against infections in other birds, the following experiments were carried out. Serum from healthy birds from birds which had passed the acute phase of an infection and from birds in the acute phase was prepared and dried. Birds injected with the healthy serum were found to be more susceptible to infection than normal birds. The same was true of birds injected with the second type of serum, but birds injected with the acute serum did not appear to suffer from the infection which followed inoculation though as regards numbers of parasites the infections were as intense as in the other treated birds. It would appear that the serum of birds in the acute phase of infections contains some substance which is unable to suppress the infection in fresh birds though it is capable of warding off the ill effects of this infection. Before pronouncing finally on the question the authors propose carrying out further experiments to test this view more fully. C M W

BLOOM (William) & TALLAFERRO (William H.) Regeneration of the Malarial Spleen in the Canary after Infarction and after Burning.—*Jl Infect Dis* 1938, July-Aug Vol. 63. No. 1 pp 54-69 With 5 plates. [21 refs.]

It is a common occurrence for infarcts to form in the spleens of canaries infected with *Plasmodium cathemerium*. They are haemorrhagic in character and result from thrombosis of the splenic veins. They extend from the hilum to the capsule which does not become involved in the primary necrotic process. Such infarcts, even when large and involving the entire spleen, become completely regenerated. The first step in repair is the appearance of macrophages between the healthy spleen and capsule tissue and the necrosed area. These macrophages arise from the reticular cells, macrophages and lymphocytes of the adjacent healthy tissues and from haematogenous agranulocytes (lymphocytes and monocytes). A young scar is formed containing many fibroblasts and macrophages. The scar is then infiltrated with lymphocytes which migrate from the healthy tissue and blood vessels or arise *in situ* by the transformation of fibroblasts into large lymphocytes and the proliferation of medium and large lymphocytes. Nests of proliferating lymphocytes associated with the smaller arteries give rise to new nodules, while the fibroblasts become the reticular cells of both the red and white pulp. The venous sinuses arise from the scar capillaries.

The same type of regeneration follows experimental burning of the tip of the spleen but it is slower owing probably to the absence of the capsule which the operation of burning has destroyed. C M W

L. DECOURT (Ph) & SCHNEIDER (J) Les lacunes de nos connaissances sur le cycle plasmodial chez l'hôte vertébré [Gaps in our Knowledge of the Plasmodial Cycle in the Vertebrate Host].—*Bull Soc Path Exot* 1938, Juin 6 Vol 31 No 7 pp 603-609 22 refs

ii — & — Note préliminaire sur la recherche de la localisation et de la morphologie des plasmodes pendant les périodes d'infestation latente [Localization and Morphology of Plasmodia during Latent Infestation].—*Ibid* pp 609-614

i. In the first of these papers the authors review the observations which have been made to discover the fate of malarial sporozoites which have been injected by mosquitoes. The question as to what happens to them between their injection and the appearance of malarial parasites in the blood still remains unanswered. The view held by some that the recently discovered endothelial schizonts are developed only from sporozoites the authors regard as untenable. They believe that these schizonts are not essential stages in the development of malarial parasites but are rather accidental by-products of the normal cycle. They are of irregular occurrence and are found in very varying numbers in infections following direct blood inoculations as well as sporozoite infections.

ii. In the second paper are recorded experiments which were suggested by observations which had been made on the property of mesenteric lymphatic glands to store up bacilli such as those of typhoid fever and to discharge them with pathogenic effects when certain stimuli were applied to the splanchnic nerve. It seemed possible that

malarial parasites might similarly be stored in the lymphatic glands particularly as prolonged search for parasites had been carried out without result in practically all other organs and tissues of the body during the latent phases of infection.

The experiments were carried out with *Plasmodium gallinaceum* of fowls. In the place of actual glands the fowl possesses masses of lymphoid tissue. An emulsion of such tissue from a fowl which had apparently recovered from its infection injected in very small dose (0.002 cc) into a clean fowl produced an intense infection, whereas the injection of large quantities of spleen emulsion failed to infect. A similar result was obtained by injection of a small dose of thymus emulsion. A microscopic examination of the infecting material did not reveal any recognizable malarial parasites. On the other hand in the cytoplasm of the lymphoid cells were found red to purple staining granules 1 to 1.5 μ in diameter. Similar granules have also been seen in the large lymphocytes of the blood but only just before the appearance of malarial parasites in the red blood corpuscles. The granules have never been found in healthy birds. A possible light was thrown on the nature of these granules by observations made on the behaviour of malarial parasites kept in sodium citrate solution at 28°C. The parasites within the red cells were seen to break up into daughter cells and these without leaving the cell became transformed into chromatin-like granules resembling those mentioned above.

It is evident that further study is required before a final opinion can be given on the part played if any by these granules in the development of malarial parasites but the result of this is promised soon.

C M W

BISHOP (Ann) TATE (P) & THORPE (Mary Vincent) The Duration of *Plasmodium relictum* Infection in Canaries.—*Parasitology* 1938 Sept Vol 30 No 3 pp 388-391

It has been shown that infections of *Plasmodium relictum* may persist in the peripheral blood of canaries as ordinary schizogonic stages for as long as 8 years and 3 months and that during this period the blood is infective to clean birds.

C M W

BASU (B C) Studies on a Malarial Infection in a Paddy Bird.—*Jl Malaria Inst of India* 1938, Sept Vol 1 No 3 pp 273-284 With 1 text fig & 14 figs. on 1 plate. [64 refs.]

The parasite described from India appears to be a new species for which the name *Plasmodium heroni* is proposed. It occurs in the pond heron *Ardeola grayi* Sykes in which it produces frequently a heavy and fatal infection. The schizonts give rise to 6 to 26 merozoites the larger schizonts often occupying the side of the red cell and encircling the nucleus. The gametocytes are elongate while the pigment is brownish black in colour. The infection was readily inoculable from heron to heron but not to sparrows, crows domestic fowls or canaries. Development in *Culex fatigans* up to the oocyst stage was observed. A search of the internal organs of infected birds failed to reveal any endothelial schizonts such as have been described for *P. gallinaceum*.

C M W

MANWELL (Reginald D.) & HARING (Ann T.) *Plasmochin and Atabrin Therapy in Plasmodium vaughani Infections.*—*Rev. di Parasit.* Rome. 1938. Sept. Vol. 2. No. 3. pp. 207-218. With 24 figs. on 1 plate [17 refs.]

Infections in canaries of *Plasmodium vaughani* a bird malarial parasite belonging to the group of small organisms of which *P. rossi* is the type and *P. hexamerum* and *P. nucleophilum* other members, have been shown in the experiments recorded in this paper to be highly susceptible to both atabrin and plasmoquine. Complete sterilization of the birds was obtained with both drugs after about a week's treatment. The other organisms are also susceptible to the drugs a fact which shows their close relationship to one another. All these parasites resemble one another in that they multiply slowly while relatively large numbers of organisms are present in the blood of infected birds during the chronic phases of infection. C M IV

HELMINTHIASIS.

PARALS OF ABSTRACTS IN THIS SECTION

MENDHEIM (p. 588) mentions LOOSS a method of collecting helminths for examination.

Helminth eggs were found on the legs of flies by POKROVSKY and ZIMA (p. 589).

AFRICA and DE LEON (p. 589) studied the phagocytic action of giant cells after the eggs of various helminths had been injected into the peritoneum of monkeys. *Ascaris* eggs are surrounded by the giant cells the eggs of *Fasciola* and *Schistosoma* are crushed or penetrated or pulled asunder by the cells and heterophyid eggs are surrounded only by histiocytes and endotheliocytes, without giant cells. COLBERTSON (p. 590) states that the immunity developed against helminths is similar to that against other infectious agents both as regards the host and the parasites.

NICHOLS and GUKAWARDANA (p. 590) describe a method of composting town refuse and night soil which causes the destruction of all *Necator* material and *Ascaris* eggs.

The remainder of the abstracts in this section deal with the proportion of the various helminths found in the examination of communities in Africa, America and China. The majority are records of examinations of faeces by different methods but FISK (p. 591) gives the results of careful examination of the whole of the alimentary tract in 120 consecutive autopsies. C IV

MENDHEIM (H.) Ueber eine Zweckmässige abänderung der Looss'schen Schüttelmethode nebst Bemerkungen zur helminthologischen Technik. [A Useful Alteration of Looss's Shaking Method and Remarks on Helminthological Technique.]—*Ztschr. f. Parasitenk.* 1938. Aug. 19. Vol. 10. No. 3. p. 438.

Looss it is said, advised for the collection of helminths in a state satisfactory for examination that they should be made to extend themselves by shaking the intestinal contents with saturated sublimate

solution allowing to settle and adding half saturated sublimation solution Mendheim advises apparently as something new and as improvement that the worms themselves should be picked out and first washed in water or normal saline As a stain para-carmin is advised and for subsequent bleaching some days in undiluted Lugol solution.

Clayton Lane

POKROVSKY (S N) & ZIMA (G G) Mouches comme transporteurs des oeufs des helminthes dans les conditions naturelles [Flies as Carriers of Helminth Eggs in Nature]—*Med Parasit & Parasitic Dis* Moscow 1938 Vol 7 No 2 In Russian pp 262-263 French summary p 264]

Of 1,911 flies examined 0.47 per cent carried worm eggs namely *Diphyllobothrium* and *Hymenolepis* each by 3 flies *Ascaris* by 1 and *Enterobius* by 2 and they did so mostly on their legs The need for exclusion of flies from shops is stressed.

C L.

AFRICA (Candido M) & DE LEO (Walfredo) Observations on the Mechanism of Phagocytosis of Various Helminth Ova.—*Livro Jubilar do Prof L. Travassos* Rio de Janeiro 1938 pp 1-10 With 5 plates. [10 refs.]

The eggs concerned were those of *Ascaris lumbricoides*, *Fasciola gigantica* the heterophyid *Monorchotrema lishokui* and *Schistosoma japonicum*. The method was by serial sections stained with haematoxylin and eosin—in the case of the first three worms of nodules formed in the mesentery and omentum after intraperitoneal injection of the eggs into *Afarcus cynomolgus* in the fourth worm, of natural material from man. The observations were confined as much as possible to the mechanism of the phagocytic action of giant cells and these are in fact largely pictured as machines.

In the case of *Ascaris* eggs a wrapping of giant cells is formed round them but there seems no attempt on the part of the phagocytes to make an opening on or break the eggshells forcibly. This engulfment is commoner with eggs that have become embryonated, while these cells have appeared as early as 4 and have persisted in a well nourished state till as late as 74 days after inoculation while in a monkey that died six months after this only a few giant cells loitering lazily are left around the place where eggs were presumably located before. Fibrosis advances from the periphery of the pseudotubercles formed round egg clusters.

In eggs of *Fasciola* there is no larval development but the action of the giant cell is described as hugging and crumpling the egg by means of its powerful arms battering the shell, getting inside it expanding and cracking it into fragments or acting like a steam roller upon an empty egg. As to schistosome eggs three mechanical mental pictures are drawn of the giant cell—A fracture of the shell by the action of the nuclei into a wedge and forcing this into the shell by the action of the attacking cell's cytoplasm an encirclement without a nuclear wedge so that centripetal pressure breaks the shell at its weakest point and an anchoring of cytoplasmic processes at convenient points in the surrounding fibrous tissue a simultaneous pull from all directions and the tearing asunder of the whole shell. Heterophyid eggs do not evoke giant cells only sheets of pure histiocytes and

endotheliocytes in fibrous tissue stroma. This very noticeable indifference of the giant-cells towards heterophyid eggs, we will interpret as an example of negative chemotaxis." C. L.

CULBERTSON (James T.) Recent Contributions to the Immunology of Helminthic Infections.—*Arch. Pathology*, 1938. Jan. & Feb. Vol. 25 Nos 1 & 2. pp 85-117 256-280 [5 pages of refs.]

A summary of the literature on immunity to helminths (which has at least in the main, been abstracted in this *Bulletin*) is summed up thus —

It is apparent from what has been given here that the subject of immunity against helminths has been attacked by a large number of workers and that their contributions have covered many aspects of the whole field. Although there are still some who hesitate to agree that immunity to any helminth has been experimentally established (Schmid) the great majority of workers are more favourably inclined and tend to assume the point of view that the mechanism of immunity against helminths is similar to that against other infectious agents. The manner in which the state of immunity against helminths is attained, the humoral and cellular responses of the immune host against these parasites, and the effects of the defense agencies of the host on the parasites are so nearly identical with the immune phenomena associated with other types of infectious agents that one must either accept the fact that immunity is developed against the helminths or believe that no immunity is manifested against any agent of disease.

NICHOLLS (Lucius) & GUKAWARDANA (Samson A.) The Destruction of Helminth Ova in Flight Soil by Composting.—Reprinted from *Ceylon J. Sci.* (Sect. D. Med. Sci.) 1939 Feb. 11 Vol. 5. Pt. 1. 8 pp. With 5 figs. on 1 plate.

In Ceylon, night soil is in places disposed of by composting which produces fine odourless mould valuable as a manure. This investigation was undertaken to determine whether the rise in temperature which occurs in the process sufficed to destroy the free living ankylostome and *Ascaris* stages.

The town refuse, freed from pots, pans, coconut husks and suchlike is stacked in rectangles of 6 by 4 feet and 4 feet high. In each rectangle is dug a trench 4 by 2 feet and 2 feet deep which is filled with night soil and covered with the refuse which had been dug out. The whole is then sprinkled with water daily for a week. The rectangle is then so mixed that the edges become the middle. In the middle is then dug a trench corresponding to 7 per cent. of the volume of the rectangle and this is filled with night soil covered and watered as before for another week. At the end of 2, 3 and 4 weeks this mixing, trenching, covering and watering are repeated but the amounts of faeces added are respectively 5, 3 and 3 per cent. of the volume of the heap. No further addition of faeces is made but the daily moistening and weekly turning over are continued for 3 months by which time the material has become a fine mould. The fermentation which has been going on has raised the temperature this rise is greatest at the junction of faeces and refuse and in all but one of the heaps tested it reached 60°C. In the exception 57°C. Controls showed that a temperature of 45°C. killed all *Necator* material within 2 hours, and one of 42°C. within 12 hours. In the final compost all *Ascaris* eggs were dead and any

larvae present were those of free-living nematodes. The turning over of the rectangular heaps in the manner described is a completely essential part of the procedure which was as effective in the rains as in the drier seasons. C L

FISK (Guy H.) Helminthiasis in Lagos, Nigeria.—*Trans Roy Soc Trop Med & Hyg* 1939 Feb 28 Vol 32. No 5 pp 645-652.

The results of a count of gastro-intestinal worms obtained at 120 consecutive routine autopsies.

The whole gastro-intestinal tract was opened and its mucosa scraped in a white tray, visible worms were picked out and the faecal matter washed with sedimentations usually about 12, till no more worms were found. Search was not made for *Strongyloides* though these showed as larvae in nearly every stool examined in the laboratory while examination for schistosomes was limited to the microscopic investigation of material scraped from suspicious-looking patches on the mucosa of the bladder. Six of the cases were under 5 weeks old and had no parasites and of the remaining 114 the infection rate was just over 90 per cent. while in those over 15 months it was 96. There were 47 *Necator* infections with 1 870 worms in all the highest number in one person being 184 for *Ancylostoma* the corresponding figures were 22 368 and 147 for *Ascaris* 90 1 117 and 78 for *Trichuris* 72, 895 and 89. Of these worms the proportions of males to females varied from 1 to 1.5 in *Ascaris* 1 to 2 in *Trichuris* and *Ancylostoma* and 1 to 3 in *Necator*. *Taenia saginata* was present 4 times, whereas in Northern Nigeria the percentage of incidence is about 50 in the former area meat is little eaten. Schistosome eggs were found in 8. In a child of 1 month and 8 days there were 9 *Necator* and 147 *Ancylostoma* this is the only person who died as the direct result of infection and it is suggested that her mother must have set her down on the ground near a latrine [FOSTER (this Bulletin 1933 Vol 30 p 221) found that in pre-natal infection of a bitch with *A. caninum* eggs appeared in her pups faeces eleven days after infection great care having been taken to prevent their infection after their birth. *A. caninum* is very near to *A. duodenale* anatomically] Hookworm infections are held to be often an indirect cause of death. No *Enterobius* were apparently recovered from the lengths of intestine removed. C L

VAN DEN BERGHE (Louis) Les parasites intestinaux des pygmées Efé de l'Ituri (Congo Belge) [Intestinal Parasites of the Efé Pygmies of Ituri, Belgian Congo].—*Ann Soc Belge de Méd Trop* 1938 June 30 Vol 18. No. 2 pp 293-296

In spite of their timidity it was found possible to make faecal examinations on 42 male Efé pygmies of pure stock.

The pygmies live in symbiosis with the large negroid Bantus of the Walese race exchanging meat got by hunting elephant or the small antelope *Cephalophus* (the latter caught in nets after a beat by the women) for the agricultural produce of the Bantus. Every Walese village has its clan of pygmies living somewhere within 2 or 3 days march but at no fixed place. The faeces were examined by smear by centrifugal precipitation with washings and by [? gravity]

floatation in saturated salt solution. The percentages of infection found were *Ascaris* 22, *Necator* (established by getting the adults from washed stools) 40 *Trichuris* 27.5 and *Schistosoma mansoni* 11. No cestodes or *Strongyloides* were seen. One *Planorbis* was found after a long search in a small stream, and cysticerci were found in *Cephalophus* on two occasions. The percentages of infections found in the symbiotic Bantus were *Ascaris* 73 *Necator* 80 *Trichuris* 15 *S. mansoni* 27.5

C. L.

CLEMENT (L.) Contribution à l'étude du parasitisme intestinal chez les indigènes du territoire de Ruengeri (Ruanda) [On the Intestinal Parasites of the Inhabitants of Ruengeri (Ruanda)]—*Ann. Soc. Belge de Méd. Trop.* 1938, June 30 Vol. 18, No. 2, pp. 347-349

A report on examinations of faeces from 19,063 children between the ages of 2 or 3 and 15 or 16, the method of examination being unstated.

The percentages of detected infections were—*Ascaris* 94 *Trichuris* 72, "Taenia" 10.6 ankylostomes 1 *Strongyloides* 0.1 negative 4.3. Figures for the six different provinces are also given. The low percentage of hookworm infection is due to the cold climate. C. L.

LEATHERS (W. S.), KELLER (A. E.) & McPHERSON (W. A.) The Prevalence, Distribution and Intensity of Infestation of *Ascaris lumbricoides*, *Trichocephalus trichiura* [sic], *Hymenolepis nana*, *Enterobius vermicularis* and *Hymenolepis diminuta* in Fifty-Six Counties of Florida.—*Amer. J. Hyg.* 1939, Mar. Vol. 29, No. 2, Sect. D, pp. 57-66. [10 refs.]

This paper continues the report abstracted in this *Bulletin* 1938 Vol. 35 p. 669, this part dealing with the infections, other than those by hookworms, which were discovered by examination of 0.005 cc. of faeces by the Stoll-Hamshier method.

Of the 29,062 faecal specimens from white persons, there was detected *Ascaris* infection in 1.9 per cent, with an average intensity corresponding to 22,000 eggs per cc. and with highest figures in pre-school and school children. Of these 571 persons, 215 harboured unfertile eggs only, 159 fertile eggs only, and 197 both sorts, the eggs per cc. numbering 3,000, 15,000 and 58,000 respectively. When infection was familial its average weight, as measured by egg numbers, increased in each member of the family in proportion to the number of them which were infected. Of the 4,121 specimens from negroes 8.5 per cent. were positive with an average of 33,600 eggs per cc. and of these 268 persons there were unfertile eggs only in 78, fertile eggs only in 45 and both sorts in 145, the eggs numbering respectively 2,700, 18,000 and 56,000 per cc. For *Trichuris* the percentage of infections detected in white persons was 0.4, though it was as high as 11.9 in St. Johns County, and for negroes 0.19. For infection with *H. nana* the detected percentage was 0.9 in white persons and 0.16 in negroes, while for *H. diminuta* the corresponding figures were 0.06 and 0.12. C. L.

FONSECA (Rafael Calvo) KOURI (Pedro) & BASNUEVO (José G.)
 Porcentaje y distribución geográfica de la verminosis intestinal
 en Cuba. [Percentage and Local Distribution of Intestinal Worms
 in Cuba.]—*Rev Med Trop y Parasit* Habana. 1938 Sept.-
 Oct. Vol. 4 No 5 pp 231-261 With 5 figs. [29 refs]
 English summary

The method of diagnosis was to suspend a small piece of faeces in water by shaking to screen and centrifuge after adding a drop of acetic acid and to examine one preparation from the precipitate.

Of 7,246 examinations the percentages of infection discovered were Trichuris 37.44 Ascaris 16.86 Necator 5.97 Enterobius 2.16 Strongyloides 0.33 Taenia 0.2 *H. nana* 0.07 *F. hepatica* 0.04 *Entamoeba coli* 15.72 *Giardia* 4.25 *E. histolytica* 1.21 The local incidences are given and it is added that Taenia is most often found in resident Spaniards and Syrians and that Chinese show a high percentage of infection with Clonorchis no Cuban however being infected. C L

WALTER (E.) Studie neber die Verbreitung der Helminthen in der Bevölkerung Venezuelas. [The Distribution of Helminths in Venezuelans.]—*Ztschr f Parasitenk* 1938. Aug 19 Vol. 10 No 3 pp 432-435 With 1 fig

About half the material referred to in the title had already been investigated by Dr CHACIN ITRIAGO at Lausanne On his death his widow gave it to the Institute of Hygiene and Parasitology of that University and Professor GALLI VALERIO entrusted it to Walter for completion and report. It consists of 1,846 faecal specimens reported on in detail for geographical distribution in 707 and in general in 639 more. The percentages of infection discovered by the unstated method of diagnosis were respectively for these two sets of specimens — Ascaris 48.8 and 46.5 Trichuris 82.1 and 79.8 *Ancylostomum duodenale* 39.6 and 40.7 Ascaris and Trichuris 44.7 and 34.7 Ascaris and *Ancylostomum* 17.4 and 20.7 Ascaris, Trichuris and *Ancylostomum* 17.3 and 16.3 Taenia 1.55 and 0.9 and in addition there were 3 of *Schistosoma mansoni* 1 of lamblia, and 1 of a fourfold infection with Ascaris Trichuris *Ancylostomum* and Taenia. C L

DE ARAGÃO (R. Moniz) Incidência verminótica na população de João Pessoa. [Incidence of Worms in João Pessoa.]—*Brasil Medico* 1938. July 23 Vol 52. No 30 pp 679-680

From 1931 to 1937 the number of stools examined at the Central Laboratory of the Director General of Public Health of the State of Parahyba has been 4,972 with 74.5 per cent positive for worms the percentages of infection with different worms for these persons were Ascaris 51.7 Trichuris 31.2 Enterobius 19.0 Necator 14.8 Schistosoma 2.5 Of 830 persons classified by age the following figures hold. For 90 sucklings examined the infection rates were total 73 Ascaris 48.8, Trichuris 25.5 Enterobius 7.7 Necator 20 Schistosoma 0 for 495 of pre-school age the percentages were for all infections 82.8 Ascaris 70.6 Trichuris 27.3 Enterobius 49.2, Necator 7.2 Schistosoma 2.7 for other ages the percentages of infections in 246 examined were for all infections 77.6 Ascaris 41.0 Trichuris 24.8 Enterobius 10.5 Necator 22.5 Schistosoma 1.8 [It would have been valuable to learn the means of diagnosis which gave such a high percentage of Enterobius infections.] C L

ANDREWS (Mary V.) A Survey of Intestinal Parasites in Chinese Hospital Patients in Shanghai.—*Chinese Med J* 1938. Oct. Vol. 54 No. 4 pp 341-350 [10 refs.]

The result of 5,205 faecal examinations of 2,888 patients in Shanghai or 1.8 examinations per person instead of the 3 aimed at. The investigation covered a period of over 5 years. It was routine work in two-thirds of the specimens but in the other third the patients were selected for particular reasons.

For protozoa two films were examined under the oil immersion one in normal saline the other in double strength Gram's iodine solution. For helminths, one film was made in normal saline, one specimen was concentrated by hydrochloric acid and ether and one sedimented by Tomb and Helmy's method [this *Bulletin* 1932, Vol. 29 p 410] while for schistosomes the miracidia were hatched out. The table shows the numbers of positive findings.

Comparison of the different methods used for the detection of helminthic ova

Parasite	Total number of times found	Number of times found by each method			
		Direct smear	Concentration	Sedimentation	Faust & Meleney
<i>Ascaris</i>	218	183	142	142	
<i>Hookworm</i>	259	132	258	153	
<i>Trichuris</i>	375	163	364	178	
<i>Fasciolopsis</i>	28	13	13	24	
<i>Clonorchis</i>	15	7	14	9	
<i>Schistosoma</i>	354	67	82	172	325

The apparently favourable findings of *Ascaris* ova by direct smear are illusory for fertile eggs were more readily found by concentration and unfertile eggs by sedimentation and the combined positive results these gave exceeded those got by smear. In 107 cases adult hookworms were recovered, *A. duodenalis* in 80 *N. americanus* in 51 and both in 24. The high number of schistosome infections is due to faeces being sent for examination in nearly all suspected cases. *Taenia* eggs were found in 8 those of *H. nana* in 1 of *Enterobius* in 9 *Clonorchis* in 67 *Fasciolopsis* in 60 *Paragonimus* in 1 and *Heterophyes* in 1. For protozoa the corresponding figures were *E. histolytica* 128 *E. coli* 314 *E. nana* 239 *I. biluchii* 53 *G. lamblia* 144 *C. mesnili* 17 *Trichomonas hominis* 75 *Tricercomonas* 8 *Isospora hominis* 1. The percentage in which protozoa were discovered is 24 that for helminths 61. C. L.

NARIKARA (Norio) YUMOTO (Yoshika) OSAKA (Hiyoishi) & MAEDA (Toshimori). Intestinal Parasite Infections of Japanese and Formosan Chinese School Children in Taihoku City.—*Taiwan Igakkaï Zasshi* (*Jl Ved Assoc Formosa*) 1938. Oct. Vol. 37 No. 10 (403) [In Japanese pp 1581-1604 [45 refs.] English summary pp 1605-1606.]

Diagnosis was by examination of 8 smears from one stool passed by each person, 971 Japanese and 1,383 Formosan Chinese.

The material was concentrated by breaking up a few grams of faeces in about 10 cc. of normal saline centrifuging decanting and apparently repeating this process several times. A portion of the fine sediment thus obtained was examined in 6 smears 3 for helminths and 3 for protozoa. The Donaldson's eosin-iodine solution was also used for the identification of protozoan cysts. The percentage rates of infection found were for Japanese and for Formosan Chinese respectively: hookworm 1 2 2 Ascaris 22 25 53 56 Trichuris 22 14 37 78 Enterobius 1 65 1 54 Paragonimus 0 1 0 15 Metagonimus 0 21 0 *H. diminuta* 0 1 0 *H. nana* 0 0 0 7 *E. histolytica* 1 24 5 5 *E. coli* 3 39 8 29 *E. nana* 4 33 12 18 *I. blutschli* 0 31 0 81 *G. lamblia* 10 5 15 62 *T. hominis* 0 0 44

The results of this examination showed that the frequency of intestinal helminthic and protozoan infections of Formosan Chinese was much higher than that of Japanese but much less than that of Yokogawa and Wakushima a conclusion reported for several years ago. It demonstrates that the sanitary conditions of Formosan Chinese have been improved over these several years.

Hsu (H. F.) Studies on the Food and the Digestive System of Certain Parasites. II. On the Food of *Schistosoma japonicum* *Paragonimus ringeri* *Dirofilaria immitis* *Spirocerca sanguinolenta* and *Rhabdias* sp.—Reprinted from *Bull. Fox Mem. Inst. Biol. Zool. Ser.* 1933 Oct. 20 Vol. 8 No. 4 pp. 347-368 With 32 figs (8 coloured) on 15 plates

BACILLARY DYSENTERY AND INTESTINAL PROTOZOAL INFECTIONS*

PRICES OF ABSTRACTS IN THIS SECTION

LIPPELT (p. 596) found Targem a complex colloidal preparation of silver to have a marked inhibitory action on cultures of the Shiga-Kruse Flexner and Sonne strains of *Bact. dysenteriae*. It is well tolerated by animals and in a clinical trial on four patients with dysentery it gave good results.

DORRILL (p. 597) describes the life history of *Entamoeba coli* and the process of excystation. The large "trophic" amoebae reproduce by binary fission without any evidence of a sexual process such as has been described. He discusses nomenclature and decides that *Entamoeba coli* is the correct name. TYZZER and GEIMAN (p. 598) found that *E. coli* in a patient had ingested red blood cells. Careful examination showed that they were not *E. histolytica*.

BOUGHTON and BYRD (p. 598) found that mixed intestinal protozoal infections occur too frequently to be accounted for by mere chance whereas mixed flagellate infections do not. SANGIORGI (p. 598) KESSEL and SINTSIN (p. 599) and KOURI *et al.* (p. 599) report on surveys of intestinal protozoa.

MACKENZIE and BEAN (p. 599) cured by means of methylene blue in an enema, a patient with diarrhoea due to *Balantidium coli*.

* For amoebic dysentery see this *Bulletin* 1939 Vol. 36, pp. 281-305

DE PAULA E SILVA (p. 599) reports cure of 9 patients by the giving of a strict milk diet, and of another by the administration of peroxyd. HSIUNG (p. 600) shows that *Balanulium coli* and *B. suis* occur in the pig and FISHER (p. 600) found that almost all the pigs in a district in Hungary were infected by one or the other.

In Buenos Aires, BACIGALUPO (p. 600) states that *Iodamoeba* infection occurs in 26-67 per cent. of pigs and in 1 to 2 per cent. in man, but apparently the *Iodamoebae* are distinct and pigs do not infect man. MOLLARY and AURULOVIC (p. 600) report cure of a patient infected with *D. fragilis* by emetine and trepanol.

CICCHITTO (p. 601) describes abnormal forms of *C. mairii* and CIFERRI and REDAELLI (p. 601) discuss the systematic position of *Blastocystis*.

Giardia infections—NARIHARA (p. 601) has estimated the survival time of *Lambia* cysts subjected to the action of various reagents.

PONTORI (p. 601) reports a case of enteritis in which *E. histolytica* and *G. lamblia* were found. FOURNIER (p. 602) quotes two cases in which *lamblia* were found by duodenal tubage. They were not responsible for the symptoms of the patients however since one was a case of schistosomiasis and the other of chronic appendicitis. DESCHREES (p. 602) holds that *lamblia* may be harmless commensals or definitely pathogenic but that the finding of *lamblia* in bile obtained by duodenal tubage is no proof that the bile passages are infected.

Treatment by salvarsan is advocated by BREUER (p. 603) DE PAULA E SILVA (p. 603) and v. FRIEDRICH (p. 603) who all obtained good results. LERTE (p. 603) uses entero-vioform orally with success.

The remainder of the papers report on the treatment of *Giardia* infection with atabrin (or quinaquine which is the same thing). All agree that it is most efficient in curing the condition quickly. The usual doses (of about 0.3 mgm. daily for 5 days) are advised and the flagellates often disappear after a few tablets. FALLA ALVAREZ *et al* (p. 605) consider that as various gastro-duodenal and nervous symptoms disappear following atabrin treatment, there can be no doubt that *lamblia* are pathogenic.

C Wilcocks

LIPPELT (Heinrich) Ruhrbacillen und Targemin. (Dysentery Bacilli and Targemin. —*Klin. Woch.* 1938. Apr 30 Vol. 17 No. 18 pp 636-637 11 refs.)

There exists considerable doubt regarding the use of serum therapy in bacillary dysentery so that an efficient intestinal disinfectant becomes very desirable. Such a substance should fulfil two purposes —

1. It should act upon the actual micro-organism of the disease.
2. It should in no way damage the tissues of the patient.

Targemin is a complex colloidal combination of albumin with the diacetyl-tannic acid silver salt. It is found to have no appreciable action upon the mucous membrane of animals and is well tolerated when administered by the mouth. It appears to be a suitable substance for bacillary dysentery. Favourable results have been recorded in the treatment of stomach and intestinal disorders. Albuminate of silver and diacetyl-tannin have both been used in intestinal therapy. A combination of these two substances is particularly well tolerated, whilst their antispasmodic and antidiarrhoeic characters are specially valuable for the treatment of dysentery.

Experiments were made on cultures of Shiga Flexner and Sonne as well as members of the typhoid and *Proteus* groups. In a dilution of 1 10 000 it exerted a lethal action within five minutes. Experiments were conducted both at room temperature and at 37°C in the incubator.

The inhibitory effect of Targedin was especially marked in the case of the Shiga Kruse, Flexner and Sonne strains. The conclusion arrived at is that the substance is specially suitable for the treatment of bacillary dysentery and bears out the reputation Targedin has already acquired in gonococcal infections.

In man a therapeutic trial has been made in four dysentery cases (Y and Sonne) given in doses of two tablets by mouth three times daily with favourable results. A carrier of the infection was also successfully cleared of organisms.

CASILLANOS (Agustín) *Entero-colitis sanguinolenta*. Estudio general (Haemorrhagic Entero-Colitis).—*Vida Nueva* 1939 Jan 15 Vol. 43. No 1 pp 1-95. With 18 figs. on 8 plates.

DOBELL (Clifford) *Researches on the Intestinal Protozoa of Monkeys and Man IX. The Life-History of Entamoeba coli with Special Reference to Metacystic Development*.—*Parasitology* 1938 June Vol 30 No 2 pp 195-239 With 61 figs. on 3 plates. [34 refs.]

In this paper the author describes with his accustomed care the life history of *Entamoeba coli* based on the cultural study of strains isolated from the marmoset species of *Macacus* and man and the experimental transfer from one to another of these hosts. It is noted that as regards the encysted stages the nucleus with its coarser chromatin and eccentric karyosome is the chief feature distinguishing *E. coli* from corresponding stages of *E. histolytica*. As is well known the mature cyst contains eight nuclei but before excystation the enclosed amoebae frequently lose some of the nuclei, to the number of one to four. Excystation is brought about by the retraction of the cytoplasm from the double wall of the cyst the formation of pseudopodia which stroke the wall till finally a considerable tear is made and the escape through the rupture of the multinucleated amoeba which without any nuclear divisions such as occur in the escaped amoeba of *E. histolytica* ultimately divides into uninucleated amoebulae. It will be recalled that the four-nucleated amoeba of *E. histolytica* escapes from its cyst through a small pore. The uninucleated amoebulae grow into the large trophic amoebae which reproduce by binary fission. At no stage in the development was there any indication of a sexual process such as has been described by certain observers.

The paper is illustrated by 61 figures in black and white arranged in three plates. On the excellence of these and on the lucidity with which every detail of the life cycle is discussed and described it is unnecessary to comment as the high standard of the author's publications is familiar to all his readers.

At the end of the paper in a Memorandum on the Genus *Entamoeba* Opinion 99 of the International Commission on Zoological Nomenclature is seriously questioned. By the decision of the Commission it is laid down that *Entamoeba* is a synonym of *Endamoeba* which was a genus founded by LEIDY for an amoeba of the cockroach. It is

argued that by this decision both *E. coli* and *E. histolytica* are referred to the genus *Endamoeba* an impossible position as no one has ever attempted to prove that the two human amoebae belong to the same genus as the amoeba of the cockroach. In arriving at their decision the Commission is shown to have gone "beyond their competence" so that if Opinion 99 is accepted some other generic name will have to be found for the human amoebae. The author's conclusion is that those who write *Endamoeba coli* can do so with a clear conscience as Truth and Reason and even the International Code are on their side.

C. M. Wenyon.

TYZZER (Ernest E.) & GETMAN (Quentin M.) The Ingestion of Red Blood Cells by *Endamoeba coli* and its Significance in Diagnosis.—*Amer. J. Hyg.* 1938 Sept. Vol. 28 No. 2 pp. 271-287. With 35 figs. on 2 plates. [22 refs.]

In a case of intestinal obstruction due to a papillomatous polyp of the sigmoid a blood-streaked mucous discharge was observed and in it were seen numerous amoebae with included red blood cells. A careful study of the amoebae, including culture and inoculation of kittens, failed to provide any evidence of the existence of *Endamoeba histolytica*. Everything pointed to the amoeba being *E. coli* so that it became evident that this was a case in which *E. coli* was actively ingesting red blood corpuscles in the intestine. It is pointed out that if the presence of red blood corpuscles in the amoebae had been accepted without any further evidence as sufficient for the diagnosis of an *E. histolytica* infection a mistake would have been made which might have condemned the patient to an unnecessary and costly course of treatment.

The paper is illustrated by three dozen microphotographs showing the characters of the amoebae and their cysts. They leave no doubt as to the correctness of the conclusions drawn.

ROSAFELD (Gastón) O valor zoonológico da ameba coli. [The Significance of *E. coli*—Arch. Prazis de Med. Cirurg. y Especials. 1938 Feb. Vol. 1^o No. 2 pp. 157-159.]

BURGHT (Donald C.) & BYRD (Elton E.) On the Incidence of Mixed Infections with Intestinal Protozoa.—*Amer. J. Hyg.* 1938 Jan. Vol. 27 No. 1 pp. 88-94.

It is well known that in surveys of groups of people for intestinal protozoa a number of mixed infections always occur. By a statistical analysis of the results of two such surveys the authors have shown that the occurrence of mixed amoebic infections is too frequent to be accounted for by mere chance. The same remark applies, but less definitely, to mixed amoebic and flagellate infections, whereas mixed flagellate infections occur only as frequently as can be expected from a chance distribution.

VANGIORGI (G.) Forme rare di protozoi intestinali nelle Puglie. Rare Intestinal Protozoa in Puglie.—*Pathologica* 1938 Oct. 15 Vol. 30 No. 564 pp. 421-422. [13 refs.] English summary. (5 lines.)

In examinations of stools carried out in Puglie, Italy, the author has met with the following intestinal protozoa—*Endolimax nana*, *Endamoeba bütschlii*, *Dientamoeba fragilis*, *Pentastrichomonas intestinalis* and *Isofovea bigemina*.

C. M. W.

KESSEL (John F.) & SINTSYN (D.) A Survey of Intestinal Protozoa among Children and Adults in Los Angeles.—*Jl Parasitology* 1938 Oct Vol. 24 No 5 pp 433-436

The survey was based on the examination of 585 adults seeking work as kitchen employees in the Los Angeles County Hospital 753 adult clinic patients seeking medical attention for conditions other than gastro-intestinal in nature and 678 children from a Los Angeles City Juvenile Detention Home. In the first group six consecutive daily stools were examined while in the other two groups only a single one following a saline purge was examined. The findings are given in a table which separates the males from the females. The results resemble other similar surveys but show various minor variations which the authors indicate in their text. Of 2016 persons examined 33.7 per cent showed positive results. *E. histolytica* was found in 3.3 per cent. *E. nana* in 11.0. *D. fragilis* in 1.7 and *Giardia* in 4.8 per cent.

MACKENZIE (D. L.) & BEAN (H.) Balantidial Dysentery.—*Lancet* 1938, Jan 8 pp 84-85 With 2 figs

About six months after admission to the County Mental Hospital, Ramhill, a female patient 31 years of age was found to be suffering from diarrhoea due to *Balantidium coli* infection. In attempts to stain the living ciliates with Löffler's methylene blue it was observed under the microscope that as they took up the stain their movements ceased. Accordingly the case was treated by running into the large intestine two pints of the stain after the colon had been washed out. The treatment was repeated the next day. Free ciliates were no longer found but gradually diminishing numbers of cysts were passed for a fortnight when the treatment was repeated. No further ciliates or cysts could be detected. The source of the infection could not be traced there having been no association with pigs. The statement made by the authors that infection may occur through eating diseased flesh is incorrect.

C M W

DE PAULA E SILVA (Geraldo Siffert) Balantidíase humana aspectos clínicos e terapêuticos. [Balantidial Infection.]—*Brasil-Médico* 1938, Nov 5 Vol. 52, No 45 pp 1005-1015 With 2 charts [31 refs.] English summary

Two cases of balantidiosis are detailed and the author refers to eight others in which after the usual forms of treatment by yaler emetin etc. had proved unavailing the giving of a strict milk diet, 350 cc. six times a day was followed soon in all but one by

disappearance of the parasite and of the clinical signs. In the exception there was clinical improvement, though the protozoon could still be seen on faecal examination. To this patient paroxyl (4-oxo-3-acetylamino-phenylaridic acid) was given the diarrhoea ceased and the *Balantidia* could no longer be seen. H H S

HSIUNG (Tsuen) Biometrische Untersuchungen an den *Balantidien* des Schweines in der Kultur [Biometric Studies on Pig *Balantidia* in Culture.]—*Ztschr f Parasitenk* 1938. Apr 2. Vol. 10 No 1 pp. 108-131 With 3 figs. [29 refs.]

Biometric studies on various races of *Balantidia* from pigs have shown that McDONALD's contention made in 1922 that two species of the ciliate occur in these animals is correct. These are *Balantidium coli* and *B. suis* the former being of larger average dimensions than the latter. C M IV

FÜSTHY (O) Untersuchungen ueber das Vorkommen der *Balantidiosis* in Ungarn [Incidence of *Balantidial* Infection in Hungary]—*Zent f Bak* I Abt. Orig. 1938 Aug 18. Vol. 142. No 3/4 pp. 133-137

Working in Hungary the author has found that practically every pig in the district examined is infected with *Balantidium*, of which two species *Bal. coli* and *Bal. suis* are present. An examination of 160 persons revealed an infection in only one individual 65 years of age. This infection, which gave rise to no symptoms, was undoubtedly acquired through contact with pigs. C M IV

BACIGALUPO (Juan) Algunas consideraciones sobre la *Iodamoeba butschlii* [Notes on *Iodamoeba butschlii*]—*Rev Med. Trop y Parasit Habana* 1938 May-June Vol 4 No 3 pp 141-146 With 2 figs on 1 plate

It is found that *Iodamoeba* infection occurs in 23-67 per cent. of pigs in Buenos Aires. It is evidently a common infection in these animals as it has been found in all countries in which it has been looked for. As regards human beings in Buenos Aires the *Iodamoeba* infection rate varies from 1 to 2 per cent. There is no relation between infection and occupation, certain individuals who have tended pigs for 20 years being free from infection. Attempts to infect pigs with cysts of human origin failed, though success was obtained with cysts from infected pigs. It seems that though the human and pig *Iodamoeba* are identical morphologically they are actually distinct so that pigs play no part in the spread of the human infection. C M II

MOLLARI (Mamo) & ANZULOVIC (J V) Cultivation and Pathogenicity of *Disentamoeba fragilis* with a Case Report.—*JL Trop Med & Hyg* 1938 Aug 1 Vol 41 No 15 pp 248-247

From the stools of a case of repeated intestinal haemorrhage associated with thickening in the right iliac region an amoeba identified as *Disentamoeba fragilis* was cultivated. It was maintained for 180 sub-cultures. In stained films only unimaculate amoebae were seen. The patient who had been ill for a long time was treated with emetine.

hydrochloride and treparsol for four days. A week later the course was repeated. The result was an immediate improvement followed by disappearance of the infection and return to good health. C M W

CICCHITTO (Angelo M) Su alcune alterazioni morfologiche del *Chilomastix mesnili* [Morphological Changes in *Chilomastix mesnili*]—*Ann d Igiene* 1938 Sept-Oct Vol 48. No 9-10 pp 548-554 [14 refs.]

The author describes an infection due to *Chilomastix mesnili* and notes that the flagellates are often of an abnormal or amoeboid form. He considers the possibility of the flagellate being a new species but very wisely concludes that it is actually *C. mesnili*. As a matter of fact the forms described by the author are of very common occurrence and are well known as deformed specimens to those who have experience of the flagellate. A plate in black and white illustrates the various types referred to. C M W

CIFERRI (R.) & REDAELLI (P) A New Hypothesis on the Nature of Blastocysts—*Myopathologia* The Hague 1938. May 9 Vol. 1 No 1 pp 3-6 [34 refs.]

This is a discussion of the systematic position of *Blastocystis* which everyone nowadays regards as a vegetable organism of a fungoid nature. The authors conclude that it has affinities with the unicellular achloric Autosporineae amongst the algae and they propose including them in the family Protothecaceae Printz amongst the Oöcystaceae.

PONTONI (L.) Dictosarcomatosi (reticulosarcomatosi) regionalizzata e tubercolosi delle linfoghiandole mesenteriche in lambliaoamebiasi [Generalized Reticulosarcoma and Tuberculosis of Lymphatic Glands associated with Giardial and Amoebic Infection.]—*Patologica* 1937 Oct 15 Vol. 29 No 532 pp 415-424 With 6 figs. on 2 plates. [35 refs.] English summary (5 lines)

The paper describes a complicated case of enteritis associated with enlargement of the mesenteric glands and infection with *Eutamoeba*

histolytica and *Giardia lamblia*. At autopsy a follicular enteritis was discovered while microscopical examination of the glands revealed both tubercular and malignant changes. The relationship of the pathological condition to the protozoal infections is discussed.

C M IV

FOURQUER (J) A propos des manifestations extra-intestinales de la lambliose. [Extra-Intestinal Manifestations of *Giardia* Infections.] —*Bull Soc Path Exot* 1938 Oct 12 Vol. 31 No 8. pp 716-720.

The author comments on the modern tendency of many physicians to attribute all manner of symptoms to the presence of *lamblia* in the intestine. The procedure of duodenal tubeage which is practised with increasing frequency is bringing to light many infections which otherwise would have remained undetected, while the presence of flagellates in the bile withdrawn from the duodenum is regarded as sufficient evidence of the invasion of the biliary passages and gall bladder by the flagellates. It is pointed out that there is little justification for this last conclusion. Without denying any pathogenic properties to the *lamblia* under certain conditions, the author quotes two cases which are most instructive in this connexion.

The first case, from Shanghai, was that of a child 8 years of age suffering from hypertrophic cirrhosis of the liver, splenomegaly and ascites. All the usual investigations gave no clue to the cause of the condition till duodenal tubeage revealed an enormous *lamblia* infection. The local medical men were inclined to see in this infection the cause of the trouble. Further faecal examinations were made and finally eggs of *Schistosoma japonicum* were found and the diagnosis established.

The second case was that of a French soldier in Shanghai who suffered from attacks of pain in the right hypochondrium. The pain extended over the abdomen, while the liver was abnormally sensitive. In this case examination of the stools revealed only *lamblia* cysts, while by duodenal tubeage enormous numbers of the flagellates were shown to be present in the duodenum. Various treatments were tried to rid the patient of his *lamblia* infection but without result. Finally administration of quinacrine (atebrin) proved successful and the flagellate infection was eradicated. The symptoms, however persisting, surgical interference was advised. There was thus discovered a chronically diseased appendix which was retrocaecal in position and situated high up in the abdomen.

In both these cases there had been an inclination to attribute the symptoms to a *lamblia* infection and in both it was possible to discover the cause to be quite of another nature.

In a discussion following the presentation of the author's paper M. R. DESCHAMPS emphasizes the author's point of view and notes that, as in other intestinal protozoal infections, the *lamblia* may be present as harmless commensals on some occasions while on others they may be definitely pathogenic. He agrees that their presence in bile obtained by duodenal tubeage is not proof of invasion of the bile ducts or gall bladder.

BREUER (Anneliese) Die Symptomatologie und die Behandlung der Lamblien Infektion des Menschen. [Symptomatology and Treatment of Giardia Infection in Man.]—*Arch f Schiffs u Trop Hyg* 1938. May Vol. 42. No 5 pp 201-222. With 3 figs. [93 refs.]

This is a long paper based on 104 cases of lamblia infection studied at the tropical convalescent home at Tübingen from 1929-1937. An extensive literature of the subject is reviewed and a long list of references given. Of the cases treated 26 became free of infection while 38 though cured clinically still harboured the flagellate. From the point of view of treatment the best results were obtained with arsenicals—spirocid or salvarsan. In some cases it was difficult to gauge the pathogenicity of the flagellate which occurred in 20 per cent of the cases without any symptoms and in 50 per cent in association with amoebae. C M II

DE PAULA E SILVA (Geraldo Siffert) Novos estudos sobre a giardíase [New Studies on Giardia Infections.]—*Brasil Medico* 1938. Jan. 15 Vol. 52. No 3 pp 67-73 [11 refs.]

The author who considers that *Giardia lamblia* is pathogenic and parasitizes not only the duodenum but also the biliary passages, describes the symptoms which he attributes to this flagellate infection and the successful treatment of thirty three cases by injections of full doses of neosalvarsan followed by the oral administration of stovarsol and in some cases yatren. C M III

1. FRIEDRICH (L.) Die pathogenetische Bedeutung der *Lamblia intestinalis* [Pathogenic Importance of *Giardia lamblia*]—*Klin Woch* 1938. Apr 23 Vol. 17 No 17 pp 605-608

This is a long discussion on the pathogenicity of *Giardia lamblia* from which it is concluded that every sick person found to be harbouring the flagellate must be energetically treated. There is no certain cure for the condition the best results being obtained by intraduodenal introduction of salvarsan and duodenal lavage. C M IV

LEITE (Moacyr Renault) Tratamento da cholecistite de origem lambliótica. [Treatment of Cholecystitis due to Giardia Infection.]—*Folha Med* 1937 May 15 Vol. 18. No 14 pp 220-222.

The author assumes that certain cases of cholecystitis are due to lamblia infections as proved in his opinion by the discovery of flagellates in material collected by duodenal tubage. To treat the condition he has employed entero-vioform (iodo-chlor-oxyquinolin) orally. Three tablets (each containing 0.25 gram) are given daily. Successful results are reported. C M IV

GALLI VALERIO (B.) La lamblíase et son traitement par l'atébrine [Atebrin Treatment of Giardia Infections.]—*Schweiz Med Woch* 1937 Dec 11 Vol. 67 No. 50 pp 1181-1182. [19 refs.]

The author believes that the good results he has obtained in the treatment of lamblia infections by oral administration of atebriin have completely solved the difficult problem of the chemotherapy of this condition. C M IV

MARTIN (Pierre) Le traitement de la lamblïase par la quinacrine. Résultats d'une expérience de près de deux années. [Quinacrine Treatment of *Giardia Infection*.]—*Rev Méd et Hyg Trop* 1938. Jan.-Feb. Vol. 30 No 1 pp 32-39

Since GALLI VALERIO first announced the successful treatment of lamblia infections with atabrin a number of observers have reported favourably on the action of the drug. In the present paper the author reviews the literature on the subject and gives an account of his own experience of the use of quinacrine, the French equivalent of atabrin. He reports that the drug, orally administered, cures patients of both lamblia and trichomonas infections and that when given in solution as a vaginal douche it is active against *Trichomonas vaginalis*.

C M H

TANGUY (J.) Traitement de la lamblïase par la quinacrine. [Treatment of *Giardia Infection* with Quinacrine.]—*Bull Soc Path Exot* 1937 Oct. 13 Vol. 30 No 8 pp 683-694

The author writes in favour of quinacrine as a remedy against lamblia infection. The treatment consists in taking by the mouth three times a day at meal times for five days a tablet of 0.1 gram of the drug. After a rest of five days the course is repeated. This is done a third or even a fourth time if necessary. The statement is made that the drug is as active against the cysts as against the free forms, a remark which seems to imply that the cysts and free forms represent separate infections. It would be equally logical to state that in an ankylostome infection a drug was active against the eggs as well as against the worms. In all such cases a drug which destroys the free forms will lead automatically to disappearance of cysts & eggs, since there are no longer any free forms to produce them. C M H

HELMANN (Karl) Die Behandlung der Lambliosis mit Atebrin. [Treatment of *Giardia Infections* with Atebrin.]—*Munch Wch* 1938 Oct 21 Vol. 85 No. 42 pp. 1628-1629. [14 refs.]

The author has successfully treated a series of thirteen cases of lamblia infection by oral administration of atabrin. Relatively small doses such as 0.1 to 0.2 gm. three times a day for three days are usually sufficient to get rid of the flagellates. The results are superior to those obtained by intravenous injections of neosalvarsan, which was also tried in a series of cases.

C M H

GRUENZ (Paul) Zur Therapie der Lambliosis. [Therapy of *Giardia Infections*.]—*Wien Klin Wch* 1938 June 3 Vol. 51 No 22 pp 605-606. 13 refs.

The author writes in favour of the atabrin treatment of lamblia infections, which is not only easy to carry out and free from danger but also certain in its results.

C M H

PURGES (O.) Zur Symptomatologie und Therapie der Lambliosis. [Symptomatology and Therapy of *Giardia Infections*.]—*Med Klin* 1938 Apr 29 Vol. 34 No 17 (1740) pp 580-582.

For the treatment of lamblia infections which are discussed at length in the paper the author advocates a five-day course of atabrin.

followed by a daily dose for a month of dermatol (bismuth subgallate) and a six months régime of food which is poor in cellulose and the avoidance when symptoms referable to gall bladder trouble are present of all highly seasoned and irritating food and drink.

C M W

ROMANO (Nicolas) REY (Simon) & MEILLER (Enrique) *Giardiasis intestinal formas clinicas y tratamiento* [Treatment of Giardia Infections.]—*Prensa Méd Argentina* 1938 Sept 14 Vol. 25 No 37 pp 1725-1730 [44 refs.]

In a series of 800 cases in which duodenal tubage was practised lamblia infection was detected in 80. It is concluded that the flagellate is definitely pathogenic but that if it ever invades the biliary passages it does so only exceptionally. As regards various treatments that have been tried these were far from satisfactory till atabrin was employed. In the first case a remarkable result was obtained and this was followed by the successful treatment of twenty further cases. Atabrin thus affords an easy and ready means of destroying the flagellates which often disappear after the first dose of two tablets of the drug.

C M W

BACIGALUPO (Juan) *Algunas consideraciones sobre giardiasis y su tratamiento.* *Giardia Infection and its Treatment.*—*Arch Argentinas Enferm Aparato Digest y Utric* Buenos Aires 1937 Oct.-Nov Vol 13 No 1 pp 5-16. [16 refs.]

The paper describes the treatment of a number of cases of lamblia infection by the oral administration of atabrin. It is claimed that the drug is extraordinarily efficacious in eradicating infections with this flagellate.

C M W

FALLA ALVAREZ (Laureano) SILVEIRA (Rafael) & BERNARDINO (Santiago) *El tratamiento de la lamblasis por la atabrina. Consideraciones clinicas y terapeuticas.* [Atabrin Treatment in Giardia Infections.]—*Ida Nueva* 1938 May 15 Vol 41 No. 5 pp 320-330 [19 refs.] English summary

The authors point out that various gastro-duodenal and nervous symptoms are attributable to lamblia infections for which hitherto no specific remedy was available. The loss of the infection, and with it the disappearance of symptoms following atabrin treatment would appear to settle once for all any doubts which exist regarding the pathogenicity of these flagellates.

The paper gives notes of 25 cases of lamblia infection which were cured by oral administration of atabrin. C M W

REVIEWS AND NOTICES.

ROGERS (Leonard) [K.C.S.I., C.I.E. LL.D. M.D. B.S. F.R.C.P., F.R.C.S. F.R.S. etc.] & MEGAW (John W. D.) [K.C.I.E. B.A. M.B. Hon D.Sc. (Queen's University Belfast) etc.] *Tropical Medicine*. Third Edition—pp xii+544 With 2 coloured plates & 87 text figs 1939 London J & A. Churchill Ltd., 104 Gloucester Place Portman Square [16s.]

The third edition of this standard text-book maintains the same order as previous editions. Certain diseases in the order of their exposition, are classified rather on account of the symptoms and signs they produce than on account of the aetiological agents. Thus amoebic hepatitis is included with malaria kala azar and trypanosomiasis in the section on febrile diseases caused by protozoa, but amoebic dysentery is in the section of bowel diseases with symptoms of dysentery and diarrhoea, and oriental sore is in the section dealing with diseases with the most prominent lesions on the surface of the body.

The historical introductions to the diseases have been retained and give the student an idea of the immense progress in the understanding of tropical disease which has taken place in the last half century. Although the number of pages is about the same as in the second edition, a considerable amount of new material has been added, permitted partly by excision and partly by an increase in the letter press on each page though the type is unchanged.

Much recent work is mentioned, for instance the sulphanilamide treatment of undulant fever the treatment of plague with human convalescent serum, and the nicotinic acid treatment of pellagra. Justice is done to recent work on the complex bacteriological problem of cholera, the use of vaccines of living avirulent plague bacilli in Java and Madagascar is mentioned, and the modern conceptions of yellow fever and jungle yellow fever are set out. Crowden's work on the heat insulation of buildings is referred to. The treatment of malarial splenomegaly by adrenalin after the manner of Ascoli is not mentioned however nor is Henry's melanoflocculation test for that disease though it is referred to in kala azar. The section on diseases caused by venomous animals is, as before, confined to snakes.

The classification of the typhus group of fevers according to the vectors has been retained and is undoubtedly the most useful, and a brief account of trench fever not as a member of this group but as a disease regarded as caused by a Rickettsia body has been added. Dengue and sandfly fever are again classed as mosquito dengue and sandfly dengue which makes for clarity. A fuller list of vitamin-containing foodstuffs is given.

The useful sections on general diseases in the tropics are retained and serve to remind students that their interest should not be centred

too exclusively on tropical diseases *sensu stricto*. This is especially so in the case of tuberculosis which is becoming more and more of a problem throughout the hot countries of the world.

The sections on the use of the microscope and on case taking are again included and throughout the diagrammatic representations of the phases of diseases introduced into previous editions are continued.

The book is more than a text-book, it is a work of reference which will be valuable to any practitioner in the tropics as the rapid exhaustion of the second edition shows and it possesses a distinction arising from the fact that the authors who have already assumed their place in the history of British tropical medicine write with the first-hand knowledge acquired during many years of practical experience and enquiry

C IV

SHATTUCK (George Cheever) [Harvard School of Public Health] with the collaboration of Joseph C. BEQUAERT Jack H. SANDGROUND Margaret M. HILFERTY & Samuel Drury CLARK. *A Medical Survey of the Republic of Guatemala.*—pp xi+253. With 76 tables 5 graphs 2 plates (maps) & 1 fig. 1938. Washington. Carnegie Institution of Washington.

This medical survey organized and directed by the Department of Tropical Medicine of the Harvard School of Public Health was carried out in 1932 under the auspices of the Carnegie Institution of Washington. It is, as may be surmised a well-documented survey containing no less than 76 tables and will doubtless be for many years the chief source of information for English readers on medical matters in Guatemala.

The population of Guatemala estimated at 2½ millions consists as to 65 per cent. of Indians and 35 per cent. of Spanish-Indians called ladinos or Latins.

Dr Shattuck writes on the infectious diseases, including malaria leishmaniasis syphilis and yaws and other topics such as anaemia in the highlands goitre pulse rates and blood pressures.

Dr Hilferty deals with statistics Dr Sandground with helminthic infections Dr Bequaert with arthropods and the distribution of *Phlebotomus* in South and Central America. Dr Clark has a short chapter on the diseases of the Peten District. Latins have higher birth-rates and death-rates than Indians but this may be due to better reporting.

As to the history and probable origin of the infectious diseases of Guatemala yellow fever was first recorded in 1859 and the last epidemic was in 1924. Tests show the presence of resistant individuals. Cholera has not been seen since 1857 and plague has never been established. Shattuck believes that nearly all the more deadly epidemic diseases known in the New World since its discovery by Columbus have been imported from the Old World within historic times.

A study of 812 patients examined in the highlands is tabulated. It includes 29 pellagrins. The study was designed to throw light on the prevalence of syphilis of which 28 cases were recognized. The chief problem of the Peten District is the prevalence of chancro ulcer a form of leishmaniasis acquired by the gatherers of the basic material of chewing gum. Malaria is a major sanitary problem. *A. albimanus* is the most dangerous vector. Leishmaniasis in America is fully

discussed. The presence of autochthonous cases was not recognized with certainty till 1909 when the causal organisms were found. There is a close correlation between its distribution and that of species of *Phlebotomus* which bite man. No case of visceral leishmaniasis has been found. Syphilis is treated at some length. A positive diagnosis was made in twice as many Latins as Indians and the portion of complete clinical latency was high in both races. Shattuck did not encounter yaws, but it has been reported.

In regard to the helminthic infection of Guatemala all the cosmopolitan parasites are present and both species of hookworm but no *Wuchereria bancrofti* or *Schistosoma*. According to table 78 reproduced from a Guatemalan journal ankylostomiasis is second on the list as a cause of death, coming between malaria and pneumonia. The source of *Onchocerca volvulus* in this country is not clear. It is not found elsewhere in Central and South America.

In the concluding chapter by Dr. Shattuck in which health problems are discussed the activity of the Health Services is apparent. Smallpox is so well controlled by vaccination that the mortality from it is no longer significant. The book is indexed and contains two useful maps.

SUMMARY OF RECENT ABSTRACTS

VII HELMINTHIASIS *

General

SCOTT and HEADLEE (p. 672) as a result of a study of the weights of series of consecutive stools consider that correction of helminth egg count figures for the consistency of the stools is unnecessary but hold that in published papers the figures for both corrected and uncorrected data should be made available for comparison with other work.

In the examination of stools for helminth ova GALLIARD *et al* (p. 267) find a double gravity precipitation technique superior to sugar Telemann's and Garin's methods. LEE (p. 216) employs an enrichment fluid of acetic and hydrochloric acids formal and distilled water with which faeces are mixed before centrifuging.

ARTIGAS (p. 218) uses a mastic-cresote fluid after treatment with acetic acid and cresote for the mounting of helminths and small arthropods.

HUKUDA and AKI (p. 218) report that ordinary rinsing does not remove the various ova found on *Tukemona* sold in markets.

HALPÉRINE (p. 670) shows that rise of temperature and loss of moisture in a mixture of faeces and peaty material causes destruction of *Ascaris* and *Trichuris* eggs.

COCHAUX (p. 669) describes *nzadi* or *lupusu* as a syndrome of heavy hookworm or *Ascaris* infection combined with avitaminosis.

The following list of the percentages of helminthological findings detected in surveys by the use of methods of varying accuracy has been constructed from the abstracts in this section —

* The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938 Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

Translodes.

Schistosomiasis—In the Sudan (p. 266) it is reported that infection with schistosomes has declined remarkably during the last ten years.

DOWDESWELL (p. 590) found *Physopsis nasuta* and *Bulinus forskali* to be hosts of *S. haematobium* in Kenya. *Ph. nasuta* is the host for *S. bovis*. ZAVATTARI (p. 665) shows that the distribution of *Bulinus contortus* and vesical schistosomiasis in Libya correspond. In India DE NELLO (p. 596) considers *Melanoides tuberculatus* and *Limnaca luteola pinguis* to be hosts of *S. haematobium* and describes an autochthonous human case.

SHAW and GHAREEB (p. 665) draw attention to the importance of pulmonary damage in schistosomiasis. In 282 autopsies on persons infected there were lesions in the lungs of 33 per cent and in 2 per cent these were the cause of death. Embolism by ova from extra pulmonary worms may cause parenchymatous tubercles in which the ova escape from the arterioles. focal arterial lesions consisting of necrosis of intima and media following impaction with capillary formation and hypertrophy of the proximal muscle coat and Ayerza's disease consisting of rows of tubercles in the lumen of the vessels caused by repeated embolisms. The latter gives the appearance of strands of silver wire throughout the lungs and the lesions result in hypertrophy of the right heart. In 10 instances the actual worms were found in the pulmonary vessels.

MAKAR (p. 268) describes the appearances of congestive and atrophic lesions of schistosomiasis in the prostatic urethra as seen through the urethroscope. From a study of the literature BOGLIOLO (p. 260) concludes that *S. haematobium* is found unusually often in cancer of the bladder which is probably caused by the irritation of the eggs. *Cysticercus fasciolaris* and adult *Gongylonema neoplasticum* are associated with cancer in animals.

With reference to treatment by foudin DIAMANTIS (p. 599) reports the death of a child treated for *S. haematobium* infection. The death was due to antimony poisoning and he estimates that 2 000 persons are killed by antimony poisoning every year in Egypt. Since tartar emetic is largely used in treatment the author disagrees with the suggestion advanced by KHALIL of examining the urine for pyrocatechin (contained in foudin) as a measure of tolerance. It is also not certain that the proportions excreted by bowel and kidneys are constant. The author advises that no more than four antimony injections be given in all amounting to 0.18 gram of antimony and thereafter emetine should be administered.

GAUNDER (p. 220) suggests that foudin may have the effect of lessening the clotting power of the blood and that therefore operations should not be performed until at least four weeks after the completion of a course of this drug.

SERRA (p. 219) reports good results in the treatment of 15 cases of intestinal and vesical schistosomiasis by dicuprene intravenously, paludex orally and a combination of the two but prefers oral paludex. CAWSTON (p. 599) failed to cure two patients by administering cuprochin by the mouth.

KHALIL and AZIM (p. 665) show that the introduction of perennial irrigation in Egypt has resulted in an enormous increase in the number of infections by *S. haematobium*. Canals are now to be cleaned yearly, outflows to drains are to be made and dead ends abolished. BUCHANAN

Trematodes

Schistosomiasis—In the Sudan (p. 266) it is reported that infection with schistosomes has declined remarkably during the last ten years.

DOWDESWELL (p. 595) found *Physopsis nasuta* and *Bulinus forskali* to be hosts of *S. haematobium* in Kenya. *Ph. nasuta* is the host for *S. bovis*. ZAVATTARI (p. 665) shows that the distribution of *Bulinus contortus* and vesical schistosomiasis in Libya correspond. In India DE MELLO (p. 596) considers *Melanoides tuberculatus* and *Limnæa luteola pinguis* to be hosts of *S. haematobium* and describes an autochthonous human case.

SHAW and GRAKEEB (p. 665) draw attention to the importance of pulmonary damage in schistosomiasis. In 282 autopsies on persons infected there were lesions in the lungs of 33 per cent and in 2 per cent these were the cause of death. Embolism by ova from extra-pulmonary worms may cause parenchymatous tubercles in which the ova escape from the arterioles. focal arterial lesions consisting of necrosis of intima and media following impaction with capillary formation and hypertrophy of the proximal muscle coat and Ayerza's disease consisting of rows of tubercles in the lines of the vessels caused by repeated embolisms. The latter gives the appearance of strands of silver wire throughout the lungs and the lesions result in hypertrophy of the right heart. In 10 instances the actual worms were found in the pulmonary vessels.

MAKAR (p. 268) describes the appearances of congestive and atrophic lesions of schistosomiasis in the prostatic urethra as seen through the urethroscope. From a study of the literature BOGLIOLO (p. 266) concludes that *S. haematobium* is found unusually often in cancer of the bladder which is probably caused by the irritation of the eggs. *Cysticercus fasciolaris* and adult *Gongylonema neoplasticum* are associated with cancer in animals.

With reference to treatment by foudan DIAMANTIS (p. 599) reports the death of a child treated for *S. haematobium* infection. The death was due to antimony poisoning and he estimates that 2,000 persons are killed by antimony poisoning every year in Egypt. Since tartar emetic is largely used in treatment the author disagrees with the suggestion advanced by KHALIL of examining the urine for pyrocatechin (contained in foudan) as a measure of tolerance. It is also not certain that the proportions excreted by bowel and kidneys are constant. The author advises that no more than four antimony injections be given in all amounting to 0.18 gram of antimony and thereafter emetine should be administered.

GMINDER (p. 220) suggests that foudan may have the effect of lessening the clotting power of the blood and that therefore operations should not be performed until at least four weeks after the completion of a course of this drug.

SERRA (p. 219) reports good results in the treatment of 15 cases of intestinal and vesical schistosomiasis by dicuprene intravenously, paludex orally and a combination of the two but prefers oral paludex. CAYSTON (p. 599) failed to cure two patients by administering cuprochin by the mouth.

KHALIL and AZIM (p. 665) show that the introduction of perennial irrigation in Egypt has resulted in an enormous increase in the number of infections by *S. haematobium*. Canals are now to be cleaned yearly outflows to drains are to be made and dead ends abolished. BUCHANAN

(p. 594) shows that mechanical pumping of water into irrigation canals in Egypt tends to ensure a continuous supply of snails into them and results in the over watering of the canals and the creation of a sluggish current. On the other hand, the older methods of waterwheels or counter balanced buckets, which are operated by man or animals, allow the canals to dry between waterings. The seasonal variation in venereal disease is apparently related to the falling of the Nile which leaves pools and stagnant creeks or to lowered resistance due to overwork, malaria or underfeeding. He (p. 595) holds that the first essential in prevention is the provision of wells, and the second is to find a suitable type of latrine. The key to the problem is sanitation rather than medication. In the Sudan (p. 286) the chief measures of control consist of the protection of canals against fouling, the provision of good deep wells and the treatment of cases. Villages should be placed not less than 300 metres from canals. Canals should be fenced. Latrines should be provided. The cooperation of the natives however still lags behind the efforts of the Government and the influx of labourers from outside is a danger since it is difficult to examine and treat these people efficiently.

KHALIL and AXIM (p. 667) describe how the use of copper sulphate in a concentration of 5 parts per million acting for 5 days in streams and canals of an oasis, combined with a campaign of tartar emetic injections, eliminated new infections and caused *Bilharzia* to disappear though *Melania tuberculata* and *Limnaea truncatula* persisted. The area under cultivation, which can be taken as a measure of the working capacity of the inhabitants, increased by 25 per cent. as a result. In discussing water supplies WITENBERG and YORK (p. 600) show that chlorine is the only agent which can be depended upon in practice to kill the cercariae of schistosomes and chloramine is its most effective form. Alum precipitation does not affect them and sand filtration will not hold them back. Ten minutes after chlorination the concentration of chlorine should be —For gaseous chlorine 0.6 per million for sodium hypochlorite 0.42 for chloramine 0.22. The water should not be used for 30 minutes after chlorination.

MAKAR (p. 267) found coupled schistosomes in the wall of a gall bladder removed at operation in Egypt. This is believed to be the first time that biliary cholecystitis has been reported during life. Ova of *S. haematobium* were found in the urine and of *S. mansoni* in stool. STEIN (p. 598) found schistosome eggs, believed to be terminal spined in the gall bladder and liver of a Bantu native in South Africa.

SCOTT (p. 596) considers the regularity of the output of eggs by *S. mansoni* to be constant enough to justify the use of the dilution egg count method as in studies of *A. duodenale*. The egg output is less variable when expressed as eggs per cc. of stool than as eggs per unit of time usually *per diem*. Stoll's method was used. The figures quoted in the original abstract however indicate considerable variations between maximum and minimum findings in the same patient and in the relative frequency of eggs of *A. duodenale* and *S. mansoni*.

DOWDESWELL (p. 595) considers that *Planorbis stanleyi* Smith is the intermediate host of *S. mansoni* in Central Kavirondo, Kenya.

VAN DEN BERGHE (p. 219) shows that *S. mansoni* may not be limited to the network of the inferior mesenteric vein. Solitary females may be found alone in the veins near the bowel, but in the liver solitary males are more common. Paired worms are found in the large mesenteric arches, and the worms may inhabit any part

of the portal system POYS (p 597) believes that there are two types of infection with *S. mansoni* hepatosplenic and intestinal with an initial stage common to both This consists of a febrile reaction with abdominal symptoms cough and eosinophilia The second stage is chronic and the pathological reaction is fibrosis In the intestinal type there are dysenteric episodes with enlargement of the liver and spleen In the third stage that of cirrhosis the hepatosplenic form cannot be distinguished from Banti's disease and the intestinal form tends towards obstruction of the bowel PERDOMO HURTADO (p 598) reports the case of a boy with cysts of *E. histolytica* and eggs of *S. mansoni* in the stool and enlargement of the liver Emetine and iatren were not effective in four days but under foudadin the condition quickly improved.

KOPRISCH (p 268) describes *S. mansoni* infection in the rabbit and rat. The changes are not the same as those in man but this may be due in part to the fact that the animals were given a single infection whereas man is usually subjected to repeated infections

MULLER and TESCH (p 218) report the first autochthonous case of infection with *S. japonicum* in the Celebes. WU (p 597) finds that in China cattle are significant in the spread of *S. japonicum*. For oxen an average of 12.6 per cent and for buffaloes 18.7 per cent. were found infected by liver examination.

TERANGUI and MASILUGAN (p 594) found that the sera of various vertebrates (except cat and rabbit) possessed marked cercaricidal properties against the cercariae of *S. japonicum* the titres of warm-blooded known hosts were low those of susceptible cold blooded vertebrates high The titre of the serum of infected guineapigs was much higher than that of normal guineapigs.

CHU (p 268) states that *S. japonicum* is the cause of about 20 per cent of cases of cirrhosis of the liver in Nanking Moderate anaemia is common and high eosinophilia and leucocytosis are important in diagnosis Tartar emetic is the most useful drug foudadin is only effective in very large doses and neostibosan is useless.

Other Trematodes—HUECK and WEN HUAN HUI (p 601) report that of 24 persons infected with *C. sinensis* and treated with foudadin 10 became negative for ova. SHIMIZU and KAWADA (p 269) report that in Japan measures for the prevention of infection by *C. sinensis* include the keeping of ducks infected with *Notocotylus attenuatus* These infect snails (*B. striatulus japonicus*) and render them sterile In two villages the numbers of snails have markedly decreased as the result of the application of this measure during several years. Again, paradise fish destroy the snails and are bred for that purpose and further measures include health propaganda by lectures and cinematograph displays.

LA RUE and AMEEL (p 220) show that the normal definitive host of *Paragonimus* in North America the mink has disappeared from many parts of its former range as the result of trapping The crayfish is present over a large part of the same range however but the snail *Pomatiopsis lapidaria* is still unknown from a large part of the area occupied by mink and crayfish and it is the snail which is evidently the most important factor in limiting the distribution of *Paragonimus*.

MORI (p 220) traces the course of *P. westermani* in experimental animals used as definitive hosts and believes that larvae pierce the small intestine penetrate the diaphragm (through the liver if necessary) to the lungs pulmonary vessels or bronchi. Some may reach the

lungs by the blood stream. WANG and HSIEN (p. 602) find that the X-ray appearances of paragonimiasis are multiple, fairly well circumscribed, usually isolated patches of infiltration in various parts of the lung field. They provide presumptive evidence only but when found in cases in which there is an atypical history of tuberculosis with sputum negative for tubercle bacilli, paragonimiasis should be suspected even if no ova are found.

AFRICA *et al* (p. 601) report the finding of *Heterophyes heterophyes* and *Monorchotremas taihokis* in scrapings of the intestine from a dead Filipino. Eggs were found in the myocardium and spinal cord. The authors also report heterophyid eggs in the heart muscle in another case, and a cellular response typical of that condition but without eggs in a third. Adults were found in the intestine and eggs in the calcified mitral valves of both of the latter. ALICATA and SCHATTENBURG (p. 601) in Hawaii describe a case of infection with a heterophyid *Stellantchasmus falcatus* the fresh water mullet *Mugil cephalus* is probably an intermediate host.

KUANG WU (p. 221) reports that metacercariae of *Fasciolopsis buski* have been found on two new plants, *Salvinia natans* and *Spirodela (Lemna) polyrrhiza* which are common in the endemic area of Chekiang. WU (p. 299) found that *F. buski* developed to maturity in pigs and rabbits and that immature worms were present in dogs and a young buffalo after feeding with cysts. Other animals tested were apparently resistant. Only one of over 200 children affected with *F. buski* examined by MCCOY and CHU (p. 221) was found to be suffering from the classical symptoms of diarrhoea, distended abdomen, oedema of the face and stunted development. hexylresorcinol treatment (doses 0.4 to 1 gm.) resulted in the disappearance of eggs in 54 per cent. Calculations of the estimate made of the numbers of worms based on egg counts, are criticized by LAKE.

BRUG and TESCH (p. 218) found ova indistinguishable from those of *Echinostoma ilocanum* in 47 per cent. of 68 samples of faeces in the Celebes. SKRJABIN (p. 789) reports infection of a patient with *Echinostoma parvulum* the first to be reported in man.

Cestodes

Experimenting on himself TARASSOV (p. 270) found that after swallowing 7 plerocercoids of *D. latum* 7 heads were subsequently expelled. Fifteen months later he swallowed 8 plerocercoids later expelling two heads. After an interval of one year he swallowed 7 and a year later 6 all without infection, but from 6 more swallowed after another year 4 heads were expelled. After these various expulsions the passage of onchospheres and segments ceased in all instances. He therefore considers that infection with *D. latum* gives rise to immunity lasting 2 or 3 years but not longer and findings in the inhabitants of a village support this opinion.

In the *Journal of the American Medical Association* (p. 759) it is stated that the process of kippering does not kill the plerocercoid larvae of *D. latum* but saturation with brine is fatal after a month if penetration is thorough. Ordinary smoking is ineffectual but hot smoking for one hour or more at 75°C is fatal.

MUELLER (p. 667) gives the features which differentiate *Diphylobothrium mansonioides* from *D. mansoni*; these cannot be abstracted. He points out that in the widespread areas in the United States where this worm affects native wild-life man must be constantly exposed to

infection through drinking water from natural sources. Infected Cyclops are widely scattered.

HELLER (pp 223-602) treats ocular sparganosis with intravenous novarsenobenzol with excellent results. The dose is 30 cgm. for adults and two to six doses are given at 4 or 5 day intervals. This should not be exceeded.

In the southern U.S.A. SUNKES and SELLERS (p 225) report that of 7,249 tapeworm findings in man 93.6 per cent. were *H. nana*. *T. saginata* occurred 58 times *H. diminuta* 82 *T. solium* 8 *D. latum* once and *D. carinatum* once.

DAMON (p 602) gives details of a method of staining with picric acid and preparing tapeworm proglottids for preservation in such a way as to make clear the outline of the uterus.

PENFOLD *et al* (p 604) have succeeded in hatching the ova of *T. saginata* by artificial gastric digestion followed by artificial pancreatic digestion.

PENFOLD *et al* (p 224) found that some oncospheres of *T. saginata* were viable if kept in normal saline at 2 C. to 5°C. for 13½ weeks or in the saline for 9 weeks and then exposed on pastures for 8 weeks in mild conditions or kept on dry pastures for 14½ weeks or dry for 2 days under laboratory conditions. If dried in normal saline i.e. in salt solution becoming progressively stronger however none was alive after one day.

SANDGROUND (p 676) treated 16 patients with tapeworm with carbon tetrachloride in a dose of 4 cc. The parasites were eliminated in 12. 3 were not followed up properly and 1 vomited the drug. Hexylresorcinol and tetrachlorethylene may have greater taeniacidal value than the results of a small reported investigation indicate. LANE however (who has stated that 1.55 cc. of carbon tetrachloride may be fatal) points out that the dosage used by Sandground is even greater than that which proved fatal to two patients with *Trichurus* infection reported on p. 675 and that to evaluate an anthelmintic, a large series of patients should be followed up.

MAPLESTONE and MUKERJI (p 283) found three recurrences in 13 patients treated for *Taenia* infection with tetrachlorethylene.

KRAYER (p. 604) recommends pumpkin seeds for the expulsion of tapeworms and gives details of the preparations.

MAPLESTONE and BHADURI (p 224) comment on the rarity of cysticercosis in Indians in comparison with British troops. Pigs are frequently infected. They suggest that Indians may have an enhanced resistance to infection by the oncosphere and that the strobiles may on occasion be digested so freeing the eggs in cases of cysticercosis without strobiles as is the case for *D. latum*. LANE suggests that air convection is a factor.

RAO (p 225) considers that cysticercosis of the brain (although X-ray was negative) might have been the cause of jerking movements of one arm in a patient in India. A cysticercus was found in the other arm.

CASTELLANI (p 225) describes a condition in which small nodules of fibrous tissue with no sign of cysticercus occurred in 3 patients with positive Wassermann reactions. They had been diagnosed as cysticercosis but cleared up under antisyphilitic treatment.

NARIHARA (p 270) reports *H. diminuta* infection of a child in Taihoku city.

BACIGALUPO (p. 668) names *Embla argentina* as a new intermediate host of *H. diminuta*. SCOTT (p. 668) gives a list of other insects in which cercocysts have been seen.

ZIMMERMAN (p. 605) suggests that the dog flea *Ctenocephalus canis* is probably the intermediate host of *Dipylidium caninum* and the dog louse *Trichodectes canis* that of *D. sexcostatum*.

SAMI (p. 603) reports 28 cases of hydatid cyst in the Punjab and details the habitats. In 153 local dogs, 45 showed *Echinococcus granulosus* and the infection rate in herbivores was 1 per cent. in sheep and goats and 150 of 168 cattle.

DUNGAL (p. 603) reports a hydatid cyst in the left ventricle of the heart with perforation into the pericardium. Death was due to carcinoma of the stomach. It is suggested that hexacanth embryos may reach the coronary arteries via the patent foramen ovale where this exists in hydatid infestation of the heart.

YMAZ APPIATTE (p. 223) describes techniques for separating toalbumin and anatoxin from hydatid fluid. The albuminoid fraction gives stronger intradermal reactions and possesses higher specific antigenic potency than the saccharide fraction or the pure fluid.

DE WAELE and DE COOMAN (p. 604) report on the experimental infection of various animals with hydatid in Belgian Flanders. It is found mainly in the horse.

C. H. Wilcocks

(To be continued)

HELMINTHIASIS

PRECIS OF ABSTRACTS IN THIS SECTION

NASTASI (p. 618) has investigated the incidence of schistosomiasis and the larval hosts in Libya. ZAVATTARI (p. 618) reports that schistosomiasis, both vesical and intestinal is more widely spread in Abyssinia than was thought and urges further investigation.

MARTINS and Dos ANJOS (p. 618) report an infection rate of 85.18 per cent with *S. mansoni* in a little town in Minas Geraes, and of 28.73 in the whole area. CAWSTON (p. 619) contends that the shape of schistosome eggs is of value in promoting adhesion to mucus or faeces so preventing drying before they reach water. HOFFMAN (p. 619) failed to infect *Plasmodium corvini* with the miracidia of *S. mansoni*.

EL GAZAYERLI (p. 619) reports finding a healthy male schistosome in a branch of the left coronary artery. HASSAN (p. 619) investigated the spectroscopic changes in the serum in schistosomiasis. CAWSTON (p. 620) points out the importance of examining whole urine of not using a cystoscope in untreated persons, and of using filtered and sterilized solutions of tartar emetic in schistosomiasis.

MAINZER (p. 620) shows that there is a great discrepancy between the clinical findings and the X-ray appearances of the lungs in schistosomiasis. The latter consist of distinct foci, increased striation and intensified hilar shadows. There may be symptoms suggesting tuberculosis, pulmonary fibrosis or asthma. He (p. 620) regards an increase in blood eosinophilia under antimony treatment in a doubtful

case as favouring the diagnosis of schistosomiasis. KENAWA (p 620) reports two cases in which venous hum in bilharzial cirrhosis of the liver was associated with a probable connexion between the portal and systemic systems.

ASHKAR (p 621) treated 24 patients with anthiomaline with considerable success. He gives details of dosage and of the various effects produced by the drug. IMPALLOMONTI (p 621) reports favourably on intravenous stibional B in the treatment of schistosomiasis. DIAMANTIS (p 622) urges mixed antimony and emetine treatment in comparatively small doses. KUNERT (p 622) used provocative injections of germanin after courses of sodium antimony tartrate to stimulate the passing of eggs and so test the value of the original treatment. DAVID (p 622) failed to free the urine from schistosome eggs by the use of dicuprene and cuproquine.

MINAJILA (p 623) advises the use of 1 per cent quicklime in the water of ditches and of a steam jet in mud for the destruction of *Oncomelania nosophora* the host of *S. japonicum*. MARTINS and VERSIANI (p 623) in view of the increase in *S. mansoni* infection in Belo Horizonte advise the examination of all inhabitants the treatment of the infected the construction of latrines and the provision of a sanitary service.

KOBAYASHI and YUMOTO (p 624) describe abnormalities in *C. sinensis*. NIETO ROARO and CABALLERO (p 624) discuss the possibility of the adaptation of imported *C. sinensis* to alternative hosts in Mexico where Bithynia are not found. MUTO (p 624) records a new fresh water fish intermediate host of *C. sinensis*.

KINUGASA (p 624) reports favourably on the use of founadim in *C. sinensis* infections. CHU (p 625) found that *in vitro* and in a concentration of 1 in 40 000 which approximates to a possible concentration in the blood, gentian violet malachite green and Nile blue killed *Clonorchis sinensis* within 24 hours. Gentian violet was the most effective and this result supports previous work in experimentally infected animals.

ERHARDT (p 625) investigated the effect of osmotic pressure and changes in pH on *Opisthorchis*. AFRICA (p 625) mentions various *Haplorchis* flukes from the Philippines.

AZIM (p 626) shows that heterophyids are found in 59 to 75 per cent of dogs and 90 per cent. of cats in Egypt.

BACIGALUPO (p 626) shows that *Limnaca vatrix* is an effective host of *F. hepatica* in Cuba. BÜRG (p 626) records a child with infection by *F. hepatica*. MANCAUX and ALCAY (p 626) show that infection with *F. hepatica* simulated appendicitis in one patient. osinophilia of 21 per cent led to examination for eggs. KOURI (p 626) use emetine with success in the treatment of *F. hepatica* infections. *C. sinensis* infections are common among Chinese in Cuba.

BUCKLEY (p 627) reports that *F. buskii* and *Gastrodiscoides hominis* are common in man in Assam. *Segmentina trochoideus* is an intermediate host of *F. buskii*.

KINUGASA (p 627) details the symptoms found in a series of children infected with *Paragonimus*.

AN DEN BERGHE *et al* (p 628) report that *Dicrocoelium dendriticum* have been found in two Europeans in the Congo and in monkeys not in the natives who cook vegetables well, before eating

VASTASI (Antonino) Schistosomiasis e malacofauna nel Sahara Libico (Fezzan e Gat) [Schistosomiasis and Snails in the Libyan Sahara (Fezzan and Gat)]—*Polidimico Sez. Prat.* 1938. Oct. 17 & 24 Vol. 45 Nos. 42 & 43 pp 1907-8 1911-15 1951-2, 1955-6 1959-61 With 1 map [16 refs.]

An investigation further determining the local incidence of schistosomiasis and the snail hosts in detail in Fezzan and Gat.

The map makes clear the places where infection with *S. haematobium* has been detected and where *Bulinus contortus* has been found. *Planorbis pfeifferi* was present at Gat in the extreme southwest of the area in question but infection with *S. mansoni* seems absent. Very probably the nature of land or water it is felt, is mimical to *Planorbis*. [See also this *Bulletin* 1934 Vol. 31 p 773.]

Clayton Lane

ZAVATTARI (Eduardo) I problemi sanitari dell'Impero schistosomiasis e malacofauna nell'Africa Orientale Italiana. [Sanitary Problems of the Empire Schistosomiasis and Snails in Italian East Africa.]—*Ann d'Igiene* 1938. Sept.-Oct. Vol. 48. No. 9-10 pp 573-582. [23 refs.]

After a consideration which is confessed as necessarily incomplete, there is urged the need for determining the local distribution of the schistosomes of their manifestation as urinary or intestinal parasites, and of their respective snail intermediaries. Before the recent war the only place in which there was certainly endemic vesical schistosomiasis was the lower valley of the Shabeli there were a few doubtful cases reported elsewhere but intestinal schistosomiasis had never been diagnosed. During the war it became clear that vesical infection was wider pread and that the intestinal form was important but the environmental conditions determining its presence were unknown and these have to be ascertained in the interest of all inhabitants.

C L

MARTINS (A. Vianna) & Dos Anjos (W. Versiani) Schistosomose mansoni no norte de Minas Geraes [Mansonian Schistosomiasis in the Northern Part of the State of Minas Geraes, Brazil. —*Brasil Medico* 1938 Sept 3 Vol 52 No 36 pp. 812-816 English summary]

The area surveyed included eight municipalities. In all of them the disease was found in percentages varying from 3.22 to 85.18. This last one, which the authors believe to be the highest ever recorded in the medical literature was found in the little town of Fortaleza (Minas Geraes). The incidence of the disease in the area surveyed, considered as a whole, was of 28.73 per cent. The authors believe that the disease was recently imported from the north-eastern region of Brazil.

The technique used was concentration by sedimentation following HOFFMAN, PONS and JAYER using two grams of faeces which method is held to be optimum for the disclosure of schistosome eggs but inferior to that of Wilts for others. In the 348 faeces examined by it the percentages of infection disclosed were—*A. lumbricoides* 41.12, *S. mansoni* 28.73, *A. americanus* 18.01, *S. stercoralis* 13.70, *T. trichiura* 6.72, *H. nana* 1.07, *E. vermicularis* 0.28 and *Taenia* sp. 1.34.

C L

CAWSTON (F Gordon) Variation in the Shape of Schistosome Ova.—
Trans Roy Soc Trop Med & Hyg 1939 Jan 28. Vol. 32.
 No 4 pp 553-554

An explanation, on the ground of advantage to the species of the various shapes of schistosome ova.

The elongated flattened eggs of the schistosomes of cattle will by their shape adhere readily to mucous discharge if they have come from the nose or to faeces if they have come from the bowel, and this adhesion will lessen the risks of their drying before they reach water and the lateral spine of the egg of *S. mansoni* will similarly anchor it to faeces. The miracidium of *S. japonicum* gets into an operculated mollusc inhabiting rice fields and capable of surviving long periods of drying so the egg has no need of a spine or special shape [The reasoning seems to refer to eggs of the last passed directly into water overlying a ricefield.]

C L

HOFFMAN (W A) *Planorbis corneus* not an Intermediate Host of *Schistosoma mansoni*.—*Puerto Rico Jl Public Health & Trop Med* 1938 Sept. Vol. 14 No 1 pp 24-25 [Spanish version pp 26-27]

Planorbis corneus has been introduced through New Jersey into Porto Rico for use by fish fanciers in their aquaria in place of *P. glabratus* which carries schistosomiasis. All attempts during the last year to infect *P. corneus* with the miracidium of *S. mansoni* have failed. This is evidenced by the fact that continuous watching under the microscope of tentacles and head of a snail attacked by many miracidia has failed to show penetration in any instance that none of the snails passed cercariae and that dissection of the liver showed no sporocysts. Yet this snail carries avian trematodes in the Old World and some of these might find it a suitable host in Porto Rico

C L

EL GAZAYERLI (Moumr) Unusual Site of a Schistosome Worm in the Circumflex Branch of the Left Coronary Artery.—*Jl Egyptian Med Assoc* 1939 Jan. Vol. 22. No 1 pp 34-37 With 1 fig

The worm was discovered because that part of the heart in which it lay happened to be chosen for sectioning. It was a healthy male free in the lumen and the wall of the artery where it lay was healthy. The foramen ovale was closed. The man aged 24 died of suppurative meningitis of brain and spinal cord, and had had no cardiac symptoms. There were bilharzial lesions in lungs, rectum, appendix and the urinary organs and scrapings from rectum bladder and seminal vesicles revealed only eggs of *S. haematobium*

C L

HASSAN (A) The Ultra-Violet Absorption Spectra of Sera in Human Schistosomiasis.—*Jl Trop Med & Hyg* 1939 Jan 16. Vol. 42. No 2. pp 17-18. [13 refs]

It seems, therefore from our spectrophotographic investigation that the fundamental difference between schistosomiasis sera and normal ones lies in the former usually exhibiting a greater intensity. We suggest that this deviation in the absorption spectra is probably due to some changes in the relative amounts of the constituents of the serum proteins

C L

CANSTON (F Gordon) The Importance of Pathology and Dispensing in Schistosomiasis.—*Jl Trop Med & Hyg* 1939 Apr 1 Vol 42 No 7 pp 88-89

Three practical points are brought out. Urine sent for macroscopic examination must be whole urine as Canston has seen a nursing sister carefully decant the supernatant urine which had stood overnight into a bottle too small to take all the specimen so that the pathologist did not get the essential part. A cystoscope should not be passed in untreated persons, for there are few bacterially infected cases which may not be traced to such a passage. A filtered and then sterilized solution of tablets containing tartar emetic and sodium chloride is far less likely to produce coughing on intravenous injection than is an unfiltered one. C L.

MAIXNER (Fritz) Clinical Aspects of Pulmonary Diseases Induced by *Schistosoma haematobium* and *mansoni*.—*Jl Egyptian Med Assoc.* 1938 Dec. Vol. 21 No 12, pp 782-795. With 3 figs. [19 refs.]

"In this condition as in no other pulmonary disease there is mostly a striking discrepancy between the smallness of the clinical findings (obtained by percussion as well as auscultation) and the intense changes of the lungs shown by X-rays

The X-ray types of pulmonary tuberculosis whether with *S. haematobium* or *S. mansoni* are these distinct foci varying in size density and distribution increased vasculation enlarged and intensified hilar shadows. There may be cough, fever and wasting simulating tuberculosis and, after treatment has killed all parasites, contracting fibrosis may narrow bronchioles and pulmonary arteries with the respective sequelae. On the other hand there may be an allergic bronchial asthma having no such relationship as the other effects have with the habitat of the worms. [See also this *Bulletin* 1938 Vol 35 p 685] C L.

MAIXNER (F) Reactional Increase of the Eosinophil Proportion of the Blood in Schistosomiasis subsequent to Antimony Treatment a Phenomenon in Support of the Recognition of Latent Infection.—*Jl Trop Med & Hyg* 1939 Mar 15 Vol 42 No. 6 pp 88-89

In infections both with *Schistosoma haematobium* and *S. mansoni* there is apt to occur an increase in the blood eosinophilia under treatment with antimony. In doubtful cases a rise of this sort under antimony treatment favours a diagnosis of schistosome infection, though a failure of such a rise to take place does not exclude the infection. C L.

KENAWY (M. R.) Venous Hum in Bithariol Cirrhosis of the Liver.—*Lancet* 1939 Apr 8 pp 821-822. With 1 fig.

Continuing on the subject indicated in the title [see this *Bulletin* 1937 Vol 34 p 884] Kenawy reports two cases in which this hum,

usually strictly localized was associated with a slight epigastric swelling which on light pressure of the finger yielded a thrill and of the stethoscope a murmur—both disappearing on heavier pressure. Its presence is believed to point to a connexion between systemic and portal systems.

C L

ASHKAR (M. F.) Treatment of Schistosomiasis with Anthiomaline (a Preliminary Report).—*Jl Egyptian Med Assoc* 1938. Sept. Vol. 21. No 9. pp 614-619

Report on 24 patients with urinary schistosomiasis treated intramuscularly with antimony thiomalate of lithium in a 6 per cent solution.

Injections into dogs showed anthiomaline to be more toxic than founadin as 3 to 2. Injections into 2 men in doses increasing from 1.25 to 4.5 cc. showed dead ova after giving 3.25 and 24.75 cc. respectively. Injections of 1 cc. gave rise to thirst headache joint pains and a feeling that the teeth were loose but pulse temperature and blood pressure were unchanged. Seven patients had twelve injections given every other day of 1.5 and 3 cc. and then ten of 4.25 cc. living ova ceased to be passed after giving 21.5 to 55.5 cc. in one patient dysenteric symptoms came on but were disregarded and disappeared in another abdominal pain and vomiting were present after the ninth and tenth injections but on the dose being reduced to 4 cc. they disappeared. The pain of the injections was very slight and the only other change noted was an increase in eosinophilia. All these treatments were on in patients. Next 10 out patients were treated, one ceased to attend, the rest had every other day maximum doses of 1 cc. for every 15 kilos of body weight this maximum as before being reached at the third injection. In 8 of them the ova disappeared or died after from 8 to 9 injections in the remaining patient they were still living after the ninth injection. 4 of the 9 had vomiting pain or headache. In the last series there were 5 daily doses and then others every other day (the dose being unstated) till the results were negative as they were after between 8 and 11 injections no symptoms being noted throughout.

IMPALLOMINI (Rosario) Di un nuovo preparato di antimonio nella cura delle schistosomiasi umane [A New Antimony Preparation in the Treatment of Schistosomiasis of Man].—*Arch Ital Sci Med Colon e Parassit* 1933. June. Vol. 19. No 8. pp. 370-376

Stibional B a pentavalent antimony preparation has been given with satisfaction to 20 persons with urinary schistosomiasis and to one with intestinal infection.

The drug is given intravenously in doses of 2-4.5 and 10 cc. for the first three days treatment is omitted on day four and continued in 10 cc. doses on days 5-6 and 7 and beyond this if need be. It is apt to produce fever which ceases on suspending treatment. Haematuria rapidly disappeared, the miracidium died and subjective symptoms improved.

C L

DIAMANTIS (A.) La mort subite en stibiothérapie antibilharzienne et les déductions chimiothérapeutiques qui en découlent à propos du "Fouadin Tolerance Test" du Prof. Khalil Bey [Sudden Death in the Treatment of Schistosomiasis by Antimony and Chemiotherapeutic Deductions arising therefrom as to Khalil's Fouadin Tolerance Test.]—*Rev Prat Malad. des Pays Chauds* 1938. Nov 30. 17th Year Vol 18. No. 13 pp 599-604 607-8 611-12.

Diamantis once again [see this *Bulletin* 1938 Vol. 35 p. 599] stresses the sudden and unforeseen character of the many antimony deaths in Egypt, the practical inadequacy of Khalil's fouadin tolerance test, and the necessity of giving a mixed antimony and emetine treatment in quantities which are below the lethal dose of each. C L.

KUMERT (H.) Ein Nachweis zur Dauerheilung der Bilharziois haematobia durch Infektion von Germanin (Bayer 205) [The Duration of Cure of Infection by *S. haematobium* Indicated by Injection with Germanin.]—*Zent f. Bakt I Abt. Orig.* 1939 Feb 20 Vol 143 No 3/4 pp 161-164

Writing from what is described as being at, or for the time (sur Zeit) Tanganyika Territory Kumert treated 45 persons from 12 to 15 years of age with intravenous injections of sodium antimony tartrate each of 0.12 gram for the young and 1.44 gm. for adults. He aimed at giving 12 of such injections, three a week, but did not succeed in doing so in six of the younger patients, but when a month later 33 of these patients were re-examined, the urinary deposit showed dead eggs only. He then gave provocative injections of Germanin 2 and 8 months later after the first, living eggs were passed by the six in whom 12 injections had not been given (the numbers given had been 5 8 8 8 8 and 7) and by no others after the second provocative injections no living eggs were passed, but they included none of the six who had had short treatments. C L.

DAVID (J.) Note sur l'emploi des sels de cuivre Dicuprène et Cuprochine dans la schistosomiase urinaire [Salts of Copper Dicuprine and Cuproquine, in Urinary Schistosomiasis.]—*Ann Soc Belge de Méd Trop* 1938. Sept. 30 Vol 18. No 3 pp 377-380

Neither salt freed the urine of schistosome eggs.

Dicuprene (cupro oxyquinoline disulphonate of diethylamine) was given intravenously without incident in doses of 5 cc daily with total dosage of 25 cc to 65 cc Cuproquine (sodium cupro oxyquinoline sulphonate) was given by mouth to children by nuns, according to weight but without progressive increase in the doses in totals of 6 to 15 grams but of the actual doses it is merely said that they were 0.2 gram greater than those given by VAN NITSEN [this *Bulletin* 1937 Vol 34 p 800] the children's general condition was improved. The contrast with van Nitsen's results in intestinal infection is emphasised. C L.

MRYAJIMA (Mikinosuke) On the Prevention of Schistosomiasis in Japan.—*Jl Public Health Assoc Japan* 1938 Nov Vol. 14 No 11 pp 1-6.

The measures advised for prevention of schistosomiasis are those which have stood the test of local experience. More than three-quarters of the registered deaths which take place in Japan from this infection are reported from the Yamanashi Prefecture. Up to 1925 there were in the country about 100 deaths a year from 1930 to 1934 they have averaged rather less than 70. The intermediate host *Blanfordia oncomelania nosophora* being a snail which lives partly in water and partly in soil the attack on it is twofold. In water quicklime which is cheap works well. At a strength of 2 per cent. it destroys the snail in 10 hours at 1 per cent. it is uncertain but apparently it is held to be effective in 24 hours for the advice is that a ditch in which the snails are present should be dammed up for that time and quicklime put in to bring its strength up to 1 per cent. For the snails in mud the edges of paths and the weeds parts of emptied ditches should have a steam jet thrown on them. After these methods were used the percentage of schistosome egg carriers which had before been 19.8 fell by two years to 7.9 by four years to 5.6 and by 6 years to 4.4. But *B. nosophora* began to appear again after four years and it is advised that the campaign against them should be repeated every ten years [which seems inadequate if the snails reappear in four years].

C L.

MARTINS (Amílcar Viana) & VERSIANI (Waldemar) Plano de combate á Schistosomose mansoni em Belo-Horizonte. [A Plan for fighting Schistosomiasis in Belo Horizonte].—*Hospital Rio de Janeiro* 1939 Mar Vol. 15 No 3 pp 563-570.

With an increase in the number of cases examined for Mansonian schistosomiasis from 151 in 1931 to 2,650 in 1938 there has gone an increase in detected infection from a percentage of 0 to one of 11.69. The advised procedure is the examination of the faeces of all inhabitants by some concentrative method suitable to the eggs of the parasite the treatment and re-treatment as required, of all infected, the construction of latrines and a sanitary service.

OSAKA (Kiyosi) Studies on the Biological Behaviour of the Cercariae of *Schistosoma japonicum*. Part I. Observations on the Escape of Cercariae from their Snail Hosts.—*Taiwan Igakkai Zasshi (Jl Med Assoc Formosa)* 1938 Dec Vol. 37 No 12 (405) [In Japanese pp 1952-1962. With 2 figs. [10 refs.] English summary pp 1963-1964].

GIOVANNOLA (Arnaldo) Osservazioni sui gasteropodi della Sardegna d'importanza medica e veterinaria. [Medical and Veterinary Importance of the Gasteropods of Sardinia].—*Rendiconti Istituto di Sanità Pubblica* Rome. 1938 Vol. 1 Pt. 2 pp 506-517 With 11 figs. [11 refs.]

KOBAYASHI (H.) & YUMOTO (Y) Some Studies on Abnormal Liver Flukes, *Clonorchis sinensis*.—*Taiwan Igakkaï Zasshi (Jl Med Assoc Formosa)* 1938. Sept. Vol 37 No. 9 (402) [In Japanese pp 1474-1479 With 9 figs. on 1 plate. English summary pp. 1479-1481]

The abnormalities consist of bulges and rents in the uterus with extrauterine eggs in the receptaculum seminis, excretory duct and bladder in the parenchyma, in the oral sucker and in Laurer's canal, and a few elsewhere C L

NIETO ROARO (Daniel) & CABALLERO (Eduardo) Nota acerca de la presencia de *Clonorchis sinensis* en Mexico [The Presence of *Clonorchis sinensis* in Mexico].—*An Inst Biol Mexico* 1938. Mar & June Vol 9 Nos 1 & 2 pp 165-166. With 2 figs.

Certain persons returning to Mexico after living in China were found in 1937 to be passing ova of *Clonorchis sinensis*. The fact was reported to the Public Health authorities in fear of this parasite becoming disseminated. The same applied to *Paragonimus*. Though *Carassius auratus* (the second intermediate host of *Clonorchis*) is found in Mexico the molluscan host *Bithynia*, is not nor are the crab-hosts of *Paragonimus*, so the danger is not pressing. Since however *Onchocerca volvulus* (says the author) became adapted to Mexican hosts, either introduction of the Chinese molluscs into Mexico or adaptation of the developmental stages of the *Clonorchis* to other alternative hosts might in time lead to spread of infestation by this trematode.

H H S

MUTO (S) A New Species of Fresh-Water Fishes which serves as a Second Intermediate Host of Liver Fluke, *Clonorchis sinensis* in Formosa.—*Taiwan Igakkaï Zasshi (Jl Med Assoc Formosa)* 1938. Oct Vol 37 No 10 (403) [In Japanese pp 1537-1539 With 1 fig [12 refs.] English summary p. 1539]

In the body of the paper and in the English summary this new second intermediate host is variously designated as Family Cyprinidae, Genus *Culterculus* [*Cultricalus*] (Oshima) or (Oschima) Species *Ameri* or *kueri* n sp. and in the Japanese title which clearly differs from that of the English abstract these names appear—*Culterculus Ameri* (Kregerberg). [Moreover it is difficult to regard the generic name as conforming to the Latin form prescribed in the International Code of Zoological Nomenclature but for that Muto seems in no way responsible] C L

KINUGASA (M) On the Treatment of *Clonorchis sinensis* with Fuadin.—*Taiwan Igakkaï Zasshi (Jl Med Assoc Formosa)* 1939 Feb Vol 38 No 2. [In Japanese pp 290-294 [15 refs.] English summary p 294]

It appears from the English summary that patients ceased to pass *Clonorchis* eggs after two courses of Fuadin in unstated dosage. Fuadin is therefore superior to the preparations of antimony that have hitherto been used, but it is regrettable that toxic symptoms often appear towards the latter half of the injection period. C L

- CHU (H J) Studies on *Clonorchis sinensis* in vitro. Part II. Action of Various Dyes.—*Chinese Med J* 1938 Nov Vol. 54 No 5 pp 409-415 [10 refs]

All *Clonorchis sinensis* specimens used for the experiments were adults obtained from experimentally infected rabbits and cats. The containers were Carrel flasks of the 35 type the medium consisted of inactivated horse serum diluted with an equal amount of Ringer solution. The substance to be tested was added to the medium in different amounts so that each substance was examined in concentrations ranging from 1/2 500 to 1/400 000. A concentration of 1/40 000 was regarded as of special importance since it approaches most closely a concentration which might be used for treatment in vivo.

Sixteen dyes belonging to four groups, Aniline Phthaline Acridine and Sulphonamide have been tested in vitro with regard to their clonorchicidal action. The medium consisted of horse serum diluted with an equal amount of Ringer solution to which the dyes were added in various concentrations. It was found that at a concentration of 1/40 000 which corresponds most closely to an eventual therapeutical concentration, Gentian violet, Malachite green and Nile blue sulphate killed *Clonorchis sinensis* within 24 hours. Of these three dyes Gentian violet was the most effective. This result of in vitro experiments supports previous work on the effect of Gentian violet on *Clonorchis sinensis* in experimentally infected animals.

- ERHARDT (Albert) Der Einfluss der Wasserstoffionenkonzentration unter aeroben und anaeroben Bedingungen des osmotischen Druckes und der Temperatur auf die Lebensdauer von *Opisthorchis* in vitro [The Influence *in vitro* on the Life Span of *Opisthorchis* of pH in Aerobic and Anaerobic Conditions, of Osmotic Pressure and of Temperature]—*Arch f Schiff- u Trop Hyg* 1939 Jan Vol 43 No 1 pp 15-19 With 1 fig

Opisthorchis taken at once from the gall bladder of killed cats was used. In both aerobic and anaerobic conditions the flukes lived longest in pH 5.9 to 6.3 in aerobic conditions there was a second maximum at pH 7.6. Change in osmotic pressure and lowering of temperature affected the flukes little.

C L.

- AFRICA (Candido M) Description of Three Trematodes of the Genus *Haplorchis* (Heterophyidae) with Notes on Two Other Philippine Members of this Genus.—*Philippine J Sci* 1938. July Vol. 68 No 3 pp 299-307 With 2 plates.

The *Haplorchis* flukes here described are—*H. calderoni* (Africa and Garcia 1935) from the small intestine of dog cat and man *H. vanisima* n. sp. from the small intestine of man *H. sisoni* n. sp. from the small intestine of cats and dogs experimentally transferred by CHEN from the genus *Monorchotrema* and *H. yokogawai* similarly transferred by Chen and of which *H. pumilio* becomes a synonym. During the writing of this paper several specimens of *H. laichui* were received from Palestine through the courtesy of Professor WITENBERG of Hebrew University Jerusalem. The locality of collection is unstated.

ARZI (Abdel) Helminthes parasites des chiens et des chats en Egypte. [Helminths of Dogs and Cats in Egypt.]—*Ann. Parasit. Humains et Comparés* 1939 Jan. 1 Vol. 17 No. 1 pp 32-36 [20 refs.]

Of these parasites the forms of most interest to human medicine are the heterophyids. They are found in 73 per cent of dogs in Alexandria and 59 per cent of those in Cairo while 90 per cent of cats are infected. *Dracunculus medinensis* has been found twice in the paws of dogs.

C. L.

BACIGALUPO (Juan) *Fasciola hepatica* Su ciclo evolutivo [The Developmental Cycle of *F. hepatica*]—*Rev. Med. Trop. y Parasit. Habana* 1938 July-Aug. Vol. 4 No. 4 pp 203-206 With 11 figs on 3 plates

The life cycle of *F. hepatica* in *Limnaea stagnalis* is followed through with microphotographs, showing that this is an effective host in Cuba.

C. L.

BURGI (Kuno) Ein Fall von Leberdistomatose bei einem 4-jährigen Kinde (*Fasciola hepatica*) [Infection of the Liver by *F. hepatica* in a Four Year-Old Child.]—*Schweiz. Med. Woch.* 1938 Nov 19 Vol. 68 No. 47 pp 1274-1277 With 1 fig. [18 refs.]

A boy of 4 who had been ill for three months came under observation with a diagnosis of a localized appendicular abscess. Examination showed in the stool eggs of *Ascaris*, *Enterobius* and *F. hepatica* of which last statement a microphotograph leaves no doubt. The swelling in the right lower abdominal quadrant disappeared after emetine injections and a treatment with chemo-san brought away 5 ascarids but their eggs and those of *Fasciola* persisted, and his relations refused a proposed appendicectomy in the quiescent stage nor would they bring him for subsequent examination.

C. L.

MANCERIX (A.) & ALCAY (M.) A propos d'un cas de distomatose hépatique à *Fasciola hepatica* [A Case of Liver Infection by *F. hepatica*]—*Bull. Soc. Path. Exot.* 1939 Feb. 8. Vol. 32. No. 2 pp 169-172

The eggs of *F. hepatica* were discovered in the faeces, and in the duodenal contents removed by a sound, from a woman of 26 who had thereby been saved appendicectomy for appropriately situated attacks of pain. An eosinophilia of 21 per cent. led to the examinations which discovered the eggs. She had been troubled for 3 years the attacks persisting in spite of emetine the eosinophilia rising to 28 per cent. of 27 000 white cells presumably per cubic millimetre.

C. L.

KOURI (Pedro) BARRUEVO (José G.) SOTOLONGO (Federico) & ARIZO (Vicente) Estado actual de la distomatosis hepática en Cuba. Su diagnóstico y tratamiento [Hepatic Distomatosis in Cuba its Present Incidence, its Diagnosis and Treatment.]—*Rev. Med. Trop. y Parasit. Habana* 1938 July-Aug. Vol. 4 No. 4 pp 185-202 [17 refs.]

The two liver flukes interesting medical men in Cuba are *Fasciola hepatica* and *Clonorchis sinensis*. *F. hepatica* has been known in the

local slaughterhouses from time immemorial and in human inhabitants since 1931. The clinical symptoms which have been seen in the infections are noted as are the pathological lesions but a single faecal examination does not suffice to exclude the presence of infection. The specific treatment is emetine and it is believed that it poisons the fluke by its presence in the blood which the fluke swallows after the blood has escaped into the biliary passages. Its failure to cure is suggested due to the flukes being in such cases enclosed in fibrous capsules.

C. sinensis has been found in Chinese in Cuba in a percentage of 49 of those sick and in 23.53 of those killed in accidents. The lesions and treatment are briefly considered. C. L.

BUCKLEY (J. J. C.) Observations on *Gastrodiscoides hominis* and *Fasciolopsis buski* in Assam.—*Jl Helminthology* 1939 Jan. Vol. 17 No 1 pp 1-12. With 1 map & 2 figs.

Fasciolopsis buski and *Gastrodiscoides hominis* are recorded as common human infections in Kamrup District Assam where the examination of 221 faecal specimens from different localities gave an average infection rate of 59.7 per cent with *F. buski* and 41.2 per cent with *G. hominis*. In individual infections *G. hominis* may occur in very large numbers. 989 specimens were obtained on one occasion by means of soap water enemas which are effective in removing these worms. Attempts to find the snail intermediary of *G. hominis* experimentally and by dissecting snails for natural infections were unsuccessful. The egg and miracidium are described. A list of water snails found in the endemic areas is given. As a result of experimental infections *Serminina trochodonta* is recorded as a new intermediate host of *F. buski*. A list of edible water plants which may possibly act as vehicles for the infective stages of the flukes in Kamrup is given.

KINUGASA (M.) Investigations on the Incidence of Lung Fluke Disease (*Paragonimus westermani*) in Sinitiku Prefecture I. On its Incidences in Primary School Children in Sinitiku Prefecture.—*Taiwan Igakkai Zasshi (Jl Med Assoc Formosa)* 1939 Feb Vol. 38 No 2. [In Japanese pp 277-288 English summary pp 288-289]

Examination was made of the sputum of 46,322 Formosan Chinese and 2,671 Japanese school-children with infection found in 0.64 per cent. of the first and in one child only of the second group. Taken cent. of the first and in one child only of the second group. Taken school by school the percentage of infection varied from 0 to 6.25. All but three of the infected admitted eating fresh water crabs and the children of fishmongers were more often infected than were others. Age increased the rate. There was physical and mental deterioration believed to be proportional to the weight of infection. The former showed itself by wasting cough in 90 per cent. blood in sputum in 30 per cent. pains in the chest in 20 per cent. other complaints being incapacity for exertion and asthma. The latter was seen in lowered capacity for solving problems or original thinking and poor memory. The table of contents wrongly refers to the infection as with *Clonorchis*.

VAN DEN BERGHE (L.) & DEXECRE (K.) *Dicrocoelium dendriticum* (*Fasciola lanceolata*) chez l'homme et les singes au Congo Belge. [*D. dendriticum* in Man and Monkeys in the Belgian Congo.]—*Ann. Soc. Belge de Méd. Trop.* 1938, Sept. 30 Vol. 18 No 3 pp. 509-514 With 1 plate. [17 refs.]

Eggs of *D. dendriticum* have been found in faeces of two Europeans in the Belgian Congo probably the result of eating uncooked vegetables but not in any of the negro inhabitants, who eat these well cooked. They have also been found locally in *Pan satyrus*, *Papio* and *Cercopithecus* and in one instance of each of the last two monkeys autopsy displayed a duodenal and not a biliary habitat. Local infection of sheep and snails remains to be sought for. C. L.

VELHARTS (Walter) Der Invasionsweg der Lanzettegelschmarie bei der Infektion des Endwirtes und ihre Entwicklung zum *Dicrocoelium lanceatum*. [The Infection of the Definitive Hosts by Cercariae of *D. lanceatum* and their Development.]—*Ztschr. f. Parasitenk.* 1938, Oct. 17 Vol. 10 No. 4 pp. 476-514 With 14 figs. [18 refs.]

YELLOW FEVER.

PRÉCIS OF ABSTRACTS IN THIS SECTION

JAMES (p. 631) gives figures of reported cases in America and Africa and shows that all cases in South America in 1938 were of the jungle type transmitted in the absence of *Aedes aegypti*. Vaccination is at present the only practicable method of protection and for this purpose the culture virus strain 17D which produces only slight reaction, has been used on over 1,000,000 persons. It has also been used in London.

The eastern boundary of the yellow fever area in the Sudan may extend into Abyssinia.

The Institut Pasteur of Brazzaville (p. 632) reports that the Brazza strain is the same as the Dakar strain. Protection tests show that yellow fever is widespread in the Province. There is probably some animal reservoir and infection may be transmitted by insects other than *Aedes*, though once it is established in man *Aedes* seems to be responsible for the typical epidemics.

SOPER (p. 633) points out that in South America rural yellow fever transmitted by *Aedes aegypti* and jungle yellow fever occurring in the absence of this mosquito are responsible for maintaining the non-urban endemicity. Control is based on viscerotomy, anti-*Aedes aegypti* measures and vaccination. FINDLAY (p. 633) states that in both Africa and South America the sera of 20-25 per cent. of wild monkeys in endemic areas contain yellow fever immune bodies and in America some species are very susceptible to infection. True jungle yellow fever has not yet been found in Africa. Both Findlay and Soper give figures of vaccination results, which are very satisfactory.

SCHUPPNER (p. 634) uses a 10 per cent. suspension of virus in the mouse protection test instead of 20 per cent.

VAN DEN BERGHE (p. 634) found no immune bodies in 84 human sera from Ruanda Urundi, but found one *Colobus* monkey positive in the Congo.

NICOLAU (p 635) considers the virus of yellow fever to be a coccus which by agglutination in the cells form the characteristic inclusion bodies. HINDLE however points out that filtration shown the size of the particles of the virus to be between 18 and 27 μ , i.e. one-tenth of the limit of resolution of the visual microscope.

FINDLAY and MACCALLUM (p 635) record spontaneous variation a neurotropic strain of yellow fever virus between the 670th and 750th passages in mouse brain into one which gave lesions in monkeys characteristic of pantropic strains. The importance of testing the pathogenicity of strains for human immunization is stressed. SCHÜFFNER *et al* (p 636) have maintained a viscerotropic strain which has remained true to type in *M. rhesus* (alternately dried *in vacuo*) and in mice for 405 subinoculations. Dried neurotropic virus kept *in vacuo* has been found to be still virulent after 5 years. DA FONSECA (p 636) has found the Asibi strain to persist up to 43 days in guinea pig testes.

HÖRING (p 636) finds that urea inactivates the virus the effect depending on the urea concentration, virus dilution and duration of contact. The action of urea in human blood cannot be entirely denied, and this effect of urea suggests that the virus may be of a protein nature.

WHITMAN (p 637) by experiments on the feeding of *A. aegypti* at material times on man and monkeys vaccinated with virus 17D and on the immersion of larvae in strong suspension of the virus concludes that there is little danger of the transmission of that virus by the mosquito. Similar conclusions are reached by PELTIER *et al* (p 637) using a neurotropic strain which is employed for vaccination in West Africa.

FINDLAY and MACCALLUM (p 638) discussing the possibility of the transmission of yellow fever by other arthropods report that the virus persists for 15 days in the abdomen of the cockroach *Blattella germanica* and that monkeys may be infected by intra-gastric introduction of virus. It is well known that monkeys eat small insects.

CALLOT (p 638) reports the finding of *Aedes gemiculatus* (a proved vector of yellow fever) in parts of France and describes its breeding places. ROUBAUD *et al* (p 638) found that specimens of *Aedes gemiculatus* kept at 20°-22°C (after an initial period of 5 days at 30°C) for 18 and 22 days after feeding on blood containing yellow fever virus were not infective by bite though the virus had survived in their bodies. BENNETT *et al* (p 639) demonstrated that *Aedes triseriatus* is an efficient vector but there is some evidence of attenuation of the virus in it.

SHANNOV (p 639) describes methods for collecting and feeding jungle mosquitoes for use in experiments. CARNAHAN (p 640) reports on mosquitoes trapped in Florida over a period of 2 years most of which were *Aedes*. He describes the traps used. WELCH (p 640) details the insects found in aircraft in Florida. No *Aedes* were found.

STEVENSON (p 640) found the chief lesion in the nervous system in yellow fever to be perivascular haemorrhage in the brain. Changes in the nerve cells were insignificant and he considers that there was no definite evidence of neurotropism in this series. MONTENEGRO (p 641) describes the Councilman Rocha Lima cell and others which resemble it subdividing these into identifiable atypical and suspect-atypical.

VAN DEN BERGHE (p. 641) prefers a 20 per cent. suspension of virus to a 10 per cent. suspension in the intraperitoneal mouse protection test. Serum is diluted 1 in 7. Controls with both normal and immune serum are indispensable. He also (p. 642) discusses the diagnosis in a suspected case in the Congo.

JADIN and ARNALDI (p. 642) discuss an outbreak, in the Congo which they conclude to have been of atypical yellow fever though only 1 of the 17 patients gave a definitely positive mouse protection test.

ROSS (p. 643) points out that as the sampling of populations for the mouse protection test in Africa is as yet incomplete certain areas are proclaimed as suspect by the Union Government. Aedes control is so difficult that the disinsection of aircraft is necessary. He describes the procedure at Durban, and discusses disinsection plants carried in the aeroplanes. The abstract should be read in full. In the *Public Health Reports* (p. 646) are given the regulations to be observed by air passengers in Florida and HARGETT (p. 646) deals with the same subject. CUMMING (p. 647) describes in detail the possible harbourages for mosquitoes both inside and outside certain types of aeroplanes in America. The number of such places is too large for further abstract.

ROBINEAU (p. 648) recapitulates anti-yellow fever measures in Senegal.

In the *Bulletin de l'Office International d'Hygiène Publique* (p. 648) it is stated that the results of protection tests in domestic animals do not affect the specificity of these tests in man.

SARTH *et al* (p. 648) describe the method of culture of strain 17D and the procedures for preparation of the vaccine. Circulating virus may be found in the blood of those vaccinated up to the 10th day but was not found at any time in 17 of 29 men. Antibodies developed within 28 days in all the subjects tested. The minimum dose necessary for successful vaccination is between 14 and 140 m.l.d. for mice and antibodies were still present after one year in a group tested. Reactions to this vaccine are mild. PELTIER (p. 650) gives figures which indicate the specificity of the mouse protection test for human sera, and of the results of vaccination with Laigret's phosphate vaccine and egg vaccine which, judged by protection tests, give strong protection in 95 per cent of cases. It may be advisable to repeat the vaccination every two years. DONOVAN (p. 650) reports on vaccination in America with virus attenuated by prolonged cultivation on media containing fowl embryo tissue. Reactions were slight.

FINDLAY *et al* (p. 651) consider that the aetiological agent of infective hepatitis is a virus. This has been found contaminating pooled measles serum and the occurrence of jaundice following yellow fever immunization has been traced to a filterable hepatotoxic agent in the culture medium which contained apparently normal human serum. Pools of apparently normal serum should not be used unless the medical history of all donors can be followed for at least one month.

DA FONSECA and ARTIGAS (p. 652) give results of tests of susceptibility of various Brazilian wild mammals to yellow fever virus. These cannot be further abstracted. They (p. 653) found that two young cats were susceptible to intracerebral injection of neurotropic virus whereas negative results had previously been obtained in Europe. DA FONSECA (p. 653) found the rodent *Ctenomys brasiliensis* to be very susceptible to neurotropic virus.

JAMES (S. P.) Renseignements sur la fièvre jaune reçus au cours de la période de neuf mois finissant le 30 septembre 1938. [Information on Yellow Fever received during the Period of Nine Months ending September 30th, 1938.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Nov Vol 30 No. 11 pp 2537-2541
With 1 map

Cases of yellow fever notified during the nine months ending 30th September 1938 are indicated in the following table —

SOUTH AMERICA

Country	State	No of localities with cases	No of cases	No of deaths
Brazil	Minas Gernes	43	—	161
	Pará	1	1	1
	Santa Catharina	2	—	23
	Rio de Janeiro	32	61	58
	São Paulo	5	20	—
	Federal District	2	2	2
	Cayna	1	12	3
	Amaronas	2	2	2
British Guiana	Rupununi District	Suspected jungle cases since beginning of the year		
	Georgetown	1	2	1
Colombia	Cundinamarca	5	12	12
	Santander	1	1	1
	Santander del Sur	1	1	1

AFRICA.

Belgian Congo		2	15	9
French Equatorial Africa	Oubanghi-Chari	1	1	1
French West Africa	Dahomey	1	1	1
	Ivory Coast	6	7	6
	Niger	1	1	—
	Senegal	2	2	1
	Sudan	1	1	1
British West Africa	Gambia	1	1	—
	Gold Coast	13	16	15
	Nigeria	4	5	4

The occurrence of yellow fever in British Guiana is of interest in view of the results of protection tests in Dutch Guiana [see this *Bulletin* 1939 Vol. 38 p 22]. Cases resembling jungle yellow fever are reported as occurring among the Indians in the Rupununi district and 5 out of 46 sera gave a positive protection test.

In Brazil the disease has a very wide distribution and Dr SOPER is of the opinion that the 250 deaths during the first part of 1938 indicate

at least 15 000 cases of yellow fever. All the cases occurring in South America during 1938 belonged to the jungle variety transmitted in the absence of *Aedes aegypti*.

It is evident, therefore, that at present vaccination offers the only practicable method of protection, and up to the end of September 1938 almost 1 000 000 persons had been vaccinated by the culture virus strain 17D. This vaccine produces only a slight reaction, and in at least 95 per cent. there is a certain degree of immunity after a week which increases up to the 20th day at least.

In London 3,500 have been vaccinated by the same method since September 1937 without any cases of jaundice having been observed, the previous cases probably being the result of an adventitious hepatotoxic virus present in the human serum used in making the vaccine suspensions. (See also FINDLAY *et al* below p 651.)

Positive protection tests have been obtained with sera from the Anglo-Egyptian Sudan collected from natives in villages between the White Nile and the Abyssinian frontier and this suggests that the Eastern boundary of the yellow fever area may extend into Abyssinia. It is also of interest that in Malakal during 1933 only one positive serum was found out of 50 examined, whilst in 1938, 21 out of 114 sera were positive.

**BRAZZAVILLE AFRIQUE EQUATORIALE FRANÇAISE RAPPORT SUR
LE FONCTIONNEMENT DE L'INSTITUT PASTEUR DE BRAZZAVILLE
PENDANT L'ANNÉE 1937 [SALEUN (G)] pp 57-73 With 1
folding map—Fièvre jaune. [Yellow Fever]**

An interesting summary of work on the epidemiology of yellow fever in French Equatorial Africa, including an account of the isolation of the virus from a European case of the disease occurring at Brazzaville by intracerebral inoculations of the blood into mice.

This virus, known as the "Brazza" strain has now been passaged 29 times during 1937 and regularly produces paralysis on the sixth day. Cross-immunity tests showed the identity of this strain with that isolated at Dakar. Attempts to infect guinea-pigs showed the possibility of its becoming adapted in this animal: a single experiment with a porcupine *Athysanella africana* gave negative results.

In addition a certain number of protection tests were carried out in the villages and confirm previous observations supporting the view that yellow fever has a widespread distribution in this Province. Eighteen Europeans were examined and all gave negative results including one subject who nine years previously was supposed to have had an attack of yellow fever.

Four persons vaccinated by Lagret's method three years previously were examined. One neutralized 640 mouse units and another 6 400 units: the remaining two had completely lost any protective properties.

Four other persons vaccinated with virus and immune serum 18 months previously gave negative results in three cases one only showing an immunity titre of 640 units.

Sero-protection tests with the blood of 15 cattle from the Tchad region gave 10 negative, 4 positive with titres of 640 mouse units, and 1 positive against 6 400 units. Two gorillas, 3 chimpanzees, 1 baboon, 1 Cercopithecus, 1 Cynosurus, and 2 porcupines gave negative results.

In conclusion the author points out that it is necessary to abandon the old view that the cycle of infection is man *Aedes*-man. It seems probable that there is some animal reservoir of the virus and that infection may be transmitted by other insect vectors although once established in man *Aedes aegypti* seems to be responsible for the development of the typical epidemics.

SOPER (Fred L.) Yellow Fever the Present Situation (October, 1938) with Special Reference to South America.—*Trans Roy Soc Trop Med & Hyg* 1938 Nov 28 Vol 32. No 3 pp 297-322. With 1 graph & 10 maps [21 refs.] Discussion pp 323-332.

A summary of our present knowledge of yellow fever with special reference to the work of the Rockefeller Foundation in South America. It is mentioned that in 1915 a programme of eradicating yellow fever from the Americas was begun by collaborating in the organization of anti *Aedes aegypti* measures in the few remaining seed-beds of infection. This programme seemed to succeed in various countries but failed to eradicate yellow fever from Brazil where two previously unrecognized epidemiological types rural yellow fever transmitted by *Aedes aegypti* and jungle yellow fever occurring in the absence of this mosquito were found to be responsible for maintaining non urban endemicity. The problem of rural *aegypti*-transmitted yellow fever has been solved by the extension of measures against this mosquito to the rural areas of north-east Brazil, the only region in South America where this type has been found.

Jungle yellow fever has also been found in Paraguay, Bolivia, Peru and Colombia and almost certainly occurs in Ecuador, Venezuela, Panama, British Guiana and Dutch Guiana. It has been observed in South Brazil as a wave-like phenomenon involving many of Brazil's richest districts in the years 1934-1938.

Control in Brazil is based on viscerotomy, anti-*aegypti* measures and yellow fever vaccination. As a result of viscerotomy over 140 000 liver tissues have been examined for yellow fever lesions since 1930 and more than 800 000 persons have been vaccinated during the first nine months of 1938 with satisfactory results and without serious complications of any kind [see JAMES above].

Finally the author stated that the threat of extension of yellow fever from present endemic regions of Africa to the ports of East Africa and to the Orient is sufficiently important to call for the application of these three methods to meet it.

In the discussion Dr G M FINDLAY stated that the problems in Africa were essentially similar to those in South America. The endemic zone in Africa comprised an area of about 4 000 000 square miles extending up to the Abyssinian frontier. There was also evidence that in the Malakal region yellow fever had been present within the past five years shown by the increase in the percentage of sera containing immune bodies. Whilst in both Africa and South America from 20-25 per cent of wild monkeys in endemic areas contain yellow fever immune bodies there is the striking difference that in South America some species are very susceptible to infection and show well marked clinical symptoms. In Africa the only species reacting in this manner is the Barbary ape which living north of the Sahara is not exposed to infection. True jungle yellow fever has not yet been

found in Africa but in many parts *Aedes aegypti* occurs both domestically and non-domestically

With reference to vaccination 5 700 Europeans have been immunized and no case of yellow fever has been known to occur amongst them, although between 35 and 40 cases of the disease have been recorded from non-immunized persons in the same districts. It is suggested that it might be possible to attempt immunization of the larger towns such as Lagos, Accra and Freetown, since these are potentially dangerous centres for the spread of infection.

The original article should be consulted for further points of interest discussed in this paper which do not lend themselves to abstraction.

E H

SCHUFFNER (W) Yellow Fever—Some Remarks on Dr Soper's Paper.—*Trans Roy Soc Trop Med & Hyg* 1939 Feb 28. Vol. 32. No. 5 pp 587-594

A discussion of the previous paper with special reference to statements in the article by SCHUFFNER, WALCH SORDRAGER and HOEKSTRA (see this *Bulletin* 1939 Vol 36 p 25). The author agrees with the specificity of the mouse protection test but considers that it is preferable to use a 10 per cent suspension of virus instead of 20 per cent in order to detect very small quantities of immune bodies. [See also VAN DEN BERGHE below p 641]

E H

VAN DEN BERGHE (Louis) Recherche de l'immunité amarile dans les territoires sous mandat du Ruanda Urundi. [Studies on Yellow Fever Immunity in the Mandated Territories of Ruanda Urundi].—*Ann Soc Belge de Méd Trop* 1938. Dec. 31 Vol. 18 No. 4. pp 683-685

The author mixed 50 sera collected from natives in the Ruanda Urundi territory especially in the east and on the Uganda frontier. The individuals were all 20-30 years old, and their sera did not contain any yellow fever antibodies. Another 35 sera collected from other parts of the territory were also negative with the exception of that of one individual who had lived outside the area. Accordingly there is no evidence of the existence of yellow fever immunity in the Ruanda Urundi.

This eastern limit of the disease in the Congo is difficult to explain, since it does not depend on the absence of *Aedes*. With reference to the selection of Entebbe by the Rockefeller Commission as a site for the study of this problem, the author considers that it is too far east of the endemic area and it would be preferable to choose a site such as Wan in the Anglo-Egyptian Sudan or Kilo-Bambu in the Belgian Congo.

E H

VAN DEN BERGHE (Louis) Substances de protection amarile dans le sérum d'un singe au Congo belge [Yellow Fever Anti-Bodies in the Serum of a Monkey from the Belgian Congo].—*Ann Soc. Belge de Méd Trop* 1939 Mar 31 Vol. 19 No. 1 pp 91-95

The author examined the sera of 11 monkeys including 5 chimpanzees, 4 baboons, a *Cercopithecus* and a *Colobus* monkey from the Belgian Congo. Eight of these monkeys came from regions where

yellow fever antibodies were found in the majority of young adults of the native population but only one of the monkeys a *Colobus polykomos* gave a positive protection test. E H

NICOLAU (Stéfan) Données sur la morphologie du virus de la fièvre jaune et sur la morphogénèse des inclusions qu'il provoque dans les tissus. [Notes on the Morphology of Yellow Fever Virus and of the Inclusions that it provokes in the Tissues.]—*C. R. Acad. Sci.* 1938. Oct. 24 Vol. 207 No 17 pp 750-752.

A study of sections stained by methyl blue and oxalate acid fuchsin of the tissues of mice guinea-pigs and monkeys dead of yellow fever leads the author to conclude that the virus is a small coccus. These agglutinate in the cells, and there degenerate forming the characteristic inclusion bodies.

In mice the brain was often found to contain voluminous inclusions without any internal structure coloured a deep red and occupying nearly all the nuclei of the cells of the choroid plexus and similar appearances were noted in the glial cells. In certain nuclei however very small cocci were found sometimes in chains of three to five individuals whilst in other parts of the nuclei dense masses of them or fragments of chromatin were present. Similar appearances were observed in guinea-pigs and the neurones showed transition stages from masses of the cocci to intranuclear bodies. The hepatic cells of monkeys do not give as clear results as the brains of mice and guinea-pigs but will be the subject of further study.

[These notes ignore the fact that the particles of yellow fever virus have been shown by filtration experiments to lie between 18 and 27 μ , which is approximately one tenth the limit of resolution of the visual microscope.] E H

FINDLAY (G M) & MACCALLUM (F O) Spontaneous Variation in the Neurotropic Strain of Yellow Fever Virus.—*Brit. J. Experim. Path.* 1938. Dec. Vol. 19 No 6 pp 384-388. [12 refs.]

A record of the occurrence of spontaneous variation in a neurotropic strain of yellow fever virus whereby it suddenly acquired viscerotropic properties.

A rhesus monkey was inoculated intracerebrally with a neurotropic strain of the virus that had been continuously passaged in mouse brains for five and a quarter years, involving some 750 consecutive passages during which it regularly produced neurotropic symptoms whenever it had been tested in monkeys. On this occasion however the monkey died on the 5th day after inoculation without showing any nervous symptoms but with the typical symptoms produced by the ordinary pantropic virus, such as liver necrosis haemorrhages in the stomach etc. Nevertheless the serum and liver of this monkey injected intracerebrally into mice produced encephalitis, not after an interval of 7-9 days as is the case with the true pantropic strain, but after 4 to 5 days, the interval characteristic of the well-established neurotropic strain. After four further passages in mice this virus was inoculated into a rhesus monkey and again produced death without the development of nervous symptoms but with the characteristics of the pantropic strain. On a third occasion after five further passages in mice, similar results were obtained. The examination of frozen

and dried virus that had been preserved showed that after 670 consecutive mouse brain passages the virus still produced neurotropic symptoms in monkeys; therefore this variation occurred spontaneously between the 670 and 750 passages.

[It is hardly necessary to stress the extreme importance of these results, which emphasize the necessity of testing the pathogenicity from time to time of all strains of yellow fever virus used for human immunization.] E H

SCHULTNER (W.) SNIJERS (E. P.) & WALCH SORGDRAGER (B.)
The Effect of Continued Subinoculation of Yellow Fever Virus and its Longevity in a Preserved State.—*Trans. Roy Soc Trop Med & Hyg* 1939 Feb. 23. Vol. 32. No. 5 pp. 595-596.

The authors have maintained the Dakar strain of yellow fever virus since 1928 in its viscerotropic state alternately in *M. musculus* and dried *in vacuo*. A substrain has also been kept by uninterrupted inoculations in mice and has now reached the 405th subinoculation. Both these strains have remained true to type and also are indistinguishable from a strain of the same origin that has been maintained for about 600 subinoculations in Professor Hudson's laboratory in New York.

Samples of neurotropic virus dried over phosphorus pentoxide and then kept in sealed tubes, from which the air was removed before sealing have been found to retain their virulence completely unimpaired for a period of no less than five years! E H

DA FONSECA (Flavio) Persistance de la vitalité du virus amaril inoculé dans les testicules du cobaye. [The Persistence of Virulence of Yellow Fever Virus when Inoculated into the Guinea-pig's Testes.—*C R Soc Biol* 1939. Vol. 129 No. 34 pp. 1146-1148.

Six mice and an opossum, *Didelphis aurita* were inoculated intratesticularly with the Asibi strain of yellow fever virus and 12 days later their testes examined for the presence of virus with negative results. A guinea-pig similarly inoculated showed the presence of virus in its testes after 14 days.

Neurotropic virus was found to persist in the testes of inoculated guinea-pigs in some cases up to 43 days, but in one case the virus had disappeared by the 30th day. E H

HORING (F. O.) The Action of Urea on Yellow Fever Virus.—*Trans Roy Soc Trop Med & Hyg* 1939 Feb. 23. Vol. 32. No. 5 pp. 587-589.

An account of experiments showing that yellow fever virus is inactivated by exposure to solutions of urea. Suspensions in serum saline (1:10) of mouse brains infected with the neurotropic strain, after filtration through Sertz K pads, were mixed with varying concentrations of urea, the mixtures kept at 37°C. for different periods and then inoculated intracerebrally into mice.

In one experiment 40 per cent. urea solution was mixed with falling dilutions of virus. With a dilution of 10^{-8} inactivation was complete in 60 minutes. In addition, the period to death was prolonged at least 1 or 2 days in the case of mice injected with mixtures containing urea.

When the concentration of urea was reduced the time required to inactivate the virus increased considerably with a 40 per cent.

solution and 10^{-2} virus dilution inactivation began after 30 minutes whilst with 20 per cent. it required 150 minutes to produce a similar result. The attenuated pantropic tissue culture virus was found to be much more easily inactivated for with 40 per cent urea inactivation was perceptible immediately and was complete in 20 minutes.

The effect depends on the urea concentration virus dilution and duration of contact. Although in human blood the amount of urea is not more than 30-40 mgm. per 100 cc. in febrile cases its action cannot be entirely denied since it acts for longer periods on the virus. The fact that urea inactivates yellow fever virus as it denatures proteins suggests that this virus may be of a protein nature. E H

WHITMAN (Loring) Failure of *Aedes aegypti* to transmit Yellow Fever Cultured Virus (17D). — *Amer J Trop Med* 1939 Jan. Vol. 19 No 1 pp 19-26

A description of experiments to test directly the capacity of *Aedes aegypti* to become infected when fed on volunteers vaccinated against yellow fever with vaccine virus 17D.

Of 8 patients fed on by mosquitoes on the 6th and 7th days after vaccination 2 had minimal amounts of virus in their blood on the 7th day. None of the mosquitoes fed on these patients became infected.

Twelve lots of mosquitoes were fed on rhesus monkeys after vaccination in the case of 5 lots of mosquitoes when the virus in the blood was as great or greater than in a series of human cases but none of them became infected. Four attempts were made to infect *Aedes* in the larval stage by immersing them in a strong suspension of vaccine virus. The adults emerging from the two most concentrated suspensions were found to contain virus but were unable to transmit the infection by bite. None of the three monkeys infected by the suspensions of the ground up mosquitoes had any fever nor was there any increase in circulating virus as a result of the single passage in the bodies of the mosquitoes.

It would seem therefore that there is very little if any danger of *Aedes aegypti* transmitting the 17D virus. E H

PELTIER (M) DURIEUX (C) JONCHÈRE (H) & ARQUÉ (E.) La transmission par pique de *Stegomyia* du virus amaril neurotrope présent dans le sang des personnes récemment vaccinées est-elle possible dans les régions où ce moustique existe en abondance? [Is the Transmission of Neurotropic Yellow Fever Virus, in the Blood of Recently Vaccinated Persons Possible by the Bite of *Stegomyia* in Regions where this Mosquito is Abundant?] — *Rev d'Immunologie* Paris. 1939 Mar Vol. 5 No 2. pp 172-195 With 12 charts.

A description of experiments in French West Africa to determine whether there was any possibility of *Aedes* becoming infective after feeding on the blood of persons vaccinated against yellow fever.

The authors repeatedly fed mosquitoes on numerous vaccinated subjects whose blood was shown to contain neurotropic yellow fever virus and after intervals of from 2 to 23 days attempted to infect 8 rhesus monkeys by the bites of these mosquitoes with uniformly negative results.

In a second series of experiments 2 rhesus monkeys were inoculated subcutaneously and another 2 intraperitoneally with the ground up contents of these mosquitoes. One of the monkeys inoculated intraperitoneally became infected but the other 3 remained well.

The results of these experiments confirm the view also supported by five years practical experience that the use of neurotropic yellow fever virus for vaccination does not involve any risk of infection to the general population, even in regions where *Aedes* is common. E H

FINDLAY (G M) & MACCALLUM (F O) Epidemiology of Yellow Fever
[Correspondence].—*Nature* 1939 Feb 18. Vol 143 No 3616
p 239

The persistence of yellow fever infection in rural areas during dry seasons when adult mosquitoes are either absent or present in very small numbers, suggests that other arthropods may possibly harbour the yellow fever virus, but hitherto none has been found to do so.

The authors record two recent observations suggesting that non-biting arthropods may be possible vectors. In the first place it has been found possible to infect monkeys, *Macaca mulatta* and *Cercopithecus aethiops* by introducing the yellow fever virus into the stomach by means of a soft catheter. The virus passed into the blood stream and, in the case of the Indian monkey, produced a fatal infection. Negative results were obtained in similar attempts to infect, by the alimentary tract man, dog rabbit guinea pig, rat mouse hen and pigeon.

Secondly it was found that when yellow fever virus was injected into the abdomen of the cockroach (*Blattella germanica*) kept at 19°C. the virus retained its activity for at least 15 days. It is well known that monkeys in addition to their vegetarian diet, feed on grubs and insects and, in view of the above observations it would be of interest to determine exactly what animal foods are eaten under natural conditions by monkeys in the yellow fever areas of Africa and South America. CALLOT (J) Sur quelques gîtes et associations larvaires de moustiques.
[Breeding Places of Mosquito Larvae].—*Ann. Parasit. Humains et Comparés*. 1939 Jan. 1 Vol 17 No 1 pp. 86-87

Aedes geniculatus has been found in the Department of Indre-et-Loire in different parts of Alsace and in Seme-et-Oise. It breeds in rock holes in which the water contains rotting vegetable matter and resembles that found in tree holes. [*Aedes geniculatus* has been shown to be an efficient vector of yellow fever see this *Bulletin* 1938 Vol 35 p 117] C H

ROUBAUD (Emile) COLAS-BELCOUR (Jacques) & STEFANOPOULOU (Georges-Jean) Le comportement du virus de la fièvre jaune chez le moustique *Aedes geniculatus*. [The Behaviour of Yellow Fever Virus in the Mosquito *Aedes geniculatus*.]—*C. R. Acad. Sci.* 1939. Dec 12 Vol 207 No 24 pp 1144-1146

The authors previously showed that this species is capable of transmitting yellow fever by its bite [see this *Bulletin* 1938 Vol 35 p 117] but in that experiment the mosquitoes were kept at 30°-35°C

A second series of *Aedes geniculatus* was fed on blood containing yellow fever virus and after five days at 30°C kept at 20-22°C. On the 18th and 22nd days respectively after this infective feed the mosquitoes were fed on a normal monkey and produced neither infection nor immunity. The intracerebral inoculation into mice of the contents of five of these mosquitoes produced yellow fever encephalitis showing that although these insects had not become infective by bite the virus had survived within their bodies. BENNETT (Byron L.) BAKER (Fred C.) & SELLARDS (Andrew Watson)

The Behaviour of the Virus of Yellow Fever in the Mosquito *Aedes triseriatus*.—*Science*. 1938 Oct 28 Vol. 88. No 2287 pp 410-411

— & — The Susceptibility of the Mosquito *Aedes triseriatus* to the Virus of Yellow Fever under Experimental Conditions.—*Am Trop Med & Parasit* 1939 Mar 31 Vol. 33 No 1 pp 101-105

Specimens of *Aedes triseriatus* Say, a nearctic mosquito ranging throughout the East of the United States were fed on rhesus monkeys infected with yellow fever and subsequently fed on normal monkeys.

In the first experiment with an incubation period of 17 days at 28°C six of these mosquitoes were fed on a normal monkey which showed a slight febrile reaction six days later then without any other symptoms being noticed died of yellow fever 36 days after having been bitten.

In a second experiment four monkeys were bitten by mosquitoes that had fed on an infected animal 14 to 15 days previously. Two of these monkeys died of yellow fever after intervals of 10 and 13 days during which they showed no signs of disease. The other two monkeys showed no signs of infection and did not develop immunity. In this experiment the mosquitoes producing infection had been kept for 14 to 15 days at 37°C. after ingesting the virus whilst those monkeys which survived had been bitten by mosquitoes kept for the same period at 28°C.

Mosquitoes that had fed on infected monkeys were tested for the presence of virus after 13 to 16 days by grinding them up and inoculating the suspensions into the brains of white mice. Virus was recovered from 6 out of 10 mosquitoes.

These experiments show that *Aedes triseriatus* is an efficient carrier of yellow fever but there is some evidence of attenuation of the virus in this mosquito. E H

DOMINGUEZ (F) Trois points importants dans l'histoire de la découverte de la transmission de la fièvre jaune par le moustique [Three Important Points in the History of the Discovery of the Transmission of Yellow Fever by the Mosquito].—*Bull Acad Med* 1938 Nov 15 102nd Year 3rd Ser Vol. 120 No. 33 pp 303-307

SHANNON (Raymond C.) Methods for collecting and feeding Mosquitoes in Jungle Yellow Fever Studies.—*Amer J Trop Med* 1939 Mar Vol. 19 No 2 pp 131-140 With 4 figs on 2 plates.

A description of the methods used for capturing transporting classifying and feeding the mosquitoes used in experiments to determine whether or not yellow fever infection could be produced in laboratory

animals by the bite of jungle mosquitoes within 24 hours after their capture.

A horse was used as bait for the capture of day-flying sylvan mosquitoes and details are given of the muslin cloth and mosquito net trap in which it was enclosed. The denser and more humid parts of the jungle were found to be the most favourable sites.

The original paper should be consulted for details of the transportation and feeding of the mosquitoes.

Usually one-half or more of *Mansonia* and *Aedini* fed, whilst only about one-quarter of *Sabethine* mosquitoes would take blood.

It was found that a staff of eight persons could tube, classify and feed between 2,000 and 3,000 mosquitoes per day. E H

CARNAHAN (Charles T) A Two-Year Record of Adult Mosquito Trapping in Dade County Florida.—*Public Health Rep* 1939 Apr 14 Vol. 54 No 15 pp 606-611

Adult mosquitoes which visit light have been trapped at Miami Florida without intermission for two years.

The author used six New Jersey traps—these consist essentially of an electric light visible from all sides, together with a fan which sweeps down the insects which come towards the light and delivers them into a cyanide bottle. The results of two years' work are shown in a table which gives monthly totals for all traps together, the species of mosquito being shown separately. Twenty-three species were captured, all of them known previously to occur in the locality.

In two years the traps took nearly a quarter of a million mosquitoes. About 38 per cent. belonged to the species of *Aedes* which bred in salt marshes and which were most abundant in summer. 5.9 per cent. were *Anopheles* of four species, of which *crucians* was commonest; these insects were commoner in the colder months. Over 40 per cent. of the total catch was made up of various mosquitoes which do not bite man. The monthly totals ranged from below 400 to about 55,000. There was a striking reduction of mosquitoes in the second year which the author attributes to a period of dry weather. P A Buxton

WELCH (E V) Insects found on Aircraft at Miami, Fla., in 1938.—*Public Health Rep* 1939 Apr 7 Vol. 54 No 14 pp 561-568
[Summary appears also in *Bulletin of Hygiene*]

This is an interesting summary with a series of tables, showing the orders, genera and species of insects found, alive or dead, on aircraft arriving during 1938 at Miami from Central and South America and Mexico.

In brief, of 398 aircraft inspected 187 (47 per cent.) harboured insects; these totalled 651 and 168 of them were alive. Forty dead and five live mosquitoes were found among them. *Culex quinquefasciatus* (6 dead, 3 alive), *Mansonia sudubians* (18 dead, 1 alive) and 1 dead *Anopheles albimanus*; no *Aedes aegypti* were found. The most prevalent insect was the house-fly. H H S

STEVENSON (Lewis D) Pathologic Changes in the Nervous System in Yellow Fever.—*Arch Pathology* 1939 Feb Vol. 27 No 2 pp 249-266. With 9 figs.

A study of the whole brain from 20 cases of persons who died of yellow fever and of pieces of brain tissue from 14 additional cases.

A detailed examination of the brains of these 20 cases in 3 cases including the spinal cord is reported, from which it is shown that the chief lesion was perivascular haemorrhage. These haemorrhages were most frequent in the subthalamic and periventricular region at the level of the mamillary bodies. The temporal pole was next most involved and the cerebellum only slightly less so.

Perivascular lymphocytic exudate was noted in 9 cases but with the exception of a single case this was slight. Changes in the nerve cells were insignificant and no inclusion bodies were seen. Reactive changes in the microglia and astrocytes were slight.

The author concludes that in this series there was no definite evidence of neurotropism on the part of the yellow fever virus.

MONTENEGRO (João) A cellula de Councilman-Rocha Lima [The Councilman-Rocha-Lima Cell].—*Brasil Medico* 1933 July 16 Vol 52. No 29 pp 652-654 English summary

The author defines once again what is to be understood as the typical Councilman Rocha Lima cell in the yellow fever liver. In tissue stained by haematoxylin and eosin it shows coagulative necrosis less angular and more rounded than the non-necrosed cell with a well marked edge and surrounded by a narrow clear halo. The cytoplasm is eosinophilic non-granular more refractile than normal and contains small vacuoles. The nucleus is smaller and more rounded than that of the normal cell, usually about the centre is homogeneous [i.e. shows no nucleolus] and stains a deeper red than does the cytoplasm. Rarely the cell is binucleate.

He then describes other cells which may be seen bearing greater or less resemblance to this and points out the differences. He thus makes two large divisions typical and atypical and sub-divides the latter into identifiable atypical and suspect atypical according to the degrees in which they deviate from the typical in respect of the size shape and staining of the nucleus the presence of vacuoles in the cytoplasm and its granularity and its size shape and staining properties.

VAN DEN BERGHE (Louis) Modifications techniques du test intrapéritonéal de protection amarile chez la souris [Technical Modifications of the Intraperitoneal Yellow Fever Protection Test in Mice].—*Ann Soc Belge de Méd Trop* 1939 Mar 31 Vol 19 No 1 pp 81-86 With 1 plate.

The author recommends some modifications of Sawyer and Lloyd's technique (see this *Bulletin* 1932, Vol 29 p 198) for the application of the intraperitoneal mouse protection test for yellow fever.

The serum to be examined is diluted 1/7 and the virus suspension is increased to 20 per cent. instead of the usual 10 per cent. [But this increase in strength was recommended by SAWYER himself in 1934. See this *Bulletin* 1934 Vol 31 p 837.] As a result of the small quantity of serum used it is usually possible to repeat the test when doubtful reactions are obtained.

The brains of infected mice are put in a sterile bottle containing glass beads and shaken until broken up when peptone water is added sufficient to make a 20 per cent. suspension. Then 0.5 cc. of the serum

to be examined is drawn up into a 5 cc. syringe followed by 3 cc. of the virus suspension in the bottle. When all the syringes have been used one for each lot of serum to be examined the mice are then injected in batches of 6 using 0.5 cc. for each mouse. The remaining 0.5 cc. in each syringe is kept in reserve for about half an hour in case it is necessary to inoculate another mouse. For controls the author considers it indispensable to set up two series one in which the virus is mixed with normal rabbit serum, and the other with a mixture of virus and immune rabbit serum. In these controls with normal serum 4 or more out of 6 should die of the infection and with immune serum not more than one. [See also SCHUFFNER, above p. 634]

JADIN (Jean) & ARNALDI (Enrico). *Une épidémie d'une affection ictérique à Zongo* [Possibilité d'une infection amarile atypique. An Epidemic of a Disease showing Jaundice at Zongo. The Possibility of Atypical Yellow Fever]—*Ann Soc Belge de Méd Trop* 1938, Sept 30 Vol 18 No 3 pp. 435-473 With 13 charts 1 plan & 1 map.

A detailed description of an epidemic which occurred during 1938 at Zongo a small frontier post of the Belgian Congo near Bangui where yellow fever is known to occur.

The clinical symptoms of 17 patients observed included pale and late jaundice early albuminuria which rapidly increased, and occasionally clots of blood in the stomach. The absence of any parasites in the blood or urine supported the view that it was a virus infection but the authors consider that the symptoms were not sufficiently definite in themselves to justify a diagnosis of yellow fever. There were 10 deaths out of 20 cases three of which were not seen. The results of the pathological examination of the livers of 4 cases (by Bablet) did not agree with the clinical symptoms, and all were negative as far as histological changes characteristic of yellow fever were concerned.

The results of mouse protection tests showed that the serum of only 1 patient gave a definitely positive reaction, but 3 or 4 gave feebly positive results.

The authors discuss the epidemiology of the disease and mention that 10 other patients were in contact with these cases but kept under mosquito nets and none of them became infected. Moreover the application of anti mosquito measures and anti yellow fever vaccination was followed by the disappearance of the epidemic. Accordingly they are of the opinion that it might be considered as an outbreak of atypical yellow fever

E H

Ross (G A Park) La destruction automatique des moustiques dans les aéronefs et le vecteur de la fièvre jaune dans les traversées aériennes en Afrique [Automatic Destruction of Mosquitoes in Aircraft and the Yellow Fever Vector in African Air Travel]—*Bull. Office Internat. d'Hyg. Publique* 1933, Sept. Vol. 30 No. 9 pp. 2002-2031. With 3 figs. [Summary appears also in *Bulletin of Hygiene*]

In this comprehensive paper Dr. Park Ross expresses his views on some of the problems which the advent of air travel in Africa has produced.

Naturally the possibility of the transmission of yellow fever to susceptible but hitherto uninfected areas raises problems for the health authorities which are new and not easily solved.

The author points out that whereas regular commercial air line services are comparatively easy to control private flights and planes chartered for passages not on the regular air routes, are not so readily brought within the scope of the medical authorities.

The present imperfect state of our knowledge of the distribution of yellow fever in Africa is considered, and the opinion expressed that insufficient sampling of populations by the mouse protection test has as yet been undertaken. Consequently certain areas have been proclaimed "suspect" by the Government of the Union of South Africa, these areas being those territories West of Longitude 35 East and North of Latitude 13 South and comprising any part of the Belgian Congo or Angola not included in the above.

Dr. Park Ross considers that unlike the problem in the Southern States of the U.S.A. the history of an air passenger from African territories is easy to ascertain, thus obviating the same risk in the unwitting conveyance of a human vector and reducing the health problem to one concerned almost entirely with the insect vector.

Conditions on the East Coast, both in urban and rural areas cause the South African Authorities considerable apprehension owing to the prolific breeding of *Aedes* and the heavy dhow traffic. Dhows are apparently notorious in their infestation with mosquitoes.

The difficulty of effective *Aedes* control in towns as well as in rural areas appears to be a problem baffling alike to authorities in the Southern U.S.A. and in Africa.

It is this factor more than any other that has led to the experiments in the disinsection of aircraft as a safeguard against the spread of yellow fever.

Measures taken at African aerodromes are in Dr. Park Ross's view apt to be nullified for such reasons as an insufficiency of recognized airports under control to avoid forced landings, the impossibility of ridding some aerodromes of breeding grounds (e.g. the Nile and Great Lakes) mosquito harbourage within insect flight range of the aerodromes but not under the control of the local authority and last

but not least the reluctance of some health authorities to inconvenience the air lines by disinsection of aircraft immediately on arrival and before landing passengers, cargo and mails.

Some idea of the prevalence of insects in aeroplanes can be gained from the results quoted of the inspection of 84 seaplanes arriving at Durban. In 40 no insects, in 28 living insects and in 16 dead insects were found. Of these insects culicines were found in five instances and anophelines and *Aedes* twice each.

Of the 84 planes quoted, 44 had received recent treatment with "Fht" either *en route* or at the last port of call by the Airway staff. It is to be noted that only 11 out of 40 planes arriving unsprayed brought in living insects.

An interesting description is given of the procedures taken at Durban on the arrival of aircraft. At present Durban is the southern terminus of the seaplane route of Imperial Airways.

The aircraft moor 300 yards from the shore and are required to keep hatches and doors closed. The Health Officer goes aboard and puts up an insecticide mist over one exit through which the passengers pass into a launch for conveyance to a quarantine pontoon. On the pontoon medical and immigration control is exercised, the pontoon being fitted with the requisite examination rooms etc. A medical card is filled in giving the usual details much as is done in the ordinary way with ships.

In the meantime a European Health Staff using high-pressure sprays, disinsects the plane a proceeding occupying about 20 minutes. After disinsection is completed baggage and mails may be handled.

Suspect passengers can be detained on the pontoon accommodation being provided for the purpose and the pontoon being moored off shore complete isolation can be maintained.

It is pointed out that the formalities connected with disinsection on arrival at an airport represent a certain loss in flying time and to obviate this disinsection in the air or just on landing has been tried.

Part II of the paper deals with Automatic Disinsection. In essential this comprises a plant for disinfection carried in the plane with fixed ducts leading to all compartments both for the dissemination and the removal by extraction of gases lethal to mosquitoes.

There are however certain primary difficulties to be overcome, particularly the weight of the apparatus, constructional problems and the difficulty of obtaining a really effective gaseous disinfectant. Atomized disinfectants are unsuitable for conveyance by lengthy ducts and the only reliable gas, HCN too dangerous for routine use even in dilutions suitable for killing mosquitoes.

The advent of a new type of seaplane built in effectively bulkheaded compartments partly solved one of these problems, for it was found possible to fumigate section by section while in flight.

Objections to power drive for the apparatus were overcome to some extent by the use of CO₂ as a propellant. The use of "sparklet" bulbs in this connexion is described, and the advantage of knowing that a standard charge, such as a sparklet will propel a standard amount of disinfecting solution into the space to be dealt with has obvious advantages.

It has been found to be quicker in action than aspiration types of apparatus.

Self-explanatory drawings of a Larmuth unit are given and it was found that a unit of this type for each compartment in a plane

Larmuth's Spray Ejector new type
(Reproduced half-size)

A syphon sparklet bulb containing CO_2 under pressure in excess of 400 lbs. per square inch provides the motive power. The measured dose (60 cc) of insecticide is placed in container Z. High pressure CO_2 enters Z through jet A and mixing chamber C through the "booster" jet B. Block D has two diagonal grooves cut in it to admit the insecticide forced up from container Z into chamber C. On reaching chamber C atomization occurs and is enhanced by the CO_2 under pressure escaping from jet B. [Positions of B and C are adjustable and all nozzles are easily accessible for cleaning.]

(Reproduced from *Bulletin de l'Office International d'Hygiène Publique*)

(weight 1 lb. each unit) was less in total than a large central installation with ducts to each compartment.

An ingenious type of machine the Phantomyst is also described, but for efficiency electric motor power is required and the weight is excessive.

Certain desiderata for insecticides must be insisted upon. These are —

- (1) Non inflammability
- (2) Non-clogging in the apparatus.
- (3) Quick killing in action
- (4) Non toxic to human beings.
- (5) Non-staining
- (6) Odourless within reason.

At present most insecticides have a concentrated pyrethrum extract base diluted with paraffin carbon tetrachloride or water. Large bulk should be avoided from considerations of weight and stowage.

Consideration is given at length to the fulfilment of the above postulates by these diluents with carbon tetrachloride coming first in order of merit.

Extensive tests in the flying boat *Cassiopeia* and others using Larmuth's Spray, old type and new type and Phantomyst plant were made with the plane at rest.

The solutions used were *Deskito* and *Pyagra*, and results are given in detail. It appears that complete disinsectization can be carried out in from 5-10 minutes.

In his summary and conclusions, Dr Park Ross finds —

(1) That under present conditions there is a risk of spread of yellow fever by aircraft in Africa.

(7) Conveyance by aircraft of living mosquitoes from one African territory to another should be prohibited by law

(8) Effective disinsection of aircraft is essential and should be capable of being done by unskilled hands the health authorities acting in a supervisory capacity only as in seaports.

(9) Experience shows that of the two—human factor insecticide and apparatus—the human factor is the least reliable and should be eliminated as far as possible.

(10) Automatic plant is aimed at eliminating the human factor and allowing disinsection by aircraft crews when in flight or on the ground.

(11) The essence of air travel is speed, and delay should be minimized as far as possible in carrying out health measures.

(12) Disinsection in flight prevents delay to disembarkation of passengers and freight on arrival

(13) Of insecticides tested, Aircraft Pyra and Water Soluble Daktto were equally non-inflammable the former was quicker in action more reliable and gave 100 per cent. kill in every case. Daktto was practically odourless

(14) Automatic propulsion of measured doses of insecticide as in Larmuth's ejector proved superior to aspiration types such as the Phantomyst.

(15) Experiments in the flying boat "Caslopla" showed that disinsection can be effectively carried out in from 5-10 minutes.

M T Morgan.

PUBLIC HEALTH REPORTS. 1938. Sept. 9. Vol. 53 No 36. pp 1621-1622 —Miami Health Officer acts to prevent the Introduction of Yellow Fever

Owing to the fact that the flight time of airplanes coming to Miami, Florida from actual or potential foci of yellow fever in South America, is now only ten hours, the local health officer has issued a special order regarding passengers. Any person coming to and remaining in Miami, who within six days previously has been in any district which the United States Public Health Service has declared an actual or potential focus of yellow fever must within 24 hours report in person to the Department of Public Health and be kept under surveillance until six days have elapsed. Should visitors stop temporarily in Miami and then proceed to some destination in the *Aedes aegypti* area of the United States the Miami authorities will notify the proper health authorities to keep such persons under surveillance until the six days have elapsed.

CUMMING (Hugh S.) Rapport sur les refuges pour moustiques dans les aéronefs [Report on Mosquito Harbourages in Aircraft.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Sept. Vol. 30 No 9 1938-2001 With 6 figs. on 2 plates [Summary appears also in *Bulletin of Hygiene*]

The authors of this note communicated to the International Health Office Paris by Surgeon General Cumming formerly Surgeon General of the United States Public Health Service describe every point in five types of aircraft employed by the Pan American Airways which might conceivably form a harbourage for mosquitoes. First in the interior of the aircraft there are ten main harbourages (1) Running the length of each compartment under the floor is the hold divided in three parts by longitudinal bulkheads. The floor is not lifted for disinsection although there are holes in it which would permit the entry of mosquitoes into the bilges (2) In the toilet compartment there are built in cupboards and spaces around the washbasin and toilet pedestal. Disinsectizants would not penetrate into these spaces except by direct application (3) Window curtains drawers under the seats lifebuoys, and pockets in the seats make excellent mosquito harbourages. (4) The space between the ceiling and the pilot's cabin filled with packing as isolation against sound is in relation with the ventilation. The wire mesh partitions are insufficient to prevent the entry of mosquitoes. (5) The purser's office, sanitary bucket postal compartment crew's lockers and the battery space are fairly open and can be disinfected. (6) The ventilation system comprises openings on the leading edge of the wing conduits running the length of the aircraft with various occasional openings in the cabin and in each compartment. The screening of this system is insufficient, consisting of a lattice intended merely to prevent the entry of birds. (7) In the centre of the roof of each compartment is a longitudinal space opening into the cabin. This space is intended for protection against noise but is not freely accessible and might afford harbourage. (8) Above the roof on each side of the cabin are spaces used for cables running to the tail of the aircraft. (9) Forward of the pilot's cabin there is a space used for ballast. In some cases this space communicates with the cabin but is difficult to disinfect. (10) Spaces between the bulkheads separating the compartments offer possible refuges where disinfecting vapour would not easily penetrate.

With regard to the exterior surface of the aircraft modern types are effectively aerodynamic and offer but little harbourage to mosquitoes. Nevertheless there are certain points which might do so (1) Wings ailerons stabilizers rudders for direction and altitude are hollow and communicate with the interior by openings of about an inch in diameter the object of which is to equalise atmospheric pressure in the interior and exterior of the craft. (2) The interior is connected with the wings through the tower through which all the cables lead, going from the pilot's cabin to the wing structures and round these cables are openings giving direct communication with the cabin and the wings. (3) The fins in the tail of the craft serve to support the caudal structure and the transmission of cables to the tail. (4) The struts which consolidate the wing structures and tails are aerodynamic by means of hoods that might offer refuge to mosquitoes. (5) The petrol tanks are in the wings. On the wings are filters which

are sunk leaving between them and the adjacent part of the wing important hollows by which mosquitoes might enter.

There are a number of other points of the same nature cited in the report, to which reference should be made, which might conceivably harbour mosquitoes. Thus the report shows that there are an astonishing number of spaces, hollows or crevices which by inadvertence might in theory harbour mosquitoes, but it is highly doubtful whether many of the points cited in the report would do so in practice. More likely ones seem to be closed or semi-closed spaces in the interior of the hull and wings.

The report is accompanied by photographs indicating some of the points to which reference is made. M T Morgan

ROBINEAU Instruction récapitulative sur la prophylaxie anti amarille au Sénégal. [Recapitulatory Information concerning Yellow Fever Prophylaxis in Senegal].—*Ann de Méd et de Pharm. Colon.* 1938. Oct.-Nov-Dec. Vol. 38. No 4 pp 914-945 With 2 figs.

A summary of the various measures that have been put into operation in connexion with anti-yellow fever prophylaxis in Senegal including useful administrative details such as lists of the officials responsible for their application in different branches of the service. The article should be consulted in the original by those interested in practical details of this subject in Senegal. E H

BULLETIN DE L'OFFICE INTERNATIONAL D'HYGIÈNE PUBLIQUE. 1938 Nov Vol. 30 No. 11 p 2549—Rapport de la commission de la fièvre jaune. [Report of the Yellow Fever Commission.]

The Commission agrees with the orders for the amelioration of the quarantine conditions for yellow fever in the case of vaccinated persons issued on September 14th 1938 by the Governor-General of French West Africa.

With regard to the duration of immunity after yellow fever vaccination, it is considered that it is too soon to give a definite opinion.

Finally it is stated that from a practical point of view the results of protection tests in domestic animals do not in any way affect the specificity of these tests in man. E H

SMITH (H. H.) PERNA (H. A.) & PAOLIELLO (A.) Yellow Fever Vaccination with Cultured Virus (17D) without Immune Serum.—*Amer J. Trop Med* 1938. Sept. Vol. 18. No. 5 pp 437-468 With 1 chart & 4 figs. [15 refs.]

A detailed account of a year's experience in the production and application of a cultured yellow fever vaccine virus (17D) during which time more than 69,000 persons in Brazil were inoculated with very satisfactory results.

The strain of virus came originally from the Ansb strain, which was established in tissue culture containing mouse embryonic tissue and subsequently in media containing whole fowl embryo. After 58 subcultures in this medium it was then subcultured in one containing

fowl embryo from which the brain and spinal cord had been removed and in this has been maintained for more than 200 passages. Since the titre of virus in these cultures is low the vaccine for human use was prepared from developing fowl embryos inoculated with this culture virus. Eggs with living embryos after about seven days incubation are inoculated above the embryo with 0.06 cc of the culture material and then incubated for three or four days before being taken out for the preparation of vaccine.

The pooled embryos are ground up usually in normal human serum then centrifuged at 3 000 r.p.m. for thirty minutes after which the supernatant fluid containing the virus is cleared through a Buchner funnel with a thin film of asbestos fibre, and subsequently passed through Seitz E K filter discs at 10 lb pressure. This filtrate is put up in ampoules containing 3.0 cc. or in 1.0 cc tubes. It is then frozen in alcohol-carbon-dioxide-snow and desiccated *in vacuo* over sulphuric acid. Each batch is then tested for sterility and also tested for any enhanced or viscerotropic properties or neurotropism by intracerebral inoculation into a rhesus monkey and the quantity of virus in the vaccine determined by tests in mice. Finally the vaccine is stored at 4°C. and always sent to the field packed in ice in thermos containers.

Vaccination consists of the subcutaneous inoculation of the rehydrated vaccine 0.5 cc. being the usual dose though occasionally 1.0 cc was used in the laboratory. The quantity of virus measured in M.L.D. for mouse units, varied from 500 up to 11 000.

Small groups were studied to test the presence of circulating virus and the production of antibodies. Out of 29 men virus was found in the blood of 3 on the fourth day 3 on the fifth 3 on the sixth 2 on the seventh and 1 on the tenth day. It is of interest that 8 out of 12 patients who received more than 5 000 M.L.D. of virus showed circulating virus, as compared with 3 out of 15 who received less than this dose.

Protective antibodies were demonstrated during the first 28 days in the blood of all 29 patients vaccinated. None of 24 tested after 7 days was immune and 9 out of 23 had not developed antibodies after 14 days. As a general rule the titres were low in comparison with those developed by rhesus monkeys or by humans after recovery from clinical yellow fever.

The minimal infective dose of virus necessary for successful vaccination was found to lie between 14 and 140 M.L.D. for mice. 7 out of 10 men receiving only 14 M.L.D. developing satisfactory immunity. The results of studies on more than 1,800 vaccinated persons indicate that approximately 95 per cent of those vaccinated under field conditions acquire immunity. Mouse protection tests on 9 men taken six to seven months and 21 men taken a year after vaccination, showed that protective antibodies were still present. One patient however showed the disappearance of immunity after one year and others a lowered titre indicating a diminution in the quantity of antibodies.

Any reactions to the vaccine were always mild, generally consisting of headache low-grade fever and influenza-like pains. These symptoms as a rule came between the third and eighth days, being most common on the sixth or seventh days and very rarely were severe enough to stop work. No instances of delayed reaction to vaccination have been observed.

PELTIER. L'atténuation des mesures quarantenaires antiamariles en faveur des vaccinés ayant un test de protection fortement positif. [The Amelioration of Quarantine Conditions for Yellow Fever in the Case of Vaccinated Persons giving a Strongly Positive Protection Test.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Nov. Vol. 30 No. 11 pp. 2542-2548.

The regulations in French West Africa concerning the quarantine measures for the control of yellow fever have recently been modified in the case of those giving positive protection tests.

The author gives the results of observations on the results of various serological tests at Dakar during the past four years. With regard to the specificity of the mouse protection test for the examination of human sera, it is pointed out that out of 117 specimens from natives born previously to the Dakar yellow fever epidemic in 1927-71 gave a positive test whilst 100 sera of children born since 1930 were all negative. The results of yellow fever vaccination by Laignret's method of three inoculations of a phosphatic suspension of mouse virus, and the later method of using egg-coated virus are summarized in the following table, which indicates the duration of immunity based on protection tests—

Phosphate vaccine

<i>Period after vaccination</i>	<i>Result of mouse test</i>	
Less than 1 year	Strongly positive	69
	Feebly + or negative	6
1-2 years	Strongly +	30
	Feebly + or negative	10
2-3 years	Strongly +	22
	Feebly + or negative	6
3-4 years	Strongly +	25
	Feebly + or negative	6

Egg vaccine

Less than 1 year	Strongly positive	216
	Feebly + or negative	32
1-2 years	Strongly +	34
	Feebly + or negative	10
More than 2 years	Strongly +	7
	Feebly + or negative	2

It would seem, therefore, that vaccination gives strong protection in at least 85 per cent. of the cases but that it may be advisable to repeat the vaccination every two years. E H

DOBOVAX (Anthony). Organisation de la vaccination antiamarile dans le personnel des compagnies de navigation aérienne et parmi les officiers du service de l'hygiène publique des États-Unis. [The Organization of Anti-Yellow Fever Vaccination in the Personnel of the Aerial Navigation Companies and among Officers of the United States Public Health Service.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Sept. Vol. 30 No. 9 pp. 1887-1894.

An account of the methods adopted by the United States Air Force personnel for vaccination against yellow fever. Details are given of the methods of obtaining and transporting the vaccine and also inoculation technique. The results of 601 vaccinations using a

vaccine prepared at the Rockefeller Institute consisting of virus attenuated by prolonged cultivation in media containing fowl embryo tissue [see this *Bulletin* 1937 Vol. 34 p 690] indicate that 61 per cent of the subjects had no appreciable reaction but 148 showed a rise in temperature accompanied by headache lumbar pains or various complex symptoms. This reaction generally occurred six to eight days after vaccination and only in very exceptional cases lasted for more than 24 hours.

The question of the future supply of the vaccine is raised by the author for it is unlikely that the Rockefeller Foundation will be able to continue its manufacture on a large scale. It is suggested that the National Institute of Hygiene would be the most suitable organization for this purpose. E H

DONOVAN (Anthony) *L'immunisation du personnel des lignes aériennes contre la fièvre jaune* [The Immunization of the Personnel of Air Lines against Yellow Fever]—*Bull. Office Internat. d'Hyg. Publique*. 1938. Sept. Vol. 30 No. 9 pp 1995-1997

A total of 938 vaccinations against yellow fever are recorded up to 1st April, 1938 among the personnel of the Pan American Airways. No serious reaction has ever been observed and only about one in twenty showed any reaction generally about the sixth or seventh day and this only lasted for about 24 hours. However by taking daily temperatures it was found that about a third of the subjects showed a slight rise of temperature, but in the great majority of cases without being accompanied by any subjective symptoms. FINDLAY (G. M.) MACCALLUM (F. O.) & MURGATROYD (F.) *Observations bearing on the Aetiology of Infective Hepatitis (So-called Epidemic Catarrhal Jaundice)*—*Trans. Roy. Soc. Trop. Med. & Hyg.* 1939 Feb. 28. Vol. 32. No. 5 pp 575-586 [57 refs.]

A valuable summary of recent observations with a critical discussion bringing forward evidence in support of the view that infective hepatitis in man is a virus infection.

Under the name of catarrhal jaundice at least three conditions have been described, one of which is characterized by necrotic changes in the liver and is best termed infective hepatitis. This disease cannot be transmitted with any certainty to experimental animals. The aetiological agent does not seem to be a bacterium, spirochaete or protozoan but may well be a virus since the incubation is long 35 days to 7½ months, and the disease is characterized by a leucopenia, affecting especially the polymorphonuclear leucocytes. In addition it is freely filterable through Seitz EK filters and is not visible under ordinary powers of the microscope.

The infection of a pool of measles immune serum in children resulted in the development of cases of hepatitis and the livers of fatal cases showed necrotic changes. In addition children who came in contact with these patients also developed jaundice indistinguishable from infective hepatitis.

The injection of an attenuated strain of yellow fever virus grown in a medium containing human serum, resulted in 95 cases of hepatitis. The symptoms were similar to those of infective hepatitis and one who

died of pneumonia 12 weeks after inoculation showed hepatitis. The occurrence of jaundice following yellow fever immunization has been traced to the introduction of a filterable hepatotoxic agent in the culture medium, presumably from apparently normal human serum.

It is probable therefore that the condition referred to as post-inoculation jaundice is identical with ordinary infective hepatitis and that the causal agent is a filterable virus. Consequently pools of apparently normal human serum should not be used for human inoculation unless the medical history of all donors can be followed for a considerable period of time and at least one month. [See also JAMES above p. 631 and this *Bulletin* 1939 Vol. 36, p. 30] E H

DA FONSECA (Flavio) & ANTIGAS (Paulo) Recherches sur la sensibilité d'animaux sauvages au virus amaril. [Investigations on the Susceptibility of Wild Animals to Yellow Fever Virus.]—C. R. Soc. Biol. 1938. Vol. 129 No. 34 pp. 1134-1137 [14 refs.]

At the parasitological laboratory of the Butantan Institute the authors have tested the susceptibility to yellow fever of various Brazilian wild mammals, in order to determine whether any species, other than Primates, might harbour the infection. However yellow fever virus was never found in the blood of any of the numerous wild animals tested by intracerebral inoculations into mice.

The peccary *Tajassu tajassu* is very susceptible to the intracerebral inoculation of neurotropic virus, and in this species it can be passaged in series, by using brain material. The blood was negative from the third day and the subcutaneous inoculation of a young peccary gave negative results.

A wild guinea pig *Cavia aperea (rufescens?)* is susceptible to intracerebral inoculation after passage and the virus shows alteration in virulence towards mice.

The capybara, *Hydrochoerus capybara* is very susceptible to intracerebral inoculation, showing the usual symptoms of paralysis. The virus was not present in the blood after the third day and intraperitoneal inoculations of the virus gave negative results.

The opossums, Didelphidae seem to be very little susceptible to infection. In one case virus was recovered from the brain of an animal inoculated intracerebrally 8 days previously, and in another case from one inoculated subcutaneously 9 days before but the virus was not recovered from the blood of 14 animals inoculated.

The coati-mundi, *Nasua nasica* succumbs to intracerebral but not to subcutaneous inoculation.

Takara barbara seems to be susceptible to intracerebral inoculation since it showed paralytic symptoms five days later but its organs are toxic to mice and therefore the presence of virus could not be demonstrated.

One species of armadillo *Cabassous unicinctus* contained virus in its blood 5 days after subcutaneous inoculation of the Anibi strain, but showed no other signs of infection. Another species, *Dasyurus novemcinctus* showed paralysis after intracerebral inoculation, but the virus was not recovered. Other individuals inoculated in various ways with the Anibi strain showed no signs of infection.

The subcutaneous inoculation of the Anibi strain gave negative results with the following animals—*Coenda prehensilis* *Nectomys*

squamipes *Sciurus aestuans* *Hydrochoerus capybara* *Cerdoyon thomazarae* *Didelphis paraguayensis* and *Marmosa* sp

The intraperitoneal inoculation of the same strain also gave negative results with the following —*Sylvilagus mexicanus*, *Bradyptes tridactylus* *Dasyprocta aguti* and *Herpailurus pardinoides*

The intracerebral inoculation of neurotropic virus gave negative results in the following —*Mus musculus musculus* *Epimys norvegicus* *Muridae* spp *Euphrades sexcinctus* *Didelphis paraguayensis* and *Herpailurus pardinoides*

The negative results obtained with the common wild mouse, *Mus musculus musculus* indicate the existence in this species as in the case of white mice of races varying in their susceptibility to infection with yellow fever since wild mice in other parts of the world have been found to be susceptible

E H

DA FONSECA (Flavio) & ARTIGAS (Paulo) Sensibilité du chat au virus amaril neurotrope. [The Susceptibility of the Cat to Neurotropic Yellow Fever Virus.]—*C R Soc Biol* 1938. Vol. 129 No. 34 pp. 1143-1145

Young cats two to three months old, were found to be susceptible to infection with neurotropic yellow fever virus when inoculated intracerebrally. The animals showed paralysis and the infection was passed from one cat to another and also to mice. Virus was not found in the circulation even on the third day. Young cats inoculated in various ways with the Ansb strain showed no signs of infection.

The positive results obtained by intracerebral inoculation differ from negative results obtained in Europe and indicate that cats show considerable variation in their susceptibility to infection with the neurotropic yellow fever virus.

E H

DA FONSECA (Flavio) L'hypersensibilité d'un rongeur brésilien au virus amaril neurotrope [The Hyper-Susceptibility of a Brazilian Rodent to Neurotropic Yellow Fever Virus.]—*C R Soc Biol* 1938 Vol. 129 No. 34 pp 1132-1134

A small rodent *Ctenomys brasiliensis* Blainville belonging to the family Octodontidae, has been found by the author to be very susceptible to infection with neurotropic yellow fever virus. Only two specimens were obtained. The first was inoculated intracerebrally with a small dose of virus and showed paralytic symptoms 12 days later. Emulsions of blood, liver and brain were subinoculated intracerebrally into mice. The blood was negative. One out of six mice inoculated with liver material became infected. Of three inoculated with brain material one died on the fourth day and the other two became ill on the ninth day. One of these recovered and the other was used for further passages in mice, in which it regularly produced death in four to five days. Similar results were obtained with the second specimen of *Ctenomys*. The examination of the liver of this animal showed only fatty degeneration without the typical necrosis therefore this species does not seem to be as susceptible as the hedgehog

E H

as in Bas-Congo has only had slight local repercussions. The number of inhabitants was 1 167 175 and of these 1 156 741 were examined. New cases found during the year were 4 475 (0.4 per cent). The number of old patients on 1st January 1936 was 10 655 of which 4,065 were in the recently occupied sub-sectors of Kwango. The number of patients resuming treatment was 2,348 and the total number treated during the year was 17 488. The number of cases cured was 9,368 (53.7 per cent) 425 disappeared and 396 (2.26 per cent.) died the number remaining on treatment was 7,270. These figures give a general idea of the anti trypanosomiasis activity of Foréami during 1936. Much further information is given regarding the state of the disease and the measures taken to combat it in different portions of Bas-Congo and Kwango but for details the original article must be consulted.

The standard treatment administered consisted in a preliminary injection of germanin (moranyl) 1 gm. followed by 12 or 14 injections of trypanaryl. Interesting information is given regarding the control of treatment by lumbar puncture. This was found to be quite practicable in ambulatory treatment and was not attended by any serious accidents. In all, 63,818 punctures were made 3,321 in Bas-Congo and 55,588 in Kwango. The number of punctures performed for diagnosis were 5,398 of these 4,249 were cases proved by the discovery of the trypanosomes in blood or gland juice and 1 149 were clinically suspected cases. No less than 93 to 95 per cent of the definitely diagnosed cases were punctured. The cell count in the spinal fluid of these cases is shown in the following table. The concordance of the results obtained in the two sectors is remarkable —

	0-5	5-10	10-50	50-100	100 and over
Bas-Congo	294 54.9%	111 20.7%	88 16%	12 2.2%	33 6.1%
Kwango	2,005 54%	655 17.6%	647 17.4%	150 4%	258 6.9%

The results of puncture in the suspected cases gave 25.1 per cent of changes (289 out of 1 149). In the Bas-Congo the figures were 16.1 per cent as against 32.9 per cent. in 1935. Details of various districts are given in a table.

The punctures of elimination totalled 8,840—879 in Bas-Congo and 9 161 in Kwango and the punctures of control totalled 40,863 of these 3,698 were done in Bas-Congo and 37,264 in Kwango. Further details of these are also given. This section of the report must also be consulted in the original by those interested. *IV Yorks.*

CONGO BELGE FONDUS REINE ELIZABETH POUR L'ASSISTANCE
MÉDICALE AUX INDIGÈNES DU CONGO BELGE. RAPPORT ANNUEL
1937 pp 32-48 With 1 map A—Maladie du sommeil.
[Sleeping Sickness.]

Sleeping sickness has always occupied the first place in the nosology of the regions under the care of Foréami. Although it is practically

non-existent in certain districts it is a constant menace where the vectors are numerous. In certain districts particularly Moven-Wamba Bas-Kwango and Bas-Kwila it is however present to such extent that the organization has to devote almost all its activity to an anti trypanosomiasis campaign.

Particular attention has always been given by the Foréam personnel to the subject of diagnosis. Gland palpation should always be performed by the European who thus gains an approximate idea of the end-mucity of the disease in the locality. The examination of the gland juice is made by native microscopists but their work is constantly supervised by the doctor or sanitary agent. Examination of fresh and thick blood preparations and the triple centrifugation method are also done by native specialists. Other methods of examination are undertaken by the doctors or more rarely by sanitary agents. It is claimed that this distribution of work assures efficiency and leaves the doctors sufficient leisure for more specialized work.

Two arsenic resistant strains have been isolated, one came from an old focus at Chenal and the other from Lukula where arsenic resistance has not hitherto been recognized. The latter strain which was of moderate resistance proved of extreme virulence for laboratory animals and is being examined by van Hoof. Other sporadic cases have been notified by doctors but in the absence of more detailed study it is impossible to be certain that these were cases of true arsenic resistance.

An attempt has been made to ascertain the frequency of visual disturbance following treatment by arsenicals and to determine whether these accidents were related to the age and sex of the patients. Observations made on 1 893 patients treated with trypanarsyl gave the following results—

- 1 Males were more subject to visual disturbance than females but the proportion of definite blindness was the same in both sexes.
- 2 The proportion of definite blindness was less than 1 per cent.
- 3 The frequency of accidents increased with the age of the patient.
- 4 Accidents were most common at the commencement of the course of treatment.

Treatment is always prescribed by sanitary agents and is administered at rural dispensaries by certificated natives. The courses of treatment have hardly been modified and the general directions are given by doctors. As a general rule since diagnosis is made early the courses can be standardized. Unfortunately medical supervision of very extensive thinly populated regions has hitherto not allowed of systematic control of treatment but the more intensive assistance now adopted will permit of this. European supervision is now concerned more with the regularity of the courses of treatment than with the technique of administering them. The efficacy of treatment is controlled by systematic re-examination of the patients during two years.

Although the phyto-geographical conditions—forests traversing plateaux more or less bare—may be identical in the whole extent of a sector the disease is not uniformly distributed. The cause of this is discussed at some length. High endemicity is manifestly due to the nature of the occupation of the natives and to their habits. Large clearings or the agglomeration of the people rapidly produce a fall in the index of new cases. The endemicity is also maintained by the

continuous introduction of exogenous virus or by the insubordination of the natives who refuse re-examination. Migrations also play a part. But besides these factors there are others less well known which influence the endemicity of the disease. Medical action alone cannot explain the extremely rapid retrogressions which are sometimes noticed in certain districts similar or even better work in neighbouring districts being followed by much poorer results. Possibly in districts where the disease has existed for a long time the individuals develop a certain degree of immunity and Vax Hoor has shown that a virus tends to lose its transmissibility after repeated passages through the same vertebrate host.

In the area controlled by Foréami the endemicity of sleeping sickness develops favourably. In recent foci the regression is rapid, but it is slower and less regular in old foci, and sometimes also in regions previously very heavily infected and in places where new strains are being constantly introduced. As a result of the prophylactic work the number of new cases discovered in 1937 declined by more than 1 000. It is expected that this important regression will be maintained in future years and will be especially evident in Moyen-Wamba where the epidemic is still in full force. In Bas-Kwango substantial progress has already been realized. In Bas-Kwila and in Chenal, which are very old and active foci, the improvement so evident in 1938 was less marked in 1937 but will probably be resumed. In all the remaining sub-sectors the situation is very favourable.

The nutrition of the population is an important factor in the success of an anti-sleeping sickness campaign. Figures are given in support of this contention. The report ends with details of the results of examination of the population and of the treatment of the infected in the various parts of the region controlled by Foréami. W Y

BRAZZAVILLE AFRIQUE ÉQUATORIALE FRANÇAISE RAPPORT SUR LE FONCTIONNEMENT DE L'INSTITUT PASTEUR DE BRAZZAVILLE PENDANT L'ANNÉE 1937 (SALEUX (G)) pp 74-100—Service de la surveillance de la maladie du sommeil. [Sleeping Sickness Service.]

During the year 1937 9 Europeans were found to be infected with trypanosomes. Of these 9 who were treated at Brazzaville only 3 were diagnosed at the Brazzaville Institute the remaining 6 being discovered in various parts of the Colony. Besides these 9 cases, a few others were diagnosed and treated in the Colony and sent straight home without visiting Brazzaville. Clinical details are given regarding each of the 9 cases dealt with at Brazzaville.

Among the natives 148 new cases of sleeping sickness were dealt with at Brazzaville as compared with 239 during the previous year. But this does not necessarily imply that the disease is decreasing. The 148 cases are made up as follows—discovered by itinerant missions 50 sent by dispensaries 46 sent by hospitals 17 came themselves 35. Attention is drawn to the fact that in 1936 29 197 persons were examined by the itinerant missions and 239 cases discovered (0.81 per cent) whilst in 1937 8,216 persons were examined and 50 cases discovered (0.61 per cent.) In a table details are given regarding the regions in which these cases were discovered the index of infection was small, except in Coulair where it was 2.2 per cent.

Emphasizing the importance of early diagnosis the report gives information regarding the means by which the trypanosomes were found and a diagnosis made. In 10 cases trypanosomes were found only in the gland juice in 5 cases diagnosis was made by examination of thick blood films the triple centrifugation method being negative in 6 cases triple centrifugation was positive but thick blood films negative in 70 cases both triple centrifugation and thick films were positive and in 32 diagnosis was made by lumbar puncture both blood and glands being negative.

Clearly then it is not uncommon to find that in the nervous period the glands have shrunk and the parasites have disappeared from the peripheral circulation but they multiply readily in the central nervous system. In this stage the clinical signs are not always obvious and it is necessary to interrogate the patient closely. These results show that the various methods of examination of the patient for trypanosomes are complementary to one another and must often be practised simultaneously, lumbar puncture being reserved for those in whom trypanosomes are found and for suspects i.e. persons with glands without parasites and with suspicious signs or history.

Information is given regarding the stage of the disease in the new cases at the time of their discovery and of their treatment and some details are recorded of old patients who died during the year. The general conclusion reached is that the problem of sleeping sickness has not changed the measures for dealing with it remain the same, and there does not seem to be any necessity to modify them. IV }

GEAR (J. H. S.) & DE MEILLOU (B.) Laboratory Investigations of Two Cases of Trypanosomiasis contracted in Ngamiland, Bechuanaland.—*South African Med J* 1939 Apr 8. Vol. 13 No 7 pp 233-236

Details are given of two cases of sleeping sickness contracted in Ngamiland Bechuanaland. Investigation showed the trypanosome to be *T. rhodesiense*. The fly responsible was *G. morsitans*. The authors state that the discovery of these cases reveals an endemic focus of the disease in an area further south than any hitherto reported.

HAWKING (Frank) A Quantitative Study of the Photosensitivity Induced in Trypanosomes by Acriflavine.—*Ann Trop Med & Parasit* 1938 Dec 21 Vol 32 No 4 pp 367-381 With 4 fig.

JANCsó showed that when trypanosomes have absorbed acriflavine they become photosensitive in that they soon became motionless and presumably dead when exposed to strong light on the stage of a dark ground illumination microscope. In the present paper Hawking describes a quantitative investigation of Jancsó's technique so that it can be used to measure the quantity of acriflavine in the trypanosomes or in the medium with which they are in contact.

The following is the summary of this somewhat technical paper —

1. When trypanosomes are exposed to acriflavine *in vitro* or *in vivo* they become photosensitive owing to their absorption of the compound. The degree of photosensitivity can be measured quantitatively on the stage of a dark-ground microscope as the period of illumination required to cause immobilization.

2. Equations are given for (1) the relation between the photosensitivity and the initial concentration of acriflavine in the medium, and for (2) the relation between the photosensitivity and the acriflavine-content of the trypanosomes. These equations enable the photo-sensitivity to be used to measure low concentrations of acriflavine (0.2-0.6 μ l. per ml.) or to indicate the acriflavine-content of small numbers of trypanosomes. The accuracy is about 50 per cent.

3. The resistant strain of trypanosomes shows a smaller range of individual variation than the normal one: the coefficient of variation in the resistant strain being 22 per cent. and in the normal strain 33 per cent.

BROOM (J. C.) & BROWN (H. C.) Studies in Trypanosomiasis. III.—The Electric Charge of Trypanosomes in the Salivary Glands of Tsetse Flies.—*Trans Roy Soc Trop Med & Hyg* 1939 Jan 28 Vol 32 No 4 pp 545-548.

In a previous paper [this *Bulletin* 1937 Vol 34 p. 930] the authors have shown that the electric charge of the developmental forms of *T. brucei* in the gut of *G. morsitans* is invariably negative irrespective of the sign of the charge of the trypanosomes in the animal host on which the fly was fed. As the strain with which they were then working proved to be incapable of complete development in the fly the authors were unable to study the electric charge of the trypanosome throughout its entire cycle. They have however now been able to complete their observations on a new transmissible strain of *T. brucei*.

It has been proved that, when positively charged trypanosomes are ingested by a tsetse, one reversal of the sign of the charge takes place in the gut of the fly, and a second reversal in the salivary gland. With negatively charged trypanosomes the only reversal occurs in the salivary gland. In both instances the blood trypanosomes of rats infected by the fly are predominantly positively charged. II Y

JERACE (Felice) Sulla morfologia della *Castellanella brucei* [Morphology of *Trypanosoma brucei*].—*Ann d'Igiene* 1938. Sept.-Oct Vol 48. No 9-10 pp 553-559 With 1 text fig & 12 figs on 2 plates

A strain of *Trypanosoma brucei* (referred to as *Castellanella brucei*) has been studied in various laboratory animals. It is concluded that the trypanosome exhibits an extreme polymorphism but this is based largely on observations on what are undoubtedly degenerating forms which cannot in any way be regarded as occupying a place in the normal morphology of the flagellate

HOARE (C A) & BROOM (J C.) Morphological and Taxonomic Studies on Mammalian Trypanosomes VII.—Differentiation of *Trypanosoma uniforme* and *T vivax* in Mixed Infections.—*Trans Roy Soc Trop Med & Hyg* 1939 Feb 28 Vol 32. No 5 pp 629-632. With 1 fig

In a previous paper [this *Bulletin* 1938 Vol. 35 p 701] the authors have shown that *T uniforme* and *T vivax* can be distinguished by differences in the mean and range of their lengths and that the measurement of the length of 10 individuals selected at random in any strain is sufficient for the identification of the species to which the trypanosome belongs

The correctness of this method was verified in the case of some strains of these trypanosomes preparations of which were sent to the authors by VAN HOOFF from the Belgian Congo. In all these cases the authors were dealing with pure infections, and until recently they have not had an opportunity of testing the statistical methods in mixed infections with the two species. Since the two trypanosomes differ only in length the identification of such infections by simple inspection is unreliable and inconclusive. This has been the experience of other observers and the authors encountered the same difficulty in the case of blood films from a situtunga received from CARMTCHAEI of Entebbe. The majority of the trypanosomes were small and conformed to the appearance of *T uniforme* but some were longer and were apparently *T vivax*.

In a table and histogram the frequency in distribution of 100 trypanosomes in respect of length is shown from which it appears that *T uniforme* contributed 82 per cent. of the infection and *T vivax* 18 per cent. That it was possible to differentiate the trypanosomes in a double infection affords further evidence of the independence of the two species of the *vivax* group

The authors emphasize that the only practical method for determining mixed infections with these trypanosomes is that based on a minimum of 100 measurements.

I. CRISTIANI (Michelangelo) Infezioni da tripanosomi e spirochete per via auricolare Ricerche sperimentali. [Experimental Infections with Trypanosomes and Spirochaetes by the Auricular Route].—*Arch Ital Sci Med Colon e Parassiti* 1938 July Vol 19 No 7 pp 406-415 [14 refs.]

ii. — Sulla permeabilità della mucosa nasale per alcuni protozoi (trpanosomi spirochete, sparelle) [Permeability of the Nasal Mucosa for Trypanosomes and Spirochaetes].—*Ibid* pp 416-429 [40 refs.]

i. The first paper describes experiments wherein the author has succeeded in infecting guinea-pigs and mice with various pathogenic

trypanosomes and relapsing fever and rat bite fever spirochaetes by introducing infective material into the external auditory meatus. The infections thus produced differed little from those resulting from subcutaneous inoculations.

ii In the second paper similar experiments carried out on the nasal mucosa are recorded. Both trypanosomes and relapsing fever spirochaetes are able to pass through the intact mucous membrane of the nose [see also this *Bulletin* 1939 Vol. 38 p. 111].

CORSON (J. F.) A Fifth Note on the Infectivity to Man of a Strain of *Trypanosoma rhodesiense* Three Further Passages through Antelopes and Tests on Man Two Charts of the Whole Experiment.—*Jl Trop Med & Hyg* 1939 Jan. 2 Vol. 42 No. 1 pp. 5-7

The preceding note [this *Bulletin* 1939 Vol. 38 p. 208] carried the record of this experiment to March and April, 1938. In the present paper three further transmissions by *Glossina morsitans* through antelopes each followed by infection of a volunteer are recorded and two charts are given showing the passages and tests on man from the beginning of the experiment in October 1934 to October 1938 when the strain was still infective to man. Corson concludes his paper with the following comment —

As I have said in previous papers, in my opinion only positive results should be taken into consideration regarding the infectivity to man of this strain of *T. rhodesiense*. Because some volunteers resisted infection it cannot be inferred that the infectivity of the strain to man has become less during maintenance in ruminants and *Glossina morsitans* for four years. It seems that it must be very difficult to demonstrate a decrease of infectivity to man, and practically impossible to prove that a strain has lost its infectivity to man.

W. J.

BROOM (J. C.) The Maintenance of *Glossina morsitans* in England for Experimental Work.—*Trans Roy Soc. Trop Med & Hyg* 1939 Feb. 28 Vol. 32 No. 5 pp. 633-638. With 1 chart.

The data presented in this note were accumulated in the course of a study of the developmental cycle of *T. brucei* in *G. morsitans*. The method which proved most satisfactory for the maintenance of the tsetse in Britain is briefly as follows —

Pupae of *G. morsitans* were received by air mail from Tanganyika in batches of about 2000 at fortnightly intervals. The pupae were enclosed in a bag of mosquito netting which was placed in a wooden box with six holes $\frac{1}{2}$ in. in diameter bored in each face of the box to ensure a supply of fresh air during the five days' journey. A certain number of flies always hatched out on the journey but most of them were dead on arrival.

Pupae were distributed in two or three glass jars, 4 in. deep and 4 in. wide, the tops of the jars being covered with mosquito netting. Each jar was stood in an 11 in. Petri dish containing a saturated solution of common salt to maintain a humidity of 80 per cent. saturation the whole was covered with a large bell-jar and kept at a temperature of approximately 24°C. The great majority of the flies

were hatched in an insectarium lighted by daylight, but it was found by experiment that artificial light is equally effective in causing development of the wings. From the 58 000 pupae received about 13,500 flies emerged, i.e., approximately 23 per cent.

The flies were collected every 2nd day and placed 4 or 5 together in glass tubes 4 in. by $\frac{3}{4}$ in. one end of which was covered with mosquito netting and the other end closed with a cork. These tubes were applied to infected rats and the flies given an opportunity to feed. The fed flies were then separated and placed, in tens in glass cylinders 4 in. by 2 $\frac{1}{2}$ in. the ends of which were covered with mosquito netting. Each cylinder thus contained flies all known to have had an infective feed on the same day. The unfed flies were returned to the small tubes and given a further opportunity to feed.

The complete developmental cycle of the strain of *T. brucei* used in these experiments occupied at least 25 days. During the first three weeks after the infective feed the flies were therefore fed thrice a week on clean guinea-pigs thereafter they were fed at the same intervals on chickens. The cylinders containing the fed flies were kept at a constant temperature of 24 to 25°C in a humidity of about 80 per cent saturation.

The survival of a population of 10 000 *G. morsitans* during the first five weeks of life after the infective feed is shown in a table. On the 10th day there were 7,532 flies alive on the 20th day 5,575 on the 30th day 4 038 and on the 30th day 3 423. The same data are set forth graphically in curves one curve showing the survival of the flies kept under better conditions and the other the survival of those kept under worse conditions. The difference in the relative number surviving was found to be marked throughout whereas fully one-third of the flies lived for 5 weeks under the better conditions less than one-tenth reached that age in the other case. W Y

SICÉ (A.) & TORRÉST (F) Considerations sur l'épidémiologie l'évolution clinique et la prophylaxie de la trypanosomase humaine au Soudan Français [Notes on the Epidemiology Clinical Evolution and Prophylaxis of Human Trypanosomiasis in the French Sudan.]—*Bull Soc Path Exot* 1939 Jan. 11 Vol 32. No 1 pp 88-93

The climatic conditions of the French Sudan are responsible for certain epidemiological characters which are not met with in the sleeping sickness of French Equatorial Africa.

The pathogenic agent is *T. gambiense* but sometimes trypanosomes were found in the blood or spinal fluid of patients which when introduced into guinea-pigs exhibited a polymorphism recalling that of *T. rhodesiense*. The tsetse found were *G. tachinoides*, *G. palpalis* and *G. morsitans* in the valleys of the black Volta and of the Bani the predominant species in the dry season is *G. tachinoides*. Numerous authors have drawn attention to the influence of atmospheric conditions—vapour tension and temperature—on the biology of *Glossina* in different countries. This influence is very apparent in French Sudan.

Details are given in a table of the atmospheric humidity and temperature during the months of the dry season viz. December to April, and also during the wet season, June to August. The variations in the atmospheric conditions and their influence on the density of

Glossina and on the relative number of the different species confirm the findings of NASH BURTON and LLOYD in Northern Nigeria. [See also this *Bulletin* 1934 Vol 31 p 216 1935 Vol 32 pp 369 723 1937 Vol 34 pp 533 109-111] IV 3

SICÉ (A) & TORRÉSI (F) *Considérations sur l'épidémiologie et la prophylaxie de la trypanosomiose humaine au Soudan français. [Considerations on the Epidemiology and Prophylaxis of Sleeping Sickness in the French Sudan.]—Bull Soc Path Exot.* 1939 Feb 8 Vol 32 No 2 pp 154-156

The fight against *Glossina* in the Sudan does not appear to be any easier than in other countries. Although their permanent haunts are more circumscribed than in Equatorial Africa, and the more severe climatic conditions compel the insects during 4 or 5 months of the year to take shelter in their permanent haunts, one is faced with the same difficulties in the Sudan as elsewhere. Certain individual flies ensure the survival of the species from one favourable season to the next: a relatively large number of females survive and the pupae are resistant to unfavourable climatic conditions.

The authors discuss the methods which they found most useful for destroying the insects and their pupae and emphasize that such methods as clearing of hush must be carried out under skilled direction.

IV 3

MOPEAU (R. E.) *Climatic Classification from the Standpoint of East African Biology—Jl. Ecology* 1938 Vol 28 pp 467-501

Faunal zones are associated with vegetational formations limited by climate. Though the eco-climate is ultimately fundamental it may increasingly be deduced from standard climate. Climatic maps for East Africa have yet to be made. Characteristics of the area are complicated relief, slight annual but high daily range of temperature, rarity of frost at least in screens, and marked droughts in which most of the soil moisture is lost in the first month, causing relatively insignificant loss in the later intensely dry months of biological rest.

Köppen's climate classification groups together in East Africa cultivated areas and those where agriculture is impossible and Scaetta's modification for Ruanda is of too local application. Generally seasonal incidence of rainfall is accorded too little weight and this may be true also of Meyer's rainfall-saturation deficit ratio. Evaporation data are here too scanty to be used.

Rainfall-temperature relations have been employed, but high temperature does not necessarily indicate dryness. Thus Lang's division of mean temperature into total rainfall takes no account of dry periods and De Martonne's similar index, where however 10 is added to the mean temperature, gives too low thresholds for both "dry farming" and forests in East Africa. Emberger divides total rainfall by a function of median temperature combined with extreme range because high range may indicate dryness, but the validity of a function twice introducing minimum temperature which is less important than dew point, is doubtful.

Crowther's "leaching factor" is founded on too local data, and Andrews and Mearns though allowing for dry months ignore residual effects of rainfall, so that parts of East Africa on their system appear too "dry."

Generally extremes are more important than climatic means especially where rainfall is low or sharply seasonal. Use of median instead of mean temperature or the application of the standard deviation as a measure of variability is objectionable because very low is probably more important biologically than very high rainfall and altered distribution with unchanged total fall affects desiccation and effectiveness is also governed by interception and run-off and this in turn by the nature of the soil. Mist and cloud by affording shade and causing horizontal precipitation often permit the occurrence of forest where rainfall is low.

Mean annual temperature in East Africa is determined by altitude excepting local variations near the sea and Lake Victoria. Except where local topography plays its part the tropical zone extends up to 4000 ft and the highland zone from 6000 ft above the mean temperature isotherm of 18 C. Between lies an intermediate zone. Rainfall below 40 mm in a month is probably ineffective and when a month over 40 mm occurs in a long dry period it should be discounted.

In default of evaporation data the best available classification for East Africa is one based on some function of temperature combined with the length of the wet season and the total rainfall in that season. But such a system will still be defective because it takes no account of climatic extremes horizontal precipitation caused by mist and rainfall effectiveness governed by the total fall and by the nature of the soil.

[It seems that in default of evaporation data more work should be done to elucidate the relation of evaporation to saturation deficit which may prove to be simple. Failing this Emberger's system may receive more consideration since though range of temperature may be biologically insignificant the dryness which it indicates is not. Further extreme dryness may well be a concomitant of very long dry periods which therefore on such a system are not entirely ignored.]

A comprehensive bibliography is an extremely useful feature of this paper.]

DAVE (J Burt) The Classification of Tropical Woody Vegetation-Types.—Imperial Forestry Institute University of Oxford. Institute Paper No 13 pp 1+85 1938 [2s 6d]

This paper is the work of a forest botanist who wishes to standardize the classification of types of tropical woodland. The problem of naming and defining such things as savannah orchard-bush miombo and kurumi is familiar to those entomologists who work on Glossina. The present work will help to keep them in line with what the botanists are doing.

The author stresses the need for a common terminology and a common range of observations in the description of plant communities. Nomenclature such as that of Clements for successional stages is rejected pending further knowledge but a distinction is made between temporary disturbance (cultivation etc.) and long term trends.

For primary classification Schumper's arrangement based on aerial factors is preferable to Warming's which was based on edaphic factors i.e. differences in type of soil. A useful tabular comparison of Chipp's and Champion's modifications is given.

The plant association "is defined as the largest unit of a definite assemblage of species the formation as a group of associations with both a common physiognomy and a common aerial habitat. A formation type is a group of formations with a common physiognomy. In the summary however these definitions are not sustained. The formation is there stated to be of two kinds namely climatic, governed by aerial factors, and edaphic governed by soil and drainage. The first covers large areas and the second is of purely local occurrence and of different physiognomic form. Further the formation is sometimes defined as necessarily a climax and elsewhere (climatic formation) as not necessarily a climax. The edaphic formation is regarded as possibly a sub-formation only since it may be only a part of the climatic formation. It is not clear from this why the edaphic formation or sub-formation should not be regarded as an association.

The body of the paper consists of a description of 17 tropical formations divided into the formation types of moist and dry woodland grassland and desert, with many sub-formations. There appears to be nothing to cover the unique deciduous scrub climax of East Africa, dominated by a closed woody thicket association from which grass is absent.

Besides a bibliography and a skeleton glossary there is a list of data to be recorded in the field to provide mainly qualitative answers to more than 150 questions. For the benefit of those foresters unable to deal with all these the questionnaire is divided into three parts —

1 Synecology includes qualitative and quantitative composition of the community its physiognomy phenology and biotic (actually zoological) relations. The biotic questions refer only to termites and to bird and other animal distributors of fruits and seeds it seems that the grazing trampling and marring caused by the ungulates and other animals might recommend their consideration.

2 Autecology covers specific dimensions and morphology phenology and regeneration.

3 Under habitat are included the physical factors, both climate and soil, and biotic features, all but one of these last questions relating to some form of human interference.

PIRELLA (Giuseppe) I fenomeni immunitari nelle tripanosomiasi. Studio monografico. [Immunity in Trypanosomiasis.]—*Rendiconti Istituto di Scienze Pubbliche* Roma. 1938. Vol. 1 Pt. 3 pp. 931-1078 [459 refs.]

RADNA (R.) La microscopie de fluorescence comme mode de recherche du bacille de la Lèpre et des trypanosomes. [Fluorescent Microscopy as a Method of Examination for the Leprosy Bacillus and Trypanosomes.]—*Ann Soc Belges de Méd. Trop.* 1938. Dec. 31 Vol. 18. No. 4 pp. 623-628. [11 refs.]

REICHERT in 1911 constructed a fluorescence microscope but the illumination was so poor that it would not allow of high magnifications. Later however this difficulty was overcome. The organisms are treated with fluorescent reagents, e.g. in the case of trypanosomes—trypanflavine, 2-p-acetylaminostryryl 6-dimethylaminoquinolin methosulphate, or coryphosphine. The author claims that this method facilitates the search for trypanosomes in the blood.

CORSON (J F) A Record of Some Complications which occurred in the Course of Experimental Infections of African Volunteers with *Trypanosoma rhodesiense*.—*Ann Trop Med & Parasit* 1938 Dec 21 Vol. 32. No 4 pp 437-443

In this paper the author records a somewhat high incidence of complications which occurred in the course of experimental exposure to *T. rhodesiense* infection of 43 African volunteers during 1937 and 1938 of these 28 became infected and 15 resisted infection. Each volunteer except Nos. 8 9 and 10 was exposed to infection by the bite of a single infective *Glossina morsitans*. All were treated, whether infected or not and germanin alone was used, in 1 gm. doses given intravenously. A number of notes are given regarding each of the 43 cases.

Corson states that there is no reason to think that either the infection with trypanosomes or the treatment with germanin had anything to do with the complications except with the albuminuria. The more serious complications fortunately occurred after the third or fourth dose of germanin, so that the infection with trypanosomes could be regarded as cured before the complication appeared.

PENARD (BL) BRUMPT (L.) & RAYMONDEAU (BL) Présentation d'un malade atteint de trypanosomose révélée tardivement par des convulsions et du prurit. [A Case of Trypanosomiasis Diagnosed Late by Convulsions and Pruritus].—*Bull et Mém. Soc Méd Hôpît de Paris* 1939 Mar 6 55th Year 3rd Ser No. 7 pp 324-327

The patient a native 32 years of age was sent to hospital suffering from epileptic convulsions and pruritus. A diagnosis of nervous syphilis was made and a lumbar puncture performed. The fluid gave a positive Wassermann reaction but the authors were impressed by the excess of protein and especially by the cell count of 1,800 per cmm. On centrifuging trypanosomes were found, and also malarial and other abnormal cells. Examination of blood and bone-marrow was negative the glands were not puncturable.

W 1

REYNES (V) & TRINGUIER (E.) Réflexions à propos de quelques résultats de traitement de la trypanosomiase humaine dans un centre de brousse [Reflections on Some Results of Treatment of Sleeping Sickness in the Bush].—*Bull Soc Path Exot* 1938. Dec. 14 Vol. 31 No. 10 pp. 955-968. [17 refs.]

In this article the authors review the results obtained by them in the treatment of sleeping sickness at one of the districts (Tibati) in the Cameroons where the patients have been observed closely for

dispensaries and those who came up regularly for treatment. All cases were diagnosed in June and July 1937 and were under observation up to July and August 1938.

Group 1 A.—Cases with peripheral infection of the 22 cases treated with tartar emetic-trypanoxyl and kept under observation for the full period, all were apparently well without signs of infection.

B.—Cases with nervous involvement of 32 with meningeal reaction and treated with tartar emetic trypanamide 30 (94 per cent.) were well, with normal spinal fluids and without signs of infection and 2 (6 per cent.) had trypanosomes in the blood. Of 37 meningo-encephalitic cases treated in the same way 5 had died and 6 had disappeared. 18 of the remaining 28 exhibited no signs of disease and 8 remained in *status quo* or were worse.

Group 2 A.—Cases with peripheral infection of the 41 patients treated with tartar emetic trypanoxyl and kept under observation for the full period, all were cured.

B.—Cases with nervous involvement of the 90 patients with meningeal reaction 63 (70 per cent.) were apparently cured, 14 (15.55 per cent.) showed an increase of cells in the spinal fluid, but no increase of protein, 13 (14.44 per cent.) had got worse. Of the 97 patients with meningo-encephalitis 68 were kept under observation and 11 (11.33 per cent.) had died, 37 (54.41 per cent.) were apparently normal and 31 (45.88 per cent.) were either no better or worse.

The authors conclude from this work that synergic treatment gives excellent results. The best mixture is moranyl and trypanamide, but the combinations tartar emetic trypanoxyl or tartar emetic-orsanine are also valuable.

IV Y

ROUSSEAU (G) Quelques essais de traitement de trypanosés chroniques par le mélange anthiomaline-moranyl. [Attempts at the Treatment of Chronic Trypanosomiasis with Anthiomaline-Moranyl Mixture].—*Ann. Soc. Belge de Méd. Trop.* 1939 Mar 31 Vol. 19 No. 1 pp 73-80

The firm of Specia provided the author with two powders (A) consisting of moranyl 10 gm.+anthiomaline 0.6 gm. and (B) of moranyl 10 gm.+anthiomaline 1.8 gm.

Powder B can be injected into man in doses of 0.25 to 0.5 gm., and probably even of 1 gm. without trouble. Powder A can be given in doses of 1 gm. or more without danger. Details are given concerning 8 advanced cases treated by these mixtures. The injections were made at intervals of 4 days until 10 had been given. They caused no trouble apart from the fact that some of the patients developed albuminuria after the 4th or 5th injections. Some of the cases appear to have been improved others not.

IV Y

ASTRACHAN (Girsch) & FRANKS (Andrew G) Nitritoid Reaction following an Injection of Trypanamide.—*Arch. Dermat. & Syph.* 1938 Dec Vol 38, No 6, pp. 949-950

Details are given of a case of cerebrospinal syphilis exhibiting nitritoid reactions after injection of trypanamide. The patient had previously received ninety injections of trypanamide (1 to 2.5 gm.) without any ill effect and had also tolerated injections of neocarsphenamine and a bismuth preparation. On February 11th, 1937 she

stated that she felt nauseated for a while and noticed a mild swelling and redness of the face which lasted a few minutes after the previous week's injection of 2 gm of tryparsamide. In view of this, the dose was reduced to 1 gm. and the patient was carefully observed while the injection was being given. Immediately after the injection she complained of a tickling sensation in the throat and nausea and pain in the stomach. Three minutes later the conjunctivae became suffused and a diffuse redness spread over the face and neck. Intense coughing followed and the patient complained of a choking sensation in the throat, heaviness in the chest, a feeling of swelling of the face and a burning sensation in the eyes. All these symptoms disappeared in fifteen minutes.

Tryparsamide was then discontinued but renewed seven months later after a prophylactic course of liver extract. Injections of 0.5 and 1 gm of tryparsamide were then well borne but when 1.2 gm of the drug was administered the patient complained of sudden weakness and nausea and presented redness and oedema of the face and mild conjunctivitis. A few minutes later a localized urticaria-like eruption developed and this was followed by a diffuse erythema of the whole body. This eruption disappeared in one or two days and the patient felt perfectly well. IV Y

VAN DEN BRANDEN (F.) & POTTER (R.) Essais de perfectionnement du contrôle biologique des glyphénarsines (Tryparsamide Tryponarsyl Novatoxyl Trypothane) [Attempts to perfect the Biological Control of the Glyphenarsines.]—*Ann. Soc. Belge de Méd. Trop.* 1938. June 30 Vol. 18 No. 2. pp. 299-311. With 1 fig. [11 refs.]

This work on tests for the toxicity of the glyphenarsines all appears to have been published elsewhere, and has already received notice in this *Bulletin* [1933 Vol. 30 p. 788 1934 Vol. 31 p. 207 1936 Vol. 33 p. 201 and 1938 Vol. 35 p. 349] IV Y

BERTÉ (M.) Procédé pour rendre indolores les injections sous-cutanées d'atoxyl. [Procedure for Rendering Painless Subcutaneous Injections of Atoxyl.]—*Bull. Soc. Path. Exot.* 1939 Feb. 8. Vol. 32. No. 2. pp. 180-181.

The author has been impressed with the number of patients who objected to subcutaneous injections of atoxyl on account of pain. The method of mixing the drug with the citrated blood of the patient apparently obviated this difficulty. It then occurred to Berté that as the pain of intravenous injection of 90 per cent alcohol is completely suppressed by sodium citrate possibly this substance might prevent the pain due to subcutaneous injections of atoxyl. The present method adopted by the author is to dissolve the dose of atoxyl in 10 per cent solution of sodium citrate and he has been assured by patients that this simple device suffices to prevent pain. HAWKING (Frank) A Note on the Trypanocidal Action of Atebrin in Relation to its Absorption by Trypanosomes.—*Ann. Trop. Med. & Parasit.* 1938. Dec. 21 Vol. 32. No. 4 pp. 383-386.

FISCHL and SINGER and later OESTERLIN described experiments showing that atebrin was absorbed by trypanosomes but that it

exerted no trypanocidal action from which they concluded that although the absorption of a chemotherapeutic agent is a necessary preliminary to its parasitocidal action it is not identical with it.

Hawking has reinvestigated this matter using the technique described by the reviewer and his colleagues, and has reached the conclusion that atehrin is but slightly absorbed by trypanosomes and that its degree of absorption is in relation to its small trypanocidal activity.

IV Y

LESTER (H. M. O.) The Results of Sleeping Sickness Work in Northern Nigeria.—*Trans. Roy. Soc. Trop. Med. & Hyg.* 1939 Feb. 28. Vol. 32, No. 5 pp. 615-627.

In this paper the author gives an interesting summary of the results of sleeping sickness work in Northern Nigeria during the last few years. Prior to the appointment of special sleeping sickness medical officers in 1927 a few hundred cases were treated each year at general hospitals and at Sheni. Between 1928 and 1930 sleeping sickness officers toured parts of the Northern Provinces, treating such cases as came to them to the number of 3 000 to 4 000 a year but as it was difficult for a touring medical officer to stay in any village for more than a short time few patients completed treatment.

In 1930 every effort was made to persuade patients to attend regularly for a full course of injections. No attempt was made at compulsory examination and treatment was voluntary. Towards the end of 1930 the system of compulsory surveys and mass treatment was inaugurated. It soon became evident that a large part of the central region of the Northern Provinces was heavily infected, and there were signs that the disease was spreading rapidly. It then became realised that when dealing with hundreds of thousands of cases the cost of surveying the whole area regularly would be prohibitive once a mass survey has been completed and all cases treated a field dispensary is established to deal with relapses and fresh infections. Adequate protective measures are essential anti-tsetse clearing by local communities and in some instances the removal and concentration of the population are the only certain methods of controlling the disease.

In 1937 a special Sleeping Sickness Ordinance was enacted to give the necessary legal powers, a scheme for the expansion of the Service was approved and a grant of £19,000 a year for five years, was obtained from the Colonial Development Fund to pay for a control service provided that Nigeria financed the improvement of the treatment service considered necessary.

Details are given of the present state of affairs in the various infected emirates. These must be consulted in the original by those interested. The following are the conclusions —

The findings have been given for a series of resurveys in different parts of Northern Nigeria during the last 12 months. Out of 149,820 people examined in all areas, only 2,320 cases were found, an average infection rate of 1.6 per cent. The average rate of the original surveys of the same areas was 9.4 per cent. In only one locality the Ganawuri villages which were moved to a tsetse free site, can protective measures have had anything to do with this reduction in the infection rate.

The establishment of field sleeping sickness dispensaries in the districts which have been surveyed and treated has played a big part in reducing the infection rate and in controlling the disease. In many

localities once the incidence has been diminished by mass treatment, dispensaries can cope with relapsed cases and fresh infections. Attendance at dispensaries has been greatly helped by the propaganda value of the surveys.

Although the success of this intensive treatment campaign is undoubtedly there must be no relaxation of effort. At present sleeping sickness is more or less confined to the central parts of the country in the neighbourhood of lines of communication and mining areas. Fortunately it has not yet spread to the peripheral zones which both in the east and west are heavily infested with tsetse fly.

There are some infected areas which have not been surveyed yet and there are others where resurveys are urgently needed. Up to 1935 there was evidence that sleeping sickness was still spreading in spite of all efforts, but since then there has been a great improvement. The disease is now much more under control and large scale protective campaigns have been started to consolidate the gains of recent years. It is to be hoped that in a short time mass treatment will only be required occasionally in a few areas and that communal protective clearings and voluntary treatment at dispensaries will be sufficient to control the disease.

JACK (R. W.) Annual Report of the Division of Entomology for the Year ended 31st December 1937—*Rhodesia Agric Jl* Vol. 35 No. 8. pp 652-676 also as *Bull Minist Agric (S Rhodesia)* No 1080 25 pp Salisbury August 1938. (Summarized in *Rev Applied Entom.* Ser B 1939 Feb Vol. 27 Pt. 2 p 20]

In the course of the medical and veterinary section of this report, J. H. Chorley gives an account of the situations in 1937 in the various localities in Southern Rhodesia in which control measures against *Glossina morsitans* Westw., were or had been carried out. The history of controlled game destruction and the creation of fly free buffer zones as a measure for checking the advance of the fly is very briefly reviewed, and it is pointed out that this measure has now passed the experimental stage and can with confidence be applied to any area on the periphery of a fly belt, wherever land is required for development. The immediate objects of the present policy in the various districts is outlined, but it is also suggested that the fly might be eradicated from all the infested areas in the Colony by judicious and cautious extension of controlled game destruction over a period of years and that this could be combined with the establishment of game sanctuaries in the areas cleared of fly so that no extermination of species of game animals would take place. In areas in the low veldt where elephant and rhinoceros are abundant, other measures, such as bush and tick clearing might have to be employed. Rhinoceros cannot be driven, are very localised and remain for years in the vicinity of a few favoured water holes. The area to which these measures might be applied lies outside the zone of European settlement and little mining activity is likely to develop. During the year a further area of 1,500 square miles was reclaimed.

A number of cases of trypanosomiasis of cattle occurred during the year on farms adjacent to the Nelssetter border. As most of these farms were in the basins of the Inyamadzi or Chiredza rivers or were connected by a forest belt with them, further clearing was undertaken at the junction of these two rivers where they cross the border the clearing being made approximately three-quarters of a mile wider at this point. The original clearing was maintained, all re-growth being slashed back, and grass-burning was successfully carried out in October. A further spread of *G. morsitans* in Portuguese East Africa towards the border was recorded, flies being taken at a point not more than five miles from the border.

clearing, so that the threat of invasion at the southern end of the Moleatter district has increased.

"*Amblyomma lebrunum* Koch, has extended its range northward from Vatabeleland to the Gwelo and Hartley district.

LATYER (G) La lutte contre les glossines. [The Combat against Glossina.]—*Ann de Méd et de Pharm Colon* 1939 Jan-Feb-Mar Vol 37 No 1 pp 27-40

A general discussion of measures adopted against tsetse these must depend on local conditions. By a careful study of these one will avoid errors, failures and loss of time and money. The study involves examination of the terrain, identification of the species of Glossina which infest it their biology and particularly their association with the vegetation. The entomologist should work in conjunction with the botanist and a forestry officer. The paper continues in this way with generalizations, and must be consulted in the original by those interested. W Y

MALARIA

PRICES OF ABSTRACTS IN THIS SECTION

WILSON (p 676) contrasts the fully immune state of the Digo tribe of Tanganyika Territory who are constantly infected and show no apparent ill effects in adult life, with the incomplete immunity of the Nyiramba tribe less exposed to constant infection, the adults of which suffer from attacks during the transmission season. In the former treatment should be limited so as not to interfere with the acquisition of immunity since anopheline control is impossible. In the latter treatment and control are indicated. He describes the parasites of *P. falciparum* seen in immune and non-immune persons.

SARIKJAN (p 677) shows that in Central Russia the majority of primary attacks in infants occur in the first half of the year probably because a large proportion of cases have long incubation periods.

CORRADETTI (p 677) states that malaria only occurs in the wet season in the region of Lake Tana, and that highlands above 2,000 metres are free throughout the year. He recommends prophylactic quinine in the rainy season. CICCHETTO (p 678) in Italian Somaliland finds *P. falciparum* to be the commonest parasite. Infection with *P. vivax* gives the highest spleen rate and the largest spleens.

In the Bahrein Islands, AYRIDI and MAJID (p 678) found malaria to be an important disease. *A. stephensi* is probably the only vector but is very prevalent breeding in drains, pools, wells and seepage pits. All three *Plasmodia* are found.

FARIXAUD *et al* (p 679) show that in Saigon-Cholon sporadic outbreaks of malaria occur in what is an area of extremely low endemicity. *A. taeniorhynchus* is the commonest anopheline and it may be that the enormous proliferation of this comparatively ineffectual vector is responsible for the limited transmission which takes place.

CALLENDER and GENTIKOW (p 679) attribute the higher incidence of malaria in the United States Army personnel than in the Canal employees in Panama to greater exposure and lack of immunity.

Pinto (p 680) shows that *A. gambiae* first found in Brazil in 1930 and transported there from Africa is now breeding extensively in water of many types. Sporozoite rates as high as 30 per cent. have been found, and epidemics of malaria with high mortality caused. Buxton draws attention to the gravity of the position.

Roy *et al* (p 681) remark on the prevalence of *A. stephensi* in Calcutta. It is not there a carrier of malaria though in certain other cities it is dangerous.

Sivalingam (p 681) found higher parasite counts in primary cases of *P. vivax* infection than in relapses or reinfections. Usually in primary cases high counts were associated with subsequent high temperatures but this was not so in the others.

Boyd and Kitchen (p 682) consider that if infected mosquitoes are applied to several patients consecutively the numbers of sporozoites in their glands progressively diminish. With small numbers (1-5) of mosquitoes there are significant differences in the characters of the infections produced in the first and last patients the latter having long incubation periods and short attacks. These short attacks therefore may be as significant of inadequate infection as of immunity. They also (p 682) report an incubation period of 304 days in a patient aged 15 infected with the McCoy strain of *P. vivax*.

Strickland (p 682) discusses the quinine supplies of India.

Fastovsky and Chendergitch (p. 683) after a comparative test of quinine and acrinine alone or in conjunction with plasmodine in treatment consider that the latter is as effective as the former and suitable for mass treatment. Early relapses were most frequent in *P. falciparum* infections.

Stauss (p 683) states that the daily dose of plasmoquine now regarded as sufficient is 0.01 gm. per 10 kilos body weight. He discusses the by-effects abdominal symptoms methaemoglobinaemia and blood changes. By-effects are rare with atebirin but may follow intravenous injection. The ratio of plasmoquine to atebirin should be not more than 1 to 20 as in Atepe tablets.

Pizzillo (p 685) reports three patients with recent malaria who required a second course of adrenalin treatment for cure. This treatment represents an exact reproduction of the process of spontaneous recovery.

In the *Bulletin de l'Institut d'Hygiène du Maroc* (p 686) it is stated that the guiding principles in prophylaxis are standard treatment in epidemics clinical prophylaxis of children in endemic areas and eradication of the disease in areas of feeble endemicity. The state of premunition governs the dose and rhythm of drugs as prophylactics. Weekly administration is sufficient in Morocco. Simeons (p 686) obtained excellent results in the eradication of severe endemic malaria by mass treatment by atebirin injections and plasmoquine followed by the treatment of subsequent cases by atebirin injections alone. The relapse rate was very low unlike the high rate observed in the treatment of sporadic cases elsewhere by atebirin injections and the author considers this to be due to the immunity already developed in the people of the endemic area. Immunological grouping is therefore important in treatment. Work by Winchester (p. 687) on two comparable groups of persons in Georgia, U.S.A. subject to infection with *P. falciparum* has shown considerable reduction in parasite indexes and spleen rate in the group receiving prophylactic atebirin, as compared with the control group.

TIBOURSKAJA (p. 687) found that quinoline No. 31 0.03 gm thrice daily administered to gamete carriers of *P. vivax* and *P. falciparum* rendered them incapable of infecting mosquitoes. In *P. vivax* cases the gametostatic effect lasted five days. In *P. falciparum* infections a smaller dose was sufficient. C W

HACKETT (L. W.) Le più recenti ricerche sulla malaria ed alcune loro applicazioni (Recent Researches on Malaria and Some of their Applications.)—*Rendiconti Istituto di Scienza Pubblica*, Rome, 1939. Vol. 1 Pt. 2. Pp. 433-447 With 7 figs. on 3 plates.

An interesting lecture which covers practically the whole field of malaria research. It provides an admirable summary of modern conceptions regarding the epidemiology of the disease. Norman White

WILSON (D Bagster) Implications of Malarial Endemicity in East Africa.—*Trans. Roy. Soc. Trop. Med. & Hyg.* 1939 Jan. 28. Vol. 32, No. 4. pp. 435-446 With 1 fig. [13 refs.] Discussion pp. 447-465 With 1 graph.

The authors avowed intention in presenting this paper was to arouse discussion on "the relevance of what has been called natural immunity to malaria in deciding on an anti-malaria policy. This immunity is defined as a state of acquired resistance to the ill-effects of the presence of malaria parasites, obtained by natural infection which is probably dependent upon the persistence of parasites in the immune organism. The unorthodox use of the phrase natural immunity to describe an acquired condition was unfortunate as it acquired a prominence in the discussion that was hardly justified in view of the clear definition quoted above.

A comparison is made of malaria as it occurs among the Digo of the East African coast with the malaria observed among the Nyanmba, a Bantu tribe living on a plateau in central Tanganyika. The former is an example of hyperendemic malaria to which full immunity is acquired. The spleen rate 85 per cent in children falls to 39 in adult life with a corresponding fall in the parasite rate. The average parasite count varied from 7000 per cmm. in infants to less than 200 in adults. There was a marked seasonal increase in the parasite counts of infants and very young children but none at later ages. Whatever the intensity of infected anopheline infestation of houses, there were no apparent ill-effects in older children or adults attributable to malaria. It is estimated that among these Digo an individual is likely to receive an infective bite twelve times a year. Anopheline control is economically impossible. Attempts at curative treatment, sufficient to interfere with the acquisition of a solid immunity should be avoided. Treatment in the first year or two of life pending the acquisition of this immunity should only be sufficient to save life. The malaria of the Nyanmba is also hyperendemic but the immunity they acquire is incomplete. The spleen rate of children is 87 per cent., 68 in adults. The parasite rate declined with age but the decline was very small in the wet season. Adults suffer from attacks of malaria during the transmission season. Anopheline breeding is seasonal. Anopheles were found in houses during only eight months. The

estimated number of infected bites an individual receives a year is between 4 and 8. The seasonal nature of infection explains the incomplete immunity acquired. In the case of these people drug treatment or anopheline control or both, are indicated.

P. falciparum is the predominant species the author believes immunity to *P. falciparum* to be very evanescent. He describes morphological differences of *P. falciparum* as seen in the blood of immunes and non immunes respectively. In non immunes the parasites are almost monomorphic, minute or very minute rings one to four in a cell, *appliqué* forms common and stippling of the cell difficult to obtain. In immune persons the parasites are more polymorphic.

It is to be hoped that the author will have ample opportunity of following up several promising lines of inquiry foreshadowed in his paper

N IV

SARIKJAN (S. J.) Contribution au problème de la fréquence du paludisme dans la population puérile au moment d'une explosion épidémique dans la région centrale de RSFSR. [Incidence of Malaria among Child Population in an Epidemic Outbreak in the Central Region of the USSR.]—*Med. Parasit. & Parasitic Dis.* Moscow 1938. Vol. 7. No. 4. [In Russian pp. 551-558. [19 refs.] French summary p. 558.]

When malaria appears in epidemic form in the central regions of the USSR, children not excluding infants suffer most. The majority of primary attacks of malaria in infants occur in the first half of the year more especially in the second quarter. This is probably attributable to the large proportion of cases with prolonged incubation periods. Cases of primary malaria in infants born in the preceding autumn or winter have shown that infection with malaria is possible not only in the event of the mother suffering from active malaria during pregnancy but also if she is in the period of these prolonged incubations. Moreover in the winter and early spring primary attacks may be caused by mosquitoes which have been hibernating.

CORRADETTI. Epidémiologie du paludisme dans la région du lac Tsana. [Epidemiology of Malaria in the Lake Tsana Area.]—*Bull. Office Internat. d'Hyg. Publique* 1938. Dec. Vol. 30. No. 12. pp. 2793-2795.

Inquiry carried out at the end of April and the beginning of May failed to reveal the presence of any important anopheline vector of malaria. *A. cinereus* was found as were *praedariensis transvalensis mauritanus* and larvae resembling *longipalpis*. The author concludes that in the parts of Gondar visited malaria does not occur in the dry season. Areas above 2,000 metres are free from malaria throughout the year. At lower levels malaria can occur during and after the rains. Further observations are called for in the rainy season. He recommends prophylactic quinine 0.60 gm. on three consecutive days each week from June to October inclusive in areas below 1,600-1,700 metres. In areas about 1,800 metres similar doses of quinine should be taken from the middle of August to the end of October.

CICCITTO (Angelo M.) Ricerche sugli indici malarici-splenico e parasitario—nella Somalia Italiana. (Parasite and Spleen Indexes in Italian Somaliland.)—*Riv. di Malarologia*. Sez. I. 1938. Vol. 17 No. 5 pp. 396-410 [13 refs.] French summary

The author bases his study on malaria patients treated in the hospitals of Mogadisco during four years 1934-37. The patients came from most parts of the colony. *P. falciparum* was most in evidence, 60-65 per cent. of cases versus 30-35 per cent. *malariae* 5-8 per cent. The percentage of parasite carriers among those with enlarged spleens was almost identical with the percentage of enlarged spleens among parasite carriers. Enlargement of the spleen was most frequent in *vivax* infections and the degree of enlargement was greatest. Very large spleens were rare in *falciparum* infections. The spleen rate was lowest in *malariae* infections though very large spleens were more common than in *falciparum* infections. N W

AFKIDI (M. K.) & MAJID (Syed Abdul) Malaria in Bahrain Islands (Persian Gulf)—*Jl. Malaria Ind. of India* 1938 Dec Vol. 1 No. 4 pp. 477-472. With 3 maps & 1 chart. [14 refs.]

This, the first published malaria survey of the Bahrain Islands, was carried out during a fortnight in January and five weeks in the following May and June. The inquiry was confined to the main Island of Bahrain and the adjacent islet Muharrak. Two considerable towns, Manama, population 40,000 to 50,000 and Muharrak population 30,000 to 40,000 were included in the survey. The hot humid climate is characteristic of the Persian Gulf. The average annual rainfall is but 3½ inches and there are only from 3 to 6 rainy days a year. The main island is 30 miles in length and has an area of 108 square miles. Cultivation is confined to narrow belts of date palm plantations. Here there are copious springs of warm and slightly brackish water. The total population of the archipelago is estimated at 150,000. Pearl fishing is the important industry. Recently oil fields have been discovered.

There are no morbidity nor other vital statistics available. It appears, however, that malaria has always been an important cause of sickness. Malaria is responsible for nearly a quarter of the cases treated at the Manama Hospital. The spleen rate for 234 children between 4 and 14 years of age in Manama was 38.9—the corresponding rate for Muharrak town was 13.1. The parasite indexes for these towns were 21.8 and 6.3. The anophelines identified were *stephensi*, *fluvialis*, *culiseta*, *pulcherrimus* and *sergenti*. *A. stephensi* was much the most prevalent and the only species found infected. It is probably the only vector. It was found breeding in agricultural drains, leakage pools, shallow domestic wells and garden pits containing seepage water. In some dammed irrigation wells and garden pits increase in the salinity of the water precluded the breeding of *A. stephensi*. In the 34 positive blood films, among the 249 examined in January the species of parasite found were—*falciparum* 10 versus 13 *malariae* 10 and *falciparum* with *malariae* 1.

This interesting and well documented report concludes with a series of recommendations concerning the temporary and permanent control of malaria in Bahrain. N IV

FARINAUD (E.) RAMIJEAN (R.) & FAVOT (M.) *Nouvelles recherches sur le paludisme à Saigon. [New Investigation of Malaria in Saigon.]—Rev Méd Française d'Extrême-Orient* 1938 Aug-Sept Vol. 20 No 7 pp 878-888 With 1 folding plan

Localized outbreaks of malaria occur in Saigon-Cholon from time to time. There has however been considerable discussion as to whether indigenous malaria occurs in Saigon at all. The two contiguous towns of Saigon and Cholon now united, have a population of about 360 000 unevenly distributed over an area of 55 square kilometres. The European and commercial parts of the town are well constructed but towards the fringe of the urban area native huts are scattered or grouped in what are for all practical purposes villages separated by varying distances one from the other. In these outlying parts of the town swamps and marshes communicating with the network of channels and canals that surround the town, are a prominent feature.

During the three last months of the year 15 000 children from 2 to 12 years of age in all parts of the town were examined. The estimated child population of these ages of the town is 77 000. The spleen rate was 1.36 per cent. varying in the 18 different quarters of the town from 0.15 to 3.66. The parasite index was 2.92 per cent. varying from 1.22 to 11.42. Nearly all the enlargements of the spleen observed were very small. The quarters of the town most infected are all on the outskirts near water channels or inundated land. In the maternity hospital the percentage of cases in which child bearing was complicated by an attack of malaria was 4.32 in 1937 and 3 during the first six months of 1938.

There are undoubted foci of malaria infection in Saigon-Cholon but the low endemic indexes indicate seasonal or sporadic outbreaks occurring in an area of extremely low endemicity.

The species of *Anopheles* found are *barbrosistris sinensis vagus philippinensis kochi* and *lessellatus*. *A. vagus* is much the most frequent representing almost the totality of adults captured. No important vector of malaria occurs in any numbers and the hypothesis is put forward that perhaps the enormous proliferation of such an ineffectual vector as *A. vagus* may be responsible for the limited transmission that does occur.

In spite of the little importance of malaria the authors urge the importance of filling marshes and inundated land within town limits.

A IV

CALLENDER (G. R.) & GENTIKOW (C. J.) *Malaria in the Panama Canal Department United States Army* I. Incidence of Primary Cases in 1936 and 1937—Reprinted from *Milit Surgeon* 1938 Oct. Vol. 83 No 4 pp. 299-316 With 3 figs. [18 refs.]

The incidence of malaria in the United States Army in Panama is more than thrice as high as that among employees of the Panama Canal. Among the reasons for this higher incidence are the closer proximity to anopheline breeding places of certain army posts, exposure at subposts most of which are in unsanitated areas and some of them unscreened and exposure during military operations in unsanitated areas. The Canal Zone employees are both coloured and white. The former have an immunity to *P. vivax*. Old residents have frequent recourse to quinine. In 1935 and 1936 *P. falciparum*

was responsible for 76 per cent. of the total cases of malaria among the coloured employees but only 30 per cent. among the white. In soldiers in 1936 *falciparum* was responsible for 41.7 per cent. of primary cases and 12 per cent. of relapses. Military personnel on arrival have no immunity—their tour of service in the Zone is from two to three years.

Among the soldiers there was no real decrease of primary malaria incidence in the ten years 1927-36 the annual rates fluctuating between 31.86 in 1932 and 63.84 in 1933 per 1 000 of strength. The incidence of malaria contracted in posts and subposts in 1937 was somewhat less than in the previous year—an improvement that is attributed to more efficient screening efforts at preventing mosquitoes entering buildings, and the more intensive use of insecticide. PINTO (G. de Sousa) L'invasion du Brésil par l'*Anopheles gambiae* et ses conséquences [The Invasion of Brazil by *Anopheles gambiae* and the Sequel.]—*Rev de Malariologia* Sez. I 1933. Vol. 17 No. 6 pp. 475-490.

In March 1930 SHANNON discovered *Anopheles gambiae* the great carrier of malaria in Africa, breeding at Natal in Eastern Brazil [this *Bulletin* 1932, Vol. 29 p. 834]. It was clear that the insect had been transported across the Atlantic and had recently established itself.

The present paper tells us that any misgivings that may have been felt have been fully justified. The insect is breeding in water of many types and spreading. Sporozoite rates as high as 30 per cent. have been found more than once and very widespread epidemics of malaria have been caused, accompanied by a high death rate—the case mortality being 6 to 15 per cent. In the author's view insects probably came across as adults in the weekly boat from Dakar West Africa; aeroplanes are fewer and are less likely to have carried the insects, though it is scarcely correct to say that an aeroplane would offer no opportunity of travel to a mosquito.

[The event is very grave—the invasion of tropical America by the world's most versatile and dangerous carrier of malaria. This outbreak still lacks a historian though it may be the gravest insect-borne epidemic of history. The present paper is disappointing for it

gives no information about the previous prevalence of malaria in the area invaded or about to be invaded it gives no information about the insect's rate of spreading or whether it is advancing by road and rail or across the countryside it tells nothing of the area now covered, or the population now exposed to risk it does not discuss the measures undertaken or planned for dealing with the situation] *P. A. Buxton*

ROY (D. N.) CHANDRA (S. N.) & SIDDONS (L. B.) On the Presence of a Zoophilic Race of *A. stephensi* in Calcutta.—*Jl Malaria Inst of India* 1933 Dec. Vol. 1 No. 4 pp. 417-428 [22 refs.]

The history of malaria in Calcutta is full of puzzles and anomalies. The authors of the present paper call attention once again to the abundance of *Anopheles stephensi* in the city and to the fact that it is not a carrier of malaria, though it is so dangerous in certain other cities in India. They have carried out successful precipitin tests on 115 individuals captured in Calcutta only four of these contained human blood the remainder being positive for cow or buffalo [One would gladly see a much larger collection of figures taken from different parts of the city and throughout the year]

SIVALINGAM (V.) Enumerative Studies in Benign Tertian Malaria.—*Indian Med Gaz* 1933 Dec. Vol. 73 No. 12 pp. 715-720 [11 refs.]

Parasites were enumerated in 50 cases of *P. vivax* malaria. Of these cases 22 were primary, the remainder being subsequent cases the author's designation for relapses and reinfections. The observations were made in a district of Ceylon which was free from malaria prior to the epidemic of 1934-35. Sinton's method of enumeration was used. Blood smears were made a few hours before an anticipated paroxysm. Parasite counts were higher in primary cases. Thirteen of the 22 primary cases had counts of over 10,000 per cmm. as compared with 8 of the 28 relapses and reinfections. In primary cases high counts were associated with subsequent high temperatures but there were exceptions. No such relation between parasite count and degree of fever appeared to exist in subsequent cases. The author concludes that about 900 parasites per cmm. are necessary to produce fever in primary attacks about 500 are sufficient in subsequent attacks.

BOYD (Mark F) & KITCHEN (S. F) The Clinical Reaction in Vivax Malaria as Influenced by the Consecutive Employment of Infectious Mosquitoes.—*Amer J Trop Med* 1938. Nov Vol. 18. No. 6. pp 723-728.

In carrying out immunity observations mosquitoes destined for application on the test case were previously and subsequently applied to patients considered wholly susceptible. Intervals of three or four days elapsed between successive applications of any given lot of mosquitoes. Data concerning 116 inoculations done in this manner are considered in the present report. It is inferred that if mosquitoes be applied to several subjects consecutively the number of sporozoites in their glands will gradually be depleted. There is moreover a certain mortality in lots of mosquitoes thus treated which reduces the number of sporozoites inoculated in the later patients. Results obtained with lots consisting of 1-5 and 6-10 mosquitoes are compared. With the smaller number of mosquitoes there are significant differences in the character of the infection experienced by the first and last patient of a series. Patients infected in the last application tend to have longer incubation periods and shorter attacks. These differences are not observed if many mosquitoes are employed. The duration of the clinical attack following inoculation by a moderate number of infected mosquitoes tends to vary inversely with the duration of the incubation period. Attacks of less than eight days duration may be as significant of inadequate inoculation as of immunity.

BOYD (Mark F) & KITCHEN (S. F) An Instance of Prolonged Latent Incubation Period in a Patient Infected with a North American Strain of *Plasmodium vivax*.—*Amer J Trop Med*, 1939 Nov Vol. 18 No. 6 pp 729-731

A patient aged 15 was bitten by 12 *A. quadrimaculatus* infected with the McCoy strain of *P. vivax* on 21st June. 10 of these mosquitoes were re-applied to the patient four days later. The re-application was prompted by the light quantitative incidence of infection in this lot of mosquitoes. The inoculation was regarded as a failure the patient was returned to the general wards of the hospital but smears of his blood were taken at weekly intervals. On 21st April, 304 days after the first application of mosquitoes, the patient had a chill and *P. vivax* was found in the blood. The attack lasted 24 days and terminated spontaneously. The patient had been housed in a screened ward there had been no autochthonous case of malaria in the hospital during the previous two months. Inoculation experiments indicated the probability almost certainty that infection was due to the McCoy strain.

STRICKLAND (C. F) Quinine and Malaria in India. Indian Village Welfare Association.—19 pp. 1939 London Humphrey Milford, Oxford University Press. [6d.]

This pamphlet is apparently designed to instruct, or to create public opinion regarding the supply of and demand for quinine the need for increased consumption of quinine in India, and the desirability of making India eventually self-sufficient with regard to cinchona cultivation and quinine manufacture. The present position with regard to these matters is described and a policy is advocated. The

policy is the creation of a government monopoly, a quinine control board would receive all quinine manufactured in or imported into India. Quinine would be sold at a fixed price to shopkeepers and at a fixed price by them to the public. For free distribution to necessitous persons, cinchona febrifuge would be used. There would be no free distribution of quinine. Meanwhile the quinine control board would push forward schemes for increased production. The difficulties, cost and advantages of such a scheme are discussed as is the necessity for international agreement. An informing pamphlet for the uninitiated

N II

FASTOVSKAIA (E.) & CHENDEROWITCH (R.) Données comparées sur le traitement de la malaria par la quinine et les produits synthétiques soviétiques antipaludéens, d'après le schéma établi par la commission du paludisme au comité d'hygiène de la Ligue des Nations. [Comparative Results of Treatment of Malaria with Quinine and Sovietic Synthetic Remedies in accordance with the Scheme of the Malaria Commission of the Health Committee of the League of Nations.]—*Med Parasit & Parasitic Dis* Moscow 1938 Vol. 7 No 3 [In Russian pp 299-334 With 2 figs French summary p 335]

An isolated village Pokrovskaia in a swampy area with a stable population suffering from endemic malaria was selected for experiment. *P. vivax* and *P. falciparum* cases are equally prevalent, the former being most prevalent in May, the latter in September. The village was divided into four districts in which malaria cases were treated in accordance with one of the four following methods—(1) Quinine 0.5 gm. twice a day for seven days. (2) Acriquine 0.15 gm. twice a day for seven days. (3) Quinine 0.5 gm. twice a day for seven days followed after a three days interval by plasmoquine 0.03 gm. twice a day for five days. (4) Acriquine 0.15 gm. twice a day for seven days followed after a three days interval by plasmoquine 0.03 gm. twice a day for five days. The complete treatment according to one or other of these methods was given to 1,485 patients. On the whole acriquine gave better results than did quinine. The percentages of relapses with methods 2 and 4 were 40.2 and 37.0 respectively. Quinine methods 1 and 3 had relapse rates of 44.6 and 44.4 per cent respectively. Half the relapses occurred within 45 days of the termination of treatment. These early relapses were most frequent in *falciparum* infections. The authors conclude that Sovietic synthetic remedies are in every way as effective as quinine and that in the doses used they can be recommended for mass treatment. N II

STAUSS (Hermann) Die klinischen Nebenwirkungen des Plasmoquins und des Atebrins. [Clinical By-effects in the Use of Plasmoquine and Atebrin.]—*Arch f Schiff u Trop Hyg* 1939 Jan. & Feb Vol. 43 Nos. 1 & 2 pp 19-32 55-73 [118 refs.]

Harmless by-effects which often follow the use of plasmoquine as well as the more serious which are rare have been reviewed by the author from the literature. He notes that malaria like syphilis gives rise to many symptoms apart from drugs and these must be considered. Complications such as amoebic dysentery and hookworm infections affect the blood picture markedly. Those symptoms which arise during administration of plasmoquine depend largely on dosage as

well as on individual and race. In the early days the dose given was much too large. That now recommended is 0.01 gram per ten kilo body weight per day. Stomach-ache nausea vomiting, diarrhoea tenesmus loss of appetite are some of the symptoms complained of. Other possible causes for these are discussed. Plasmoquine plus atebirin is not so well borne as either alone. If the ratio of plasmoquine to atebirin is not above 1:20 as in atepo tablets fewer complaints are recorded.

Other factors discussed regarding by-effects are food, race type of infection condition of the patient and gastric hydrochloric acid content. It is better to start plasmoquine treatment some days after the atebirin course is completed. During plasmoquine treatment a slight transitory albuminuria may arise with no permanent kidney damage. Malaria cases with albuminuria are said to benefit from plasmoquine. The cyanosis produced in some patients results from intracellular methaemoglobin formation. Pulse and respiration are not affected and the characters of an anaemia are absent. Blood vessels may contract or dilate accordingly as the drug content is low or high. The amount of methaemoglobin formed is not proportional to the dose of drug, but time and length of its appearance depend on dose to some extent. Ambulant cases treated with the drug rarely exhibited the sign, and its appearance does not call for discontinuation of treatment. Haemoglobinuria has rarely been noted following the use of the drug and according to one author methaemoglobin is chiefly present, whereas with B.W.F. haemolysis and oxyhaemoglobinuria are characteristic. In therapeutic doses plasmoquine is not haemolytic. Liver damage may arise from the drug or the disease.

Regarding the blood picture, the appearance of punctate basophilia, increase of lymphocytes changes in polynuclears and eosinophils seem to be inconstant, as well as the appearance of certain pathological white cell elements. Pulse arrhythmia during treatment was early described but is not generally noted, and blood pressure is not affected. In animals excessive dosage caused liver and other damage but electrocardiograms showed no abnormality till death approached. Transitory oedema of face and limbs, also seen in untreated malaria, has been noted. If given parenterally the intramuscular route should be used. It is claimed that all circulatory symptoms recorded during treatment with the drug can be seen in untreated malaria.

Atebirin is given as the bi-hydrochloride by mouth. The soluble dimethanesulphonate is used for injection. It often causes swelling at the site but abscesses are rare. The dose is 3×0.1 gm. daily for five days. Children take the drug well. As a prophylactic 0.4 gm. per week is taken. Decomposition occurs in aqueous solutions, and such should not be left more than twelve hours before use. The drug is partly decomposed in the body.

Alimentary canal symptoms are rare. Constipation and colicky pains have been described. In animals excessive doses may cause diarrhoea. In cases in which excretion was slow colicky pains have been reported. Aspirin hot packs or opium are recommended for treatment. Other causes for the pains are discussed.

Albuminuria is not caused by atebirin and according to some nephritis and nephroses do not contraindicate its use. The heart muscle as well as systolic and diastolic blood pressure remain unaffected except as noted with excessive doses in animals. The same is true of pulse and respiration and patients with endo- or myocarditis may take the drug, according to some authors.

By the intramuscular route absorption is rapid and intravenous dosage is never called for except in comatose or BWF cases. Weakness giddiness cramps and collapse may follow intravenous administration. The drug does not cause haemolysis either *in vivo* or *in vitro* nor does it form methaemoglobin. The changes in the white cell picture described vary with different authors. In so far as it does not affect the heat regulating centre atebirin is not an antipyretic. Being a dye it is absorbed by the tissues and a higher dose may be required at the start to give the full therapeutic effect. Psychic and neurological symptoms are described by KINGSBURY during malaria treatment with the drug. The present author discusses his views.

The yellow coloration of varying intensity which may appear in the skin of a patient from the fourth day of treatment till eight days after its cessation may last as seen in one case for 69 days. It is due to impregnation of the skin with the drug and has no relation to icterus. The conjunctivae generally escape and there are no records of vision being affected. Atebrin may even be given if icterus is present. Whether the drug can be re-absorbed from the skin and give rise to therapeutic effect is not known. Bilirubin does not appear in the urine following use of the drug. The diagnosis of atebirin coloration is given as well as the views of different authors on drug accumulation which is affected by many factors. It is of interest that distribution of the drug in tissues of generative organs does not affect reproduction. Some other diseases in which the above two drugs are useful have been described.

The last part of the article is devoted to an attempt to demonstrate the advantage of these two synthetic agents over quinine as regards accompanying by-effects. The author adduces in favour of the value of these two compounds the fact that similar types have been made in France and Russia.

PIZZILLO (Giuseppe) Sulla cura adrenalina venosa nelle infezioni malariche. Nota XII. Possibilità di un trattamento ripetuto [Intravenous Adrenalin Treatment of Malaria Possibilities of Repeated Treatment].—*Riv di Malarologia* Sez. I 1938 Vol. 17 No 5 pp 386-395 With 9 graphs. German summary.

This is a report of three cases of malaria two *vivax* and one *falciparum* infection all of comparatively recent date which were treated by Ascoli's method. The immediate results of the treatment appeared satisfactory but the disease was not eradicated. Fever returned and a second course of adrenalin injections was administered to each. The intervals between the courses of treatment were 43 32 and 93 days respectively. After the second course of treatment all three patients regained complete health. All three cases illustrate the author's previous observation that the reactivation of the malaria parasite in a subject who has been adrenalized is attended with minimum deterioration of the patient's general condition and without renewed enlargement of the spleen. In the majority of cases the standard treatment of 30 injections is sufficient to produce a cure but that there are exceptions the three cases reported are evidence. The author considers that the treatment represents an exact reproduction of the spontaneous recovery from the disease. It is not surprising therefore that the intensity of treatment should have to be increased in certain

cases. Before deciding that the treatment has failed in any given case the advisability of repeating the course should be considered.

BULLETIN DE L'INSTITUT D'HYGIÈNE DU MAROC. 1938. Jan.-June
No 1-2 pp 109-133 With 1 chart.—Extrait du rapport
annuel sur l'activité du service antipaludique en 1937 [Extract
of Annual Report on Activity of Anti Malaria Service in 1937]

Malaria work in French Morocco is now concentrated in the charge of an Anti-Malaria Service the Chief of which is directly responsible to the Director of Public Health. The Service has facilities for research and teaching at its administrative headquarters and anti-malaria stations in most parts of the Territory.

The year 1937 with which this report is concerned, had a rainfall well below normal, almost everywhere. As a result malaria was nowhere unduly prevalent. There were no severe epidemic outbreaks and pernicious attacks were not in evidence. Antilarval measures produced excellent results.

Guiding principles that have been adopted in the prophylaxis of malaria include—Standard treatment of cases of malaria in the presence of an epidemic; clinical prophylaxis of children and sufferers in endemic areas; and the eradication of the disease in areas of feeble endemicity in which such measures are justified. The dose and rhythm of administration of drugs used as clinical prophylactics in endemic areas vary according to circumstances; the most important of which is perhaps the state of premunition of the population. There are three methods of estimating the state of premunition—the splenometric index (the least reliable); the relation between the parasite index of adults and the parasite index of children; and the serological index. In practice two situations may arise. If the population living in a moderate or severe endemic zone is premunized, it is sufficient to treat the children and patients who present themselves for treatment. The spacing of the administration of the drug used, every 8, 10 or 15 days is determined by the intensity of the anophelism and the rate of gamete carriers. In the case of a population not or insufficiently premunized that is threatened by excessive prevalence of anophelines, the drug should be distributed to the whole of the population, the rhythm of the distribution being determined as in the preceding case. Experience in Morocco has shown that the weekly administration of drugs is sufficient in all circumstances arising in that country and that their administration twice a month is insufficient whenever anopheline prevalence reaches a very high level. Λ W

SMITHS (A. T. W.) Follow Up of a Mass Treatment with Injectable Atebrin.—*Indian Med Gaz.* 1938 Dec. Vol. 73 No. 12.
pp 713-715 With 1 chart.

The author previously reported the treatment of 5,600 persons at the Godak Mills in the Southern Deccan with two injections, on consecutive days, of 0.3 gm. of atebrin, followed by plasmoquine 0.01 gm. a day for three days. The relapse rate for the six following months was very low [See this *Bulletin* 1936 Vol. 33 p 797]. The subsequent malaria history of this community is reported in the present paper. Every effort has been made to ensure that all fever

cases are promptly reported to the doctor. Every new case of malaria was treated with two injections of atabrin. No plasmoquine was given nor any quinine. Oiling of pools in the river bed during the dry season was done. The chart produced gives the monthly incidence of malaria for $2\frac{1}{2}$ years before and $2\frac{1}{2}$ years after the mass treatment with atabrin injections. It illustrates a diminution almost amounting to eradication of severe endemic malaria. These results are at striking variance with the author's experience in treating elsewhere sporadic first or fresh infections with atabrin injections. In the latter the relapse rate was almost 100 per cent within one to six weeks. Oral administration of the drug gave better results in these cases. The author's explanation of his observations is that the injection of a powerful parasiticide in a primary infection reduces the parasite count so suddenly that the body is no longer called upon to produce immunity consequently an unchecked multiplication of residual parasites soon recommences. In a highly endemic malaria region a high degree of immunity already exists. It follows that an immunological grouping of cases is important in treatment.

WILCHESTER (M. E.) Atabrine Prophylaxis in Malaria. Report of Third Year's Investigation.—*Amer J Trop Med* 1933, Nov Vol. 18 No 6 pp 625-639 With 4 figs [17 refs]

After reference to results obtained by several contributors to malaria literature by the use of atabrin as a prophylactic the author describes his experience in Harris Neck McIntosh County in south-east Georgia. This low-lying coastal area contains abundant breeding places for *A. quadrimaculatus*. In 1935 all persons harbouring parasites among a Negro population of 244 were given a five-day course of atabrin. Thereafter the population was divided into two groups of comparable age distribution. The prophylactic group received 50 mgm. of atabrin a day from May 15th to the end of October. The control group received no medication after the initial treatment. This procedure was continued in the two following years both groups being enlarged. The parasite indexes of the control group and prophylactic group in the spring of 1935 were 7.8 and 9.3 in the autumn of 1937 they were zero and 16.3 respectively. During the same period the spleen index of the prophylactic group fell from 46.1 to 9.3 and of the control group from 31.8 to 16.9. All infections were *falciparum*. The reduction of malaria was not attributable to meteorological conditions. The encouraging results have decided the author to continue the work. No toxic symptoms attributable to atabrin were encountered, though some individuals during the three years received as much as 25 gm. of the drug.

TIBOURSKAJA (A.) La quinine No 31 comme médicament gametocyte. [Action of Quinine No 31 on Gametocytes].—*Med Parasit & Parasitic Dis* Moscow 1933 Vol. 7 No 4 [In Russian] pp 541-549 With 6 figs French summary pp 549-550]

The object of the investigation recorded in this paper was to determine the minimum daily dose of quinine No 31 necessary to eliminate the infectivity of gamete carriers for mosquitoes and the duration of this effect. The gametocytes of suitable patients were

counted. The patients were then bitten by large numbers of mosquitoes. Subsequent dissection revealed the percentage of these mosquitoes infected. The patients were then treated with quinine No 31 0.03 gm. either thrice twice or once a day. Twenty four hours after the last dose mosquitoes were again fed on the patients and subsequently dissected. In *errax* infections 0.03 gm. thrice daily eliminated subsequent infection of mosquitoes. Twice daily this dose prevented the subsequent infection of mosquitoes in 8 cases out of nine. In the ninth case two mosquitoes had each two oöcysts out of 44 dissected as compared with 13 infected of 22 before the administration of the drug. With a single dose a day infection was suppressed in two cases and more than halved in a third.

In three *falciparum* cases daily doses of 0.09 0.06 and 0.03 gm., respectively produced a complete gamostatic effect.

The duration of the gamostatic effect in *errax* infections following 0.03 gm. thrice daily is 5 days. A IV

LEPROSY

PRELIS OF ABSTRACTS IN THIS SECTION

MORALES MUÑOZ *et al.* (p. 690) report on leprosy in Colombia. Epidemiological and clinical information is given of 468 lepers in an institution, of whom 41 per cent. of males and 64 per cent. of females give a family history of the disease. Most of them came from a well known endemic focus.

KREMER (p. 690) shows that all reflexes may be affected in the neural forms and changes correspond roughly with the extent and severity of the disease. Changed reflexes do not return to normal after clinical cure.

ACANFORA (p. 691) reports that the Rubino reaction of the sedimentation of formalized sheep red cells in the serum of the patient is to a considerable extent specific for leprosy and suggests a modification in which known negative serum is used as a control.

FERNANDEZ (p. 692) using leprolin subcutaneously found that it provoked general, local and focal reactions in tuberculous leprosy no reaction in the lepromatous form and only local reactions in several non-lepromatous conditions.

HARRELTINE (p. 692) reporting on the National Leprosarium, Carville, states that benzocaine-chaulmoogra oil and hydriocarpate esters form the basis of treatment.

DA SILVA (p. 692) uses 30 per cent chaulmoogra in olive oil, or trichloroacetic acid for lesions of the upper respiratory tract, with the galvano-cautery for definite lepromata. VIGNE *et al* (p. 693) show that treatment with a nitrated chaulmoogra oil and novarsenobenzol produced improvement in a leper with positive Wassermann. TISSEUIL (p. 693) advocates the intradermal injection of the oils or esters of chaulmoogra and Gorli seeds in tuberculoid lesions. TISSEUIL and RIVALEN (p. 693) report good results from the use of Gorli preparations, but the unsaponifiable fractions were inactive. TISSEUIL and GUILHAUMOU (p. 694) failed to obtain beneficial results from intradermal injections of preparations of castor and cod liver oil and metbylene blue. VELDS (p. 694) found phenol red to be useless.

RADNA (p. 694) reports favourably on treatment by Loewenstein's vaccine combined with alepol or graumanyl. MALAIHOLLO (p. 694) shows that certain beneficial results occurred in patients treated for two months with intramuscular injections of serum from a sheep which had received injections of bouillon cultures of two strains of acid fast bacilli isolated from lepers.

MARIE SUZANNE (p. 695) states that there is a source of calophyllum oil in Indo-China.

FÉROV (p. 695) claims very good results in macular and nodular cases by the use of a copper compound *zymbil-cuivre*.

VISENEVSKY (p. 695) uses blockage of the sympathetic system or circular blockage of nerves of the extremities by novocain in the treatment of leprous lesions and ulcers. This method is based on the beneficial influence of anaesthetics on inflammatory processes.

CHOWHAN and CHOPRA (p. 695) advocate the use of cobra venom and the vitamin B complex in nerve leprosy. VILLELA (p. 696) advocates vitamin B₁ for the pains of nerve leprosy. Vitamins B₁ and C may aid the action of chaulmoogra.

GATTI and GAONA (p. 696) and UGARRIZA (p. 696) used cebion in addition to chaulmoogra with success in cases with septicaemia and abscesses.

General improvement and healing of ulcers took place in 15 patients treated by CLERCXX (p. 696) by diethylamine chaulmoograte.

KHAN (p. 696) obtained good results in the treatment of trophic ulcers by removing dead bone and affording rest and protection by plaster of Paris. MAYNARD (p. 697) also removes dead bone and uses a warmed mixture of beef suet ghee and beeswax as a dressing. Of 60 cases 50 healed within six months.

DE BRAUWERE (p. 697) describes treatment in the Congo. KEIL (p. 697) discusses heredity in leprosy.

In rats reinoculated with the bacillus of Stéfansky BURNET (p. 698) found no reaction similar to that of the Koch phenomenon in tuberculosis, but in mice some increased sensitivity was observed. Reinoculation stimulates phagocytosis in mice but only feebly in rats. MARCHOUX and CHORINE (p. 698) similarly failed to produce a Koch phenomenon in rats and conclude that in human leprosy superinfection may occur.

PRUDHOMME (p. 698) has preserved the virulence of Stéfansky's bacillus in Sauton's medium in which *Alcyon phlei* was growing at pH 6.5. GAVRILOV *et al* (p. 698) have grown the bacillus on Denys's medium and on potato but the maintenance of pathogenicity was difficult.

LYON (p. 699) shows that the leprosin reaction is not obtainable in rats. C W

MORALES MUÑOZ (Tomás) BERNAL LOZDOÑO (Mario) & DE SOUZA ARABJO (H C) La lepra en Colombia. Encuestas epidemiológicas [Leprosy in Colombia. Epidemiology]—*Rev Colombiana de Leptología* Bogotá. 1939 Mar Vol 1 No 1 pp. 6-35. With 8 figs

The figures given in this article are based on a study of 959 persons in the Cello de Loro lazaretto of whom 466 are segregated lepers 48 are children of those living there 62 are women living with the others but apparently healthy and 383 persons living in the environs (en la puerta) of the lazaretto in the neutral zone

Of the 466 lepers, 328 or 70.3 per cent are half-castes 78 black and 57 white or 16.7 and 12.2 per cent respectively their nationalities are tabulated and the districts from which they came. Of the total, 355 are males and 146 of these (41 per cent.) give a history of the disease in father mother or near relative of 111 females, 71 (64 per cent) have such a history The types of the disease are stated in a list giving them under fifteen subdivisions Other information includes the previous occupations of the inmates (50 per cent. having worked on the land) the length of residence duration of the disease, etc.

Forty-eight children of lepers were examined, 35 having been born in the lazaretto of these there were 23 boys and 23 girls, up to 13 years of age Four girls 8-12 years of age, show definite signs of leprosy and five other children—three boys of 6 7 and 13 years, and two girls of 8 months and 9 years respectively—show suspicious signs.

The chief points of this interesting study may be summed up as follows—

- 1 Of the 466 examined 85.4 per cent are over 20 years of age and 85.7 per cent are from the well-known endemic foci of Bolívar Atlántico and Magdalena
- 2 Forty-one per cent of males and 64 per cent. of females give a family history of the disease
- 3 Sixty per cent belong to the clinical types L2 and L3 and some have been segregated for more than 10 years without showing improvement 84 per cent have had the disease for four years or more.
- 4 About one-third, 32.4 per cent. have purely cutaneous or nervous lesions.
- 5 Of 383 living outside the leprosarium, of whom 51 per cent. were adults 1 woman has a perforating ulcer of the foot 1 girl shows a suspicious macule on the face and 2 children (girls) show suspicious symptoms.

[This is the first number of a new periodical devoted to leprosy and if the standard presented in this issue is maintained, the information should prove of much value to leprologists.] H H S

CREMER (Sylvio de Godoy) Contribuição ao estudo dos reflexos na lepra [The Reflexes in Leprosy]—*Rev Brasileira Leprológica*. S Paulo. 1939 Mar Vol 7 No 1 pp. 63-74

The results of this investigation support in general what we should expect from a knowledge of the pathology of leprosy The reflexes, superficial and deep were examined in various forms—cutaneous, nodular nervous, and mixed—and stages of the disease and details of

findings in individual patients are recorded. These may be summarized as follows: in purely cutaneous forms the reflexes are unaffected; in the forms which attack the nerves we would surmise changes and in fact all or any of the reflexes may be altered. In the purely nervous forms the degree of change corresponds roughly with the extent and severity of the disease; in the mixed forms in accordance with the degree of nerve involvement. It is noteworthy that after clinical cure of a patient reflexes which had been abolished or even diminished did not return to normal. Also in cases of neuritis in the course of the disease there may be exaggeration of reflex but not in neuritis of parts in which the reflexes had already been lost.

The above is the general rule as regards the behaviour of the reflexes; there are however exceptions though they are few. Some nerve cases of even three or four years' duration still retain their reflexes intact while others of only 5-6 months' standing show definite changes. It is suggested but further evidence is needed that the former are mild forms, the latter severe forms of the disease. If this is true their presence or absence may serve as a valuable prognostic aid in nervous leprosy.

H H S

ACANFORA (Giuseppe) Sulla reazione di Rubino [The Rubino Reaction]—*Ann. d'Igiene* 1939 Mar Vol 49 No 3 pp 152-159 [21 refs.]

The rubino reaction is the speed of sedimentation of washed formalized sheep erythrocytes in the serum of the patient. Defibrinated sheep blood is centrifuged and the plasma decanted. The cells are washed with saline several times and then suspended in an amount of saline so that the quantity of suspension equals that of the original blood taken. To this is added 10 per cent of formalin (40 per cent formaldehyde). Various dilutions of serum in saline are mixed with 0.2 cc. of the cell suspension to make a total of 1.0 cc. in tubes of 9-10 mm. internal diameter—

	1	2	3	4	5	6
	cc.	cc.	cc.	cc.	cc.	cc.
Serum	0.5	0.25	0.1	0.5	0.25	0.1
Saline	0.3	0.55	0.7	0.3	0.55	0.7
Formalized cell suspensions	0.2	0.2	0.2	—	—	—
Non formalized cell suspensions	—	—	—	0.2	0.2	0.2

Results are read after 15, 30, 45 and 60 minutes. Controls with non formalized cells are used. The reaction is positive if the agglutino-sedimentation occurs only with the formalized cells or is definitely more intense than with the non formalized cells.

In 23 tests on serum of patients with mixed leprosy the test was positive in 22. In 14 patients with pulmonary tuberculosis the test was negative; the non formalized cells settling more quickly. In 65 patients with other diseases (malaria, leishmaniasis, amoebiasis etc.) it was similarly negative.

The author suggests a modification in which instead of non-formalized cells a control of definitely negative serum is used with the formalized cells. In this case a positive result is shown by rapid sedimentation with the serum to be tested.

The test therefore appears to be to a considerable extent specific for leprosy [See also this *Bulletin* 1927 Vol 24 p. 557 1928, Vol 25 p. 978 1929 Vol 26 pp. 336 617 1930 Vol 27 p. 1006 1932, Vol 29 pp 553 850.] C IV

FERNANDEZ (José M M) Valor de la inyección subcutánea de leprolin en el diagnóstico de ciertas formas de lepra. [Subcutaneous Injections of Leprolin in the Diagnosis of Leprosy]—*Rev Brasileira Leprologia* S Paulo. 1939 Mar Vol. 7 No. 1 pp 85-90 English summary

The author has made subcutaneous injections of 1 or 1.50 cc. of leprolin in patients with lepromatous and neural types of leprosy lupus vulgaris lupus erythematosus and dermatitis facitita. He has observed

"1 In cases of tuberculoid leprosy the injection produces within 24 hours a general reaction consisting in rigors arthralgias, and temperature a local reaction at the site of injection and a focal reaction, with erythema and congestion of pre-existent lesions.

2 In the cases of lepromatous leprosy the injection of the same doses of leprolin does not produce any reaction

3. In cases of lupus vulgaris lupus erythematosus and artificial dermatitis, the injection of leprolin produces, within 24 hours, a moderate general and local reaction at the site of injection but does not produce any modification in the pre-existent lesions

"On the strength of these experiences the author suggests the use of the subcutaneous injection of 1 or 1.50 cc. of leprolin, as a diagnostic test between tuberculoid leprosy and other dermatoses, particularly those of tuberculoid nature such as Boeck's sarcoida.

HASELTERE (H E.) The U.S. Marine Hospital (National Leprosarium) Carville, La. Review of the More Important Activities for the Fiscal Year ended June 30, 1938.—*Public Health Rep* 1939. Nov 18 Vol. 53 No 48 pp 2025-2037

This report gives an account of the many activities at the well-equipped U.S.A. settlement on the usual lines, for the year ending June 30th 1938. The total patients were reduced from 365 to 349 with 75 discharges against 59 admissions and 36 deaths. Returned absconded patients numbered 17. Nearly all the patients received treatment mostly by benzocaine-chaulmoogra oil intramuscularly, and hydriocarpate esters. A satisfactory amount of improvement was observed except on the older advanced cases, a number of whom showed retrogression. New treatments were tried without any noteworthy results. Much laboratory dental, orthopaedic and neuropsychiatric work was carried out. The farm and dairy work effected a useful saving

L. Rogers

DA SILVA (Oliveo Landares) Tratamento das localizações leprosmas nas vias aéreas superiores e na bocca. [Treatment of Leprotic Lesions of the Mouth and Upper Respiratory Tract.]—*Rev Brasileira Leprologia* S Paulo 1939 Mar Vol. 7 No 1 pp. 75-84 With 6 figs. on 2 plates. English summary

The lesions dealt with are congestion dryness and localized lepromata of the mouth, pharynx, nose and larynx and the treatment recommended is, in the first place application of 30 per cent. chaulmoogra in

olive oil every other day. If as was not uncommon this resulted in bleeding the author applied 50 per cent. trichloroacetic acid after the chaulmoogra once a week. If there are definite lepromata he is in favour of galvano-cautery or of cauterization of the wound after excision of the tumour. For laryngeal lesions if there is dyspnoea tracheotomy is recommended, but the average length of survival thereafter was only a year. H H S

VIGNE (Paul) VIGNOLI BONNET (R.) & TIVOLLIER. *Maladie de Hansen cicatrisation rapide d'ulcérations trophiques par l'huile de chaulmoogra nitrée.* [*Chaulmoogra Treatment of Ulcers.*].—*Marseille Méd.* 1933. Oct. 5-15 Vol. 75 Nos 28-29 pp 385-388

A nitrated chaulmoogra oil has been prepared with a view to diminishing the acidity of the commercial oils of from 15 to 20 per cent. of acidity expressed as oleic acid, to about 1 per cent. Several heterogeneous substances are also removed from the oil in the process of treating it with nitric acid. The resulting preparation is dissolved in a fatty excipient for injection subcutaneously and put up in ampoules which can be sterilized in an autoclave at 120°C for twenty minutes. It proved to be non toxic to guineapigs in 3 cc. doses.

An old nodular case of leprosy was treated with 1 cc. intramuscular injections concurrently with those of novarsenobenzol on account of a positive Wassermann reaction. At the end of two months material improvement occurred so the case is recorded to allow others to try this method. L. R.

TISSEUIL (J.) *Action thérapeutique comparée par voies veineuse intramusculaire et intradermique des huiles et des éthyl-esters de chaulmoogra dans les lèpres tuberculoides.* [*Treatment of Tuberculoid Cases with Ethyl Esters of Chaulmoogra.*].—*Bull Soc Path Exot* 1939 Feb. 8. Vol. 32. No. 2. pp 202-207

The author reports good results from the treatment of tuberculoid lesions by the intradermal method with the oils or esters of chaulmoogra and gorli seeds but not with the soaps of gorli and esters of olive oil. Intravenous and intramuscular injection were much slower in their action. L. R.

TISSEUIL (J.) & RIVOALEN (P.) *Action de dérivés du beurre de Gorli éther éthylique des glycérides solides glycérides liquides insaponifiables en injection intradermique au niveau des taches tuberculoides.* [*Gorli Preparation Treatment.*].—*Bull Soc Path Exot* 1933. Nov. 9 Vol. 31 No. 9 pp 819-824

This paper reports on the use of preparations made from gorli seeds. Gorli butter mixed with 40 per cent. of olive oil had a good action on tuberculoid lesions and so had the solid and fluid glycerides but the unsaponifiable fractions were inactive. For the methods of making the various preparations used the original paper should be consulted. The injected skin areas showed an intense black discolouration, but this rapidly disappeared with the subsidence of the infiltration of the lesions. L. R.

TISSEUT (J) & GUILHAUMOU (F) Action de l'huile de ricin de l'huile de foie de morue du bleu de méthylène en solution à 1% en injections intradermiques dans le traitement des taches tuberculoides. [Action of Castor and Cod Liver Oil and Methylene Blue.]—*Bull Soc Path Exot.* 1938. Dec. 14 Vol. 31 No 10 pp. 900-904

The authors report on the action of the glycerides of certain fatty acids. Weekly injections into tubercloid lesions of the skin caused darkening of the patches but had no lasting beneficial effects. Similar preparations made from cod liver oil produced reactions in the injected lesions but after the inflammatory infiltration subsided the treated patches reverted to their former condition. They also tried intradermal injections of 1 per cent. methylene blue but here again they obtained no beneficial effects. L. R.

VELDS (M) Phenolroodtherapie bij lepra. 'Phanol Red in Leprosy'—*Geneesk Tijdschr v Nederl Indië* 1939 Feb 21 Vol. 79 No 8. pp 463-465 English summary (7 lines)

In connection with published favourable results with phenol-sulphonepthalein in two leper patients, this dye was given in sixteen patients at the Poelau di Tjanang Leprosarium however without any success or resulting improvement on the contrary a slow increase could be stated in five patients.

"In consequence this dye just like methylene blue does not seem to be a specific drug for leprosy

RADXA (R.) Contribution à la question du traitement de la lèpre. (Première note) Treatment of Leprosy.—*Ann. Soc. Belge de Méd Trop* 1938 June 30 Vol. 18. No 2 pp 225-232.

This is a report on combined treatment by vaccines of Loewenstein's cultures of what he believes to be Hansen's bacillus together with the chaulmoogra preparations alepol or graumanvi. This gave better results than either method used alone. Tables show that in 118 cases treated for a year 31.66 per cent were free from symptoms and from lepra bacilli, and 44.66 per cent were greatly improved. L. R.

MALAIHOLLO (J. F.) Beknopt verslag van de behandeling van leprozen met het anti-lepraseraum van Prof. Reenstierma te Semarang. [Treatment of Lepers with Reenstierma Serum.]—*Geneesk. Tijdschr v Nederl Indië* 1939 Mar 7 Vol. 79 No 10 pp 601-618

The two bacilli used for the production of the serum were a strain with variably acid-fast character isolated by KEDROWSKI in 1900 from a leproma and a similar strain isolated by REENSTIERMA from the blood of a leper in 1912. Mixed bacillon cultures were injected subcutaneously in the sheep to obtain the antiserum. Altogether 30 lepers have been treated and all chaulmoogra medication was stopped for at least one month before serum injections were begun. These injections in a dose of 10 cc were given intramuscularly in one or more series three weekly. No important bad effects resulted from the injections.

Thirteen of the patients were under close daily observation for two months and a record made of results.—(1) Lepromata and infiltrates—no effect. (2) Skin discolouration—gradual return to normal in two patients. (3) Nasal symptoms—improvement in practically all

patients within a few days but of little permanency (4) Leprosy ulcers—superficial ulcers disappeared in a few days more extensive ulcers healing in one case. (5) Anaesthesiae—restoration of sensation where the neuritis had not existed too long (6) Anaesthetic maculae—some improved but most showed no change. (7) Pareses—significant improvement in two cases. (8) Trophic ulcers—no effect and so on

MARIE-SUZANNE. L'huile de calophyllum dans le traitement de la lèpre. [Treatment with Oil of Calophyllum.]—*Rev Méd et Hyg Trop* 1938 Sept-Oct Vol 30 No 5 p 271

This brief note refers to the use of calophyllum or dilo oil by Dr NEFF in Fiji for the relief of the pains of neural leprosy and adds that a source of supply of the oil which will be tested has been found in Indo-China.

L R

FÉROV (Jean) Le traitement de la lèpre à la léproserie Saint Antoine à Harrar (Ethiopie) [Treatment at Harrar]—*Rev Méd et Hyg Trop* 1938. Sept-Oct. Vol 30 No 5 pp 261-264

The author claims very good results from the use of a copper compound he calls zymbil-cuivre This appears to be a very finely divided colloidal copper the precise method of preparing which is not disclosed but it is non-toxic can be sterilized and is dissolved in an aqueous non ionizable cinnamic ether It is said to have cured 100 per cent. of macular and 50 per cent of nodular cases and arrested the evolution of the remainder It is also claimed to be effective in grave ocular complications.

VISHNEVSKY (A. A.) Jr Novocaine Blockade in the Treatment of Leprosy—*Internal Jt Leprosy* Manila. 1938 Oct-Dec Vol. 6 No 4 pp 477-490 With 4 text figs & 9 figs. on 1 plate.

This method of treatment is based on the beneficial influence of anaesthetics on an acute inflammatory process reported by SPIES in 1901 One method of use is the blockage of the sympathetic system in the lumbar region and the adjoining part of cerebrospinal nerves. A second is circular blockage of the extremity completely interrupting its innervation Illustrations show the injection in the lumbar region of 150 to 200 cc of 0.25 per cent novocaine with two drops of adrenalin per 100 cc. Similar amounts are injected into the subcutaneous tissues around an extremity In a group of 50 cases local leprous patches and nodules are said to have been resolved and ulcers healed. In another group restoration of sensibility and motor capacity was observed and diagrams of the improvement in the sensory condition are given. In a third group lepra reactions were aborted.

CHOWHAN (J S) & CHOPRA (R. N) The Use of Cobra Venom in Nerve Leprosy—*Indian Med Gaz* 1938. Dec. Vol. 73 No 12. pp 720-725 [18 refs.]

The authors point out that in India about 75 per cent of leprosy cases are of the nerve type with symptoms of neuritis. The injections

of cobra venom relieve the symptoms in a large number of patients. The power of the venom to destroy newly formed tissues is discussed, and it is said that in tissue cultures such destruction may be brought about. Trials of cobra venom together with the vitamin B complex are advocated in nerve leprosy. L. R.

VILLILA (Gilberto G.) Ueber die Beeinflussung der Lepra durch Vitamin B₁ und C (Aneurin und Ascorbinsäure) [Vitamins B₁ and C in Treatment.]—*Arch. f. Schiffs u. Trop. Hyg.* 1939 Mar Vol. 43 No. 3 pp. 127-129

The author reports that 1 to 2 milligrammes of Vitamin B₁ intramuscularly are beneficial in the treatment of nerve leprosy pama. It also has a general effect in all cases on the weight of the patients. Injection of aneurin decreases the blood sugar and cholesterol. In dermal cases vitamin C has no direct effect but may aid the action of chaulmoogra treatment and vitamin B₁ has a similar effect. L. R.

GATTI (Carlos) & GAONA (R. Jiménez) Cebion bei der Lepra Behandlung [Cebion Treatment.]—*Arch. f. Schiffs u. Trop. Hyg.* 1939 Jan. Vol. 43 No. 1 pp. 32-33

Two cases of leprosy one in a septicaemic stage and the other with numerous abscesses, have been treated with Cebion in addition to chaulmoogra preparations with beneficial results. L. R.

UGARRIZA (Ricardo G.) Cebion bei der Behandlung von lepröser Septicaemie. [Cebion in Leprosy Septicaemia.]—*Arch. f. Schiffs u. Trop. Hyg.* 1939 Jan. Vol. 43 No. 1 pp. 33-34

A patient while under chaulmoogra treatment developed a septicaemic fever of three months duration, and laboratory tests gave negative results for typhoid and malaria. Oral tablets of cebion were followed by a decline of the fever in three days with improvement in the condition of the patient. L. R.

CLERCKX Le traitement de la lèpre par le chaulmoograte de diéthylamine Quelques observations [Treatment by Diethylamine Chaulmoograte.]—*Ann. Soc. Belge de Méd. Trop.* 1938. Sept. 30 Vol. 18. No. 3 pp. 373-376

Brief notes are given of fifteen patients treated by painless intravenous injections twice a week with from $\frac{1}{2}$ to 2 cc. doses of diethylamine chaulmoograte. Most of the cases showed general improvement and healing of ulcers took place. The effect was not so good on macules, and when they disappeared they tended to return after two months. L. R.

KHAM (Joseph S.) Treatment of Leprous Trophic Ulcers.—*Leprosy in India* 1939 Jan. Vol. 11 No. 1 pp. 19-21

The author reports good results from the removal of dead bone, etc. from chronic ulcers and then affording rest and protection from pressure by the application of plaster of Paris, and the local use of two per cent. acriflavine or of gauze. L. R.

MAYNARD (N. H.) The Treatment of Trophic Ulcers in Leprosy —
East African Med J 1938 Dec Vol. 15 No 9 p. 307

This worker advises removal of carious bone and trimming the dead skin back to the level of the base of the ulcer followed by antiseptic dressings of 1-1000 perchloride of mercury to clean the ulcers. She then fills the ulcer with a warmed mixture of an ointment composed of beef suet 2 parts, ghee (melted butter) 1 part and beeswax $\frac{1}{2}$ part and covering with cotton wool and a sewn on bandage. The application is renewed every third day for the first two weeks, and then once a week. Of 60 cases 50 healed within six months. L. R.

DE GOLDFIEM (Alice S.) & DE GOLDFIEM (Jean S.) La phytothérapie de la lèpre [The Phytotherapy of Leprosy]—*Rev Méd et Hyg Trop* 1938 Sept-Oct Vol. 30 No 5 pp 272-282.

This note gives a list of the trees furnishing oils with the composition of chaulmoogra. Some references to the literature of their chemistry are also quoted. L. R.

VELDS (M.) Welke therapie bij lepra? [Treatment of Leprosy]—*Geneesk Tijdschr v Nederl Indië* 1938, Dec 13 Vol. 78, No 50 pp 3152-3164 With 11 figs. on 2 plates. English summary

This note records figures of leprosy incidence in a part of the lower Congo. The author advocates treatment with chaulmoogra esters and Perier's gynocardate of soda and village segregation with agricultural employment. L. R.

KEIL (Ernst) Lepra und Erbfaktoren [Heredity in Leprosy]—*Arch f Schiffs u Trop Hyg* 1939 Mar Vol. 43 No 3 pp 95-102. With 10 figs. [16 refs.]

The author discusses the predisposing action of heredity in leprosy. He mentions five sets of twins with both infected in two of them and in another group of cases one of two sets of twins showed both attacked by leprosy. L. R.

BUXOT (Et.) Examen de quelques réactions d'immunité et d'allergie dans la lèpre murine [Reactions of Immunity and Allergy in Rat Leprosy].—*Arch Inst. Pasteur de Tunis* 1938. Dec. Vol. 27 No. 4 pp 360-367

The results of repeated inoculations of rats and mice with Stéfansky's bacillus are recorded. When rats are re-inoculated after an interval of six to eight months nothing of the nature of Koch's phenomenon in tuberculosis is seen. In the case of mice a tendency to abscess formation is observed after re-inoculation. With repeated re-inoculations at short intervals some degree of increased sensibility was noted but not a specific allergy. Re-inoculations into the peritoneal cavity after two to six months produced in rats a very feeble and brief phagocytosis as compared with that in mice for the leucocytes and reticulo-endothelial system do not in rats fix the bacilli in the way they do in mice. Further development of the bacilli in rats is mostly in the interstitial tissues and in mice it is more intracellular in nature.

L. R.

MARCHOUX (E.) & CHOKINE (V.) Le phénomène de Koch ne se produit pas chez le rat par réinoculation du bacille de Stéfansky. The Failure of the Bacillus of Stéfansky to produce the Koch Phenomenon in the Rat.—*Bull Soc Path Exot* 1938. Nov. 9. Vol. 31 No. 9 pp 809-815

These workers also found that the phenomenon that Koch described following the re-inoculation of tubercle bacilli into an animal does not occur on the re-inoculation of Stéfansky's rat leprosy bacillus. Instead a fresh infection results that aggravates the former one. Nor does the injection of masses of the rat bacillus provoke any signs of intoxication. We may therefore suppose that in the case of human leprosy superinfections may take place.

REVIEWS AND NOTICES

BAXERJEA (J C.) [M.B (Cal.) M.R.C.P (Lond.) etc.] & BHATTACHARYA (P. B.) [M.B. D.T.M (Cal.) Bengal Medical Service Upper etc.] *A Handbook of Tropical Diseases with Treatment and Prescriptions.* Second Edition Thoroughly Revised Re-Written Enlarged & Brought Up-to-Date—pp x+413 With 1 plate & 22 figs. (13 coloured) 1938. Calcutta U N Dhur & Co 15 College Square [Rs. 7-8-0 Cash price in Great Britain 15s.]

The preface to this book expresses the hope that it will prove helpful to senior medical students in their final examination and to practitioners, and that all unnecessary theoretical details have been avoided. These statements explain the fact that the text consists largely of long numbered lists of symptoms and points of differential diagnosis with very little indication of their relative importance. The contents are also noteworthy for important diseases occurring in other tropical countries than India are omitted such as yellow fever and trypanosomiasis as well as others that do occur to some extent in India including undulant fever yaws tropical ulcer inguinal ulcerative granuloma madura foot and lymphogranuloma. On the other hand smallpox and typhoid fever which are very prevalent in India are included with advantage to the Indian student. Under filariasis only the conditions produced by *B. bancrofti* are dealt with. Lathyrism and pellagra as well as schistosomiasis are also omitted.

Malaria rightly occupies one of the longest chapters and appears to follow very closely in an abridged form Sir John Megaw's article in Rogers and Megaw's *Tropical Medicine*. Long lists of points in differential diagnosis involve repetition and in some instances appear to be over-elaborated. Kala azar for example hardly requires separate lists of symptoms for its differentiation from acute miliary tuberculosis and Hodgkin's disease. Malaria is differentiated from pneumonia but not from dengue with which it was for a long time confused.

Many of the chapters contain much detailed information nearly all of a clinical form for pathological details are scantily dealt with. Under cholera for example no information is given on the recent

work on the value of the O antigen in identifying the true causative organism. In the differentiation of cholera from agud malaria the practical point of the low sp. gr. of the blood in malaria due to anaemia is not mentioned. In its treatment morphia is advised for the relief of cramps although they disappear rapidly following saline infusions and the drug greatly predisposes to uraemia. The description of amoebic dysentery is useful but the date of the discovery of the value of emetine is twice given as 1902 in place of 1912. Amoebic hepatitis and liver abscess are dismissed in the altogether inadequate space of one page. The chapter on leprosy is a good one. Under sprue atrophy of the mucous membrane is emphasized, although recent observations made on fresh post mortems discount its occurrence. Under epidemic dropsy Sir John Megaw's important work is not mentioned. Under snake poisoning permanganates are said to oxidise the venoms evidently a misprint for oxidize but such misprints are few.

There are very few illustrations and the magnifications of the microscopical illustrations are not given. The index consists of the main sub-divisions of the articles under each chapter with no cross references. It is of very little use. The ten pages of prescriptions deal much more with common diseases of all kinds than with tropical ones. They include mixtures for asthma, bronchitis, conjunctivitis, cough, earache, various common skin diseases, epilepsy, insomnia, lumbago etc.

The general character of this book can be gathered from the above account of its contents. It cannot be recommended as a text-book of tropical medicine but it contains a lot of tabulated facts and guides to treatment regarding the limited range of subjects it deals with, that should fulfil its avowed purpose as a help to senior students in preparing for examinations.

L. Rogers

DUMAS (J.) [Chef de service à l'Institut Pasteur]. La dysenterie bacillaire. [Bacillary Dysentery]—89 pp. With 1 plate. [Bibliography] 1938. Paris. G. Doin & Cie. 8 Place de l'Odéon. [28 fr.]

Bacillary dysentery is an important disease which suffers singularly from neglect in most text-books, so that any contribution to its more general understanding should be welcomed. The present brochure to some extent fills this gap as it entails a good general, but by no means profound, study of the disease nor can it be termed exhaustive for there are several aspects, notably bacteriological, which are somewhat sketchy and there are of course statements to which exception can be taken. It is surely untrue, for instance, to state (p. 12) that "*Amoeba histolytica* was discovered by Schaudinn in 1902".

In considering epidemiology great importance is attached to the continued existence of dysentery bacilli in the soil, but no reference is made to carriers, contaminated water or to flies as important factors in the spread of the disease.

A curious omission is that no mention is made of Sonne dysentery and this is all the more regretted because the symptomatology of Shiga and Flexner dysenteries are given separate consideration, on the assumption that they can be distinguished clinically but, at the same time, Dumas states that, in all but the very acute and

fulminating cases, differential diagnosis from *Amoebic dysentery* is difficult if not impossible to make, for the signs and symptoms of the two diseases are identical and the doctor divorced from the laboratory can do so only as the result of observing the effects of emetine therapy. A further statement which will not gain general acceptance is that as a general rule agglutination tests with the patient's serum are of great importance in diagnosis. The pathology is based upon the classical description of Ch. Dopter.

In the description of complications considerable importance is attached to perforation of the colon causing general peritonitis, to the adrenal syndrome and also to a kind of poliomyelitis 'Paralyses dysenteriques' which is not generally referred to in the text books.

The value of treatment by antidyenteric serum is emphasized and the practical effects of bacteriophage therapy discounted.

From a general standpoint this contribution to bacillary dysentery can hardly be considered international, for references to English American and workers of other nationalities who made such important war time contributions to bacillary dysentery are singularly neglected. The one exception is Broughton Alcock who is referred to as Broughton & Alcock. There are it is true 133 references confined almost entirely to French writers. One illustration a photographic reproduction of a bacillary dysentery bowel enlightens this work.

P. H. Manson Bahr

PURCELL (F. M.) [M.D. (Dublin University) M.R.C.P. (Ireland)
D.T.M. & H. (London) Colonial Medical Service Gold Coast]
Diet and Ill-Health in the Forest Country of the Gold Coast—
pp viii+77 With 62 figs 1939 London H. K. Lewis & Co
Ltd. [7s 6d]

Dr Purcell has undertaken a difficult task—to give an account of the physical condition of the people of a country district in West Africa of their diet and food-habits and of the morbid conditions associated with or due to malnutrition—on a purely clinical basis. His undertaking is made all the harder because he has no personal laboratory or experimental investigations to support his theses and for figures of food analyses has had to rely on others.

The author has divided the account into two sections the first deals with the people of Akum living in a forest district to the south of the Gold Coast Colony and their diet the second with the many clinical syndromes which he considers attributable to malnutrition.

The average height of a male adult is 5 ft. 4 in. the female about 4 inches less and their general physique is poor as compared with the tribes of the Northern Territories. Their diet is mainly vegetable meat is a scarcity and fish far from plentiful and is mostly imported salted or smoked the local supply being insignificant. A list of the available foods is given and it is shown that though the total calorie value is high the fats and protein constituents are low. Children at the school appear to be in good health though the diet comprises mainly plantain cocoyam and cassava little fruit and no meat. Even nursing mothers have only 30–50 gm. of protein daily and that of low quality and only 10 gm. of animal origin and 30 gm. fat 5 gm. only of animal fat. It is probable, seeing that the children in many cases appear well that they have adapted themselves to their diet but that they live on the borderline as it were and any stress or infection breaks

down the reserve of resistance. The fertility rate is high—6.9 children per mother—but infant mortality is also high—some 20 per cent in the first year and 43 per cent in seven years.

The second section though highly interesting is not very satisfying for the findings, as stated above are purely clinical and unsupported by any laboratory or experimental work. This is not the fault of the author for he had no laboratory and he was probably too busy to undertake experimental investigations. Nevertheless the fact remains that a large number of conditions are described and too many subdivisions made of the small total of 210 cases. The conditions detailed are ascribed to defective nutrition because they occur among poor class natives whose diet is unbalanced, because similar diseases have been described by others and ascribed to faulty nutrition and because improvement occurs when the patients are given a nourishing diet. These reasons are not very satisfying. *ankylostomiasis* is common among poor class natives and leprosy will improve before any specific treatment is given, when a nourishing diet is taken but these are not therefore ascribed to malnutrition.

Dr Purcell divides his cases into four main clinical groups: (1) With alimentary symptoms predominating followed in some by oedema in others by dermatitis. (2) Dermatitis cases without preliminary alimentary disturbance. (3) Oedema cases. (4) Nervous disorders. Alimentary symptoms cover a fairly wide range and include stomatitis, glossitis, bad dentition, bleeding gums, ulceration of the buccal mucosa and others. Oedema may or may not be accompanied by albuminuria; the latter are regarded as nephrotic or nephritic and may terminate by acute pulmonary oedema. Diarrhoea is commonly present also. It is found often in children who are still being breast fed though the mother is again pregnant the nursing being supplemented by scraps. Even at the best of times the mother's milk is of poor quality and tinned milk is better. Among the conditions characterized by dermatitis the author describes *kwashiorkor* [see this *Bulletin*, 1934 Vol 31 p 344, 1936 Vol 33 pp 410 and 734] first recorded by Dr Cicely WILLIAMS in the Gold Coast, but shows that in the same (or very closely similar) conditions described by himself maize cannot be incriminated. The pathology he does not describe and the pathogeny he regards as obscure and wisely refrains from attempting to explain it. He discusses Clarke's theory of pellagra being due to chronic prussic acid poisoning without stopping to consider whether there is any evidence that chronic HCN poisoning does occur (apart from its supposed action in causing pellagroid symptoms).

Under the heading of Nervous disorders is a very mixed bag. It includes those who are merely apathetic or emotional with fits of temper, those backward in or showing reluctance to walking, those exhibiting a sudaminal rash and head sweating. Some resemble markedly cases of *Foer's acrodynia*.

In the category of skin disorders are included cases of atrophy and eczema, dermatitis and pigmentation, *ecthyma* and ulcers the result of scratching.

Regarding treatment the author has little to say. Most of the patients were extern and treatment of any kind he found of little avail. He recommends on general lines a better diet with more meat, supply of tinned milk, retaining of red rice in place of the present method of

selling it and buying milled rice and so on and further analyses are needed and study by biochemists as well as clinicians.

The work is well illustrated and the original photographs must have been exceptionally good to bear so much reduction. Rashes and eruptions rarely show well in uncoloured photographs and when reduced to the size of a postage stamp as some of these photographs are they are really wasted and many are too dark to show much others however are very good. The whole would be improved by addition of an index.

H H S

WIGGLESWORTH (V B) [M.A. M.D. F.R.S. Reader in Entomology in the London School of Hygiene and Tropical Medicine] *The Principles of Insect Physiology*—pp viii+434 With 316 figs 1939 London Methuen & Co Ltd 36 Essex Street W.C.2. [30s.]

Dr Wigglesworth has produced a general account of the physiology of insects in which he deals with development and growth and the various systems such as the integument muscles and the organs of digestion respiration and reproduction there are also chapters on the central nervous system sense organs and the behaviour of insects. The book is fully illustrated with line drawings many of them from the author's own papers in which he has already made important contributions to many sides of insect physiology.

To readers of this *Bulletin* the significance of this book is that nearly every problem in the control of insects makes an intelligent person look for information on their physiology. For instance one could hardly use an insecticidal method (such as fumigation or poisoned baits) without having a general knowledge of the functions of an insect and particularly of its respiration or digestion and it is not only in controlling insects but also in studying the epidemiology of certain diseases that one meets riddles which the physiologist alone can answer. Why is it that rat fleas are rare in hot dry weather? Because their larvae not the fleas themselves are inadequately protected against loss of water through the tracheal system. Or why is it that malaria is so much more grave in one part of a country than another? The immediate answer depends on the local distribution of particular species of *Anopheles* penetrating the subject more deeply one frequently finds that that in turn hangs upon some point of larval physiology such as a need for calcium or an ability to extract traces of salt from natural pure waters. One cannot pretend that insect physiology will answer all our riddles but it has already explained some of them and it gives us a necessary background of knowledge.

A man concerned in controlling insects might perhaps find particular value in the chapter which deals with behaviour for he will realize that insects' behaviour is rigid and predictable at least in some directions and he may use this knowledge to avoid damage or achieve cheap control. It is exceedingly difficult for us to understand the behaviour of insects for their whole organization and the structure and position of their sense organs are so different from our own some insects can perceive ultra violet radiation carbon dioxide and water vapour so that they must live in a perceptual world very different from ours. It has therefore been a difficult matter to devise experiments sufficiently critical and subtle. But as this book shows

much progress has been made and we may now begin to understand what it is that keeps an insect active or at rest and to recognize some of the stimuli which direct its movements or bring it to places where it feeds or lays its eggs.

Readers of this *Bulletin* may be proud to notice the extent to which medical workers have developed the science of insect physiology

P. A. Buxton.

MACKENNA (Robert M. B.) [B.A. M.D., B.Ch.(Camb) M.R.C.P (Lond) etc.] *Aids to Dermatology and Venereal Disease*. Second Edition.—pp. vii+284 With 7 figs. 1939 London Baillière Tindall & Cox, 7 & 8 Henrietta Street Covent Garden WC 2. [4s. 6d.]

The Students Aid Series comprise small volumes which can easily be slipped into an ordinary jacket pocket. It is therefore absolutely impossible for any one of the books to deal exhaustively with its subject. They are not text-books but "reminders." At the same time this particular member of the group does contrive to contain a remarkable amount of accurate information. It must be realized that the mere fact that a patient happens to live in the tropics does not prevent him from suffering from an "ordinary" dermatosis for sight of this fact is apt to be lost in the luxuriance of the diseases more peculiar to the tropics. These latter do not of course occupy much space in this volume but some reference is made to the most important of them. The section on venereal diseases gives an excellent summary of the modern methods of treatment and is absolutely up to date

Sydney Thomson.

HENRY LESTER INSTITUTE OF MEDICAL RESEARCH (SHANGHAI CHINA) *Annual Report 1937-1938*.—90 pp With 2 plates.

This Report covers the work of two years and summarizes the considerable amount of work carried out, much of which has been abstracted in this *Bulletin*. Deficiency diseases nutrition the study of certain helminths and investigations in malaria and in the transmission of filariasis and relapsing fever are of interest to readers of this *Bulletin*. The long lists of papers published testify to the energy and enthusiasm of the staff under the disturbed and trying conditions which have recently existed.

[No 9

SUMMARY OF RECENT ABSTRACTS

VII HELMINTHIASIS *

[continued from p 616.]

Ankylostomiasis —KANDELARI and KAMALOV (p 671) find heavy hookworm infection in Western Georgia, Russia especially in districts of heavy rainfall. In one series 92 per cent. of the hookworms recovered after treatment proved to be *N. americanus* the remainder were *A. duodenale*.

SCOTT (p 273) estimates that of the twelve million rural inhabitants of Egypt about five million are infected with hookworm. In some villages the infection rate reaches 90 per cent. He details the techniques used in the investigation made and considers that estimations of worm burdens from egg count figures cannot usefully be made on account of the large errors involved. But he concludes that in general where a high proportion of infected persons is found there is a large number of worms in each infected person. He also (p 274) discusses soil pollution in Egypt. It is common throughout the villages and in the fields but possibly on account of dryness or excess of chlorides or some associated factor the fine clay soils do not serve as good media and few larvae can be found. Even when irrigation is carried out the moisture content often falls fairly low and the hot sun may kill the larvae. Defaecation is scattered but, near water soil infestation is widespread though seldom intense. These observations harmonize with the widespread but low grade human infection found.

KELLER *et al* (p 274) report that in comparison with investigations made by the Rockefeller Sanitary Commission in 1910-1914 their recent findings show a reduction in hookworm infection of between 33.7 per cent. and 27.3 per cent. in five of the United States. The peak incidence is between 15 and 19 years and family infection is important. LANE states that the value of the comparison depends upon whether the techniques in the earlier and later investigations were identical and that according to Stoll whose method they used,

The information from which this series of summaries has been compiled is given in the abstracts made by the Sectional Editors in the *Tropical Diseases Bulletin* 1938 Vol. 35. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

the amount of faeces examined by the authors was not enough for the detection of single worms.

PESQUERA and PASCALE (p. 276) examined 1 177 school-children by the Stoll Hamsher technique in São Paulo and found 75.4 per cent. to be infected with *Necator*. A rather higher percentage was found in those living in houses not provided with latrines than in those so equipped.

WEBB (p. 217) by systematic measurements of all hookworm-like eggs in the faeces of patients in Mauritius found 8 per cent. *Trichostrongylus*, 0.9 per cent. *Terridens dominicus* and 0.9 per cent. *Ancylostoma braziliense*-like eggs. He records a patient infected with *Trichostrongylus axei* normally a parasite of equines.

TAYLOR (p. 670) stores nematode larvae between damp filter papers in a sealed petri dish at 36°-40°C. After a year 91 per cent. of the larvae are alive. RUDOLFS (p. 672) cites unpublished evidence that a small percentage of hookworm eggs may survive sludge digestion under certain conditions. In Singapore effective destruction is ensured by heating digested sludge to 150°F. or more for at least 30 minutes.

CIMINO (p. 276) lays stress on the value of dark blue pigmentation of the tongue as a diagnostic sign of ankylostomiasis, but LARX points out that this sign has been discredited for more than 30 years. MINAMIZAKI (p. 672) shows that hookworm eggs appeared in the faeces 58 days after deliberately walking barefoot over farm land. Treatment failed to eliminate all worms, and eggs persisted for 7 years. BONNE (p. 277) describes five cases in which hookworms were found in the submucosa of the intestine. In three instances eggs and larvae were also present and in one there was destruction of the circular muscle coat. He believes that the worms were *A. braziliense*. GARIN (p. 673) records a patient from whom 302 hookworms were removed, who showed no symptoms although some anaemia was present.

LANDSBERG (p. 279) from experiments in dogs infected with *A. caninum* shows that there is a progressive increase in reticulocytes corresponding with the progressive decrease in erythrocytes and haemoglobin, without any evidence of haemolysis. This was also found in normal dogs subjected to successive bleedings and the results do not support the theory that inhibition of bone marrow activity through toxic action takes place but rather that hookworm anaemia is the result of blood loss. A reduced platelet count is one of the known changes in anaemia due to some poisoning of the bone marrow. No such change was found by LANDSBERG (p. 673) even in fatal *A. caninum* infection of dogs and this provides further evidence against the view that hookworm anaemia is produced by a toxin. Clotting power was not reduced. RYO (p. 278) emphasizes his opinion that hookworm anaemia is due to the continuous blood loss. In experiments on man with *A. duodenale* he found that the time from infection to oviposition was from 54 to 57 days. Eosinophilia became obvious a week after infection, was at its height in 6 to 7 weeks, but decreased after the 15th week. The numerical relationship between the number of worms and the intensity of the anaemia is not recognizable when the worms harboured are less than 50. The blood loss caused by one *A. caninum* experimentally measured, varies enormously with temperature the most favourable being 38°C. to 39°C. and is about 0.38 cc. per diem, but this may be multiplied 4 or 5 times if the worms are very vigorous.

Investigating the oedema of helminthic anaemia SALAH (p 673) found that in 12 of 22 cases there was hypoproteinaemia and 4 others responded to a high protein diet. He therefore suggests that replacement of blood deficiencies is a useful therapeutic measure. SILVEIRA and DE MOURA CAMPOS (p 280) give results of estimations of gaseous interchange in the blood in hookworm anaemia. These cannot be further abstracted.

In the *Lancet* (p 671) it is shown that the use of a poor diagnostic technique will give a high and false rate of cure that floatation gives higher counts than dilution but that DCF is the most accurate method in that it can detect a single normally ovipositing female hookworm and that detection of worms not egg counts must be the basis for evaluating drugs. PESSÔA and PASCALE (p 275) found that examination by the Stoll Hausheer technique detected no relationship between egg counts and hookworms recovered after treatment and that this method cannot be relied upon to detect light infections. PESSÔA (p 674) examines the findings in consecutive stools following treatment and confirms the opinion of MAPLESTONE and MUKERJI that examination of stools for worms for one day only does not give a true picture of the numbers present.

HABERT (p 392) records two patients who developed symptoms suggestive of yellow fever after taking 3 cc. carbon tetrachloride and a third who died with hepatitis of the yellow fever type after taking a dose of the drug [quantity not stated]. DANIELLA and TOURENC (p 675) report two deaths from carbon tetrachloride poisoning which are attributed to the presence of phosgene. PEU DUVALLOX (p 676) advises Didakol, or carbon tetrachloride with chenopodium and chloroform in treatment and ERHARDT (p 676) experimented on cats infected with *A. caninum* by giving various drugs including carbon tetrachloride in doses equivalent to almost 1 oz. for a man. Commenting on these papers LANE points out that no evidence was produced in the first to show that phosgene was the cause of death, and that carbon tetrachloride itself can be lethal in doses ordinarily given that in the second a large dose (4 gm.) of carbon tetrachloride is mixed with 1.5 gm. chloroform the action of which is similar and that in the third the experiments do not apply to man since the large doses killed some of the experimental animals. He makes a plea for a large scale enquiry into the safety and efficiency of anthelmintics.

MAPLESTONE and MUKERJI (p 282) give details of 96 persons treated for hookworm infection by 3 cc of tetrachlorethylene and 1 cc. oil of chenopodium and of 90 treated with 4 cc of tetrachlorethylene. Percentages of real and practical cures with the former were 65.6 and 84.4 after two treatments with the latter 77.7 and 94.4 after three treatments. Faecal examination was carried out by DCF. PESSÔA and PASCALE (p 281) claim that a dose of 4 cc of tetrachlorethylene in gelatin capsules eliminates about 95 per cent of *Necator*. Details of 51 persons treated are given and the results are calculated on findings by the Willis technique. LANE comments that the validity of the conclusions rests on the assumption that the technique is accurate.

SORONDO CAMPANERÍA (p 272) discusses oil of chenopodium. VAN WYMEERSCH (p 676) uses *Entelminutina* a preparation of male fern for ankylostomiasis.

CHAVES (p 674) discussing the value of shoes in the prevention of hookworm infection points out that as children tend to wear them in

[September 1939]

the uncontaminated environment of schools and to discard them in the home environment where contamination is likely comprehensive measures including medication and the use of sanitary latrines are necessary. Shoes have only auxiliary usefulness. COCKRILL (p. 280) shows how ankyllostomiasis has decreased in Fiji following the installation of standard borehole latrines with concrete squatting slabs. Details of the latrines are given. A campaign of education was also conducted.

CHANDLER (p. 350) shows that more larvae of *Nippostrongylus* introduced into already infected rats fail to establish themselves in the intestine than in normal controls, but that there is no evidence of increased retention in skin previously exposed to penetration, although leukocytic infiltration and eosinophilia are increased. Immunization Attempts at passive immunization with serum from rats infected with *Nippostrongylus* has produced little result.

Strongyloides Infection—OSBURN (p. 678) reports 5 cases of *Strongyloides stercoralis* infection. Two showed diarrhoea and severe anaemia probably entirely caused by the infection. SMOKE (p. 677) successfully treated 2 cases infected with *S. stercoralis* with ultraviolet light and gentian violet per os.

Ascaris Infection—HILLER *et al.* (p. 668) show that the incidence of *Ascaris* infection in North Carolina has risen since 1921. The average worm burden in each infected person increases in proportion to the number of infected persons in each family. WINSTED and LEO (p. 271) examined washings from 2745 kilograms of vegetables in China for *Ascaris* eggs without finding any, though eggs were found in the soil of vegetable gardens in 57.1 per cent of 49 samples. They therefore conclude that the contamination of vegetables is not a major source of infection.

SARGENT (p. 272) records the case of a boy in whom a mass of worms in the right iliac fossa caused acute intestinal obstruction which was relieved by enemata. Oil of chenopodium followed by sanftonin brought away 87 worms. Intestinal obstruction was caused by *Ascaris* in the small intestine in 4 children reported by CIRIANO (p. 671). Operations were performed and 2 of the children died 1 of whom had in addition volvulus of the intestine.

BROWN (p. 273) considers that anthelmintics are absorbed through the body wall of *Ascaris* and in this manner rather than by ingestion produce their effect. Delayed death of the worm results from injury of a small portion by the application of an anthelmintic locally.

Filetirosis—TAMAKI (p. 359) reports that there is much infection with *Filetirosis* on Boko Island.

O COXAR and BEATTY (p. 781) in St. Croix found 25.08 per cent. of wild *Culex fatigans* showing infection with larval forms of *Filetirosis*. Only 2.3 per cent showed the infective stage and of those infected the figure of infectivity was 9.1. Infection was highest in July. Larvae in 48 per cent of *Aedes aegypti* were found to be infective did not reach infectivity but development proceeded to maturity in *Anopheles albimanus* and *C. tritaeniorhynchus*. The effective proportion of infective mosquitoes is probably for various reasons, much less than those figures suggest. Measures for reducing human infection are suggested. BROWN (p. 760) in Kabana differentiates between crude

and corrected infection indexes in vectors of *Mf bancrofti*. From the latter category are excluded mosquitoes containing only larvae with very retarded development which if included might give a false impression of their suitability as vectors. Complete development was found in *A barbirostris* *A aconitus* *C fuscocephalus* *C whitmorei* *C fatigans* *C alis* and *rishani* and *C annulirostris*. HU (p 389) shows that *C pipiens pallens* were more frequently and more heavily infected after feeding on a heavily infected patient than on one lightly infected and when the feeding took place at a time when embryos were most numerous in the blood.

ABE (p 389) studied the biological behaviour of freed larvae of *W bancrofti* which had undergone full development in *C fatigans*. The larvae lived longest, 37 to 58 hours when placed in normal saline but were extremely sensitive to drying.

MONTESTRUC and BERTRAND (p 390) report two cases of lymphangitis in one of which streptococci and *Mf bancrofti* were found in an abscess. GORTER (p 391) gives details of the operative treatment of elephantiasis of the legs the results of which have been gratifying and which has ensured a satisfactory lymph flow. For full information the original abstract must be consulted. DE GREEF (p 762) discusses the results of operative treatment of elephantiasis. He considers that in the Congo onchocerciasis may be accompanied by elephantiasis but as LANE points out does not mention the possibility of mixed infection without microfilariae in the blood.

DASSANAYAKE (p 759) reports on an endemic area in Ceylon in which *Mf malayi* is the only filarial larva present. Circumscribed foci are present in villages situated near water tanks containing *Pistia* plants or having many naturally infected *Mansonia*. GALLIARD (p 387) states that although recent investigations in Tonking have shown a higher percentage of microfilariae than were found in 1911 the difference is probably due to the larger amount of blood examined in the later investigations. He also (p 388) reports that in Tonking *Mf malayi* is about twice as common as *Mf bancrofti* but that considerable local variations occur. *W bancrofti* was always the only cause of urogenital lesions but *Mf malayi* was present in 20 per cent. of cases of elephantiasis of the legs. LIU (p 388) found *Mf malayi* in 2 of 80 persons examined in Changsha, Hunan. HU *et al* (p 387) report the finding of *Mf malayi* as well as *Mf bancrofti* in examinations in Foochow where the former had not previously been seen. Five of fifteen *C fatigans* caught in one house were infected. In Borneo KARIADI (p 760) found the highest index of infection in *Mansonia annulifera* (22 per cent.) a domestic mosquito. *M uniformis* and *A barbirostris* are also infected and parasite indexes as high as 32.2 per cent. were found in men in the district examined.

SWEET and PILLAI (p 766) report on the success of the clearing of *Pistia* in lessening the incidence of *Mansonioides* in North Travancore which illustrates the suppression of a mosquito-borne disease by a strictly limited species control of the carrier.

LANE (p 764) discussing filarial periodicity makes a suggestion that charts of microfilaria which would be found if a series of dogs were infected with *Dirofilaria* and if the blood were examined every two hours should be correlated with the number of empty worms to be found in the hearts of the dogs after they had been killed at different hours. In a discussion of the same subject HYMAN (p 385) considers that the theory of simultaneously timed parturition can only be accepted

if the female worms are shown to be capable of producing enough embryos daily to account for the enormous numbers frequently seen and if a comparable destruction of microfilariae occur about midnight. There is no evidence on the second point but on the first he has found in dogs infected with *Dirofilaria immitis* that there is no correlation between the number of worms and the larvae found, the variation being between 10 740 and 3 750,945 per female worm. He cannot conceive it possible that single worms can produce daily the large numbers indicated. He cites an experiment by KNOTT from which it was concluded that embryos can survive in man up to 2 weeks following blood transfusion but LANE criticizes this on the grounds that it was not certainly known that the human volunteer in that experiment had not previously harboured infection unknown to the investigator. HINMAN shows that fertilized female *Dirofilaria immitis* in saline or Ringer solution at 39°C produced the greatest numbers of microfilariae within 6 to 12 hours of introduction into the media irrespective of whether the animal was killed at 7 a.m. or 7 p.m. and that the usual number produced was from 4 000 to 10 000 per worm. Admitting the insufficiencies of this experiment the author considers that if cyclical parturition were the rule in the normal habitat there should have been some indication of it under these experimental conditions. In comment LANE sets out his view that periodicity is due to simultaneous parturition, and that microfilariae in the blood are short lived owing to the action of the reticulo-endothelial cells.

JOYEUX and SAUTET (p 390) have grown *Af. immitis* in a mixture of serum and haemolysed blood from an infected dog. The average period of survival was 12 days and an increase in length of the embryos to 290-442 μ was observed in the first 6 days when measured without being fixed. LANE considers that the absence of such large forms in the blood may be presumptive evidence of rapid destruction in the body. O'CONNOR and BEATTY (p 785) examined the reaction of birds infected with *Vagrofilaria columbigallinae*. No periodicity was seen in the microfilariae present in the blood. In the livers large aggregations of lymphocytes and giant cells were seen surrounding embryos in all stages of degeneration and the whole picture suggested massive death degeneration and absorption going on continually in the organ. LANE points out the importance of this observation in relation to human filariasis.

DE CHOISY (p 762) reports apparent success in the treatment of Loa infections with anthelmintics injected on alternate days. RISHWORTH (p 763) reports a patient from beneath whose conjunctiva a female worm was removed. A second female was found under the skin of the neck. No microfilariae were found in the blood. MAPLESTONE (p 763) examined the worms and regards them as probably belonging to a new species of the genus *Loa*. He suggests the tentative name of *L. inquirenda* but the matter cannot be fully elucidated until a male is found.

STRONG (p 767) considers that in onchocerciasis the nodules do not represent the place which the flies have bitten but are probably found where lymphatics converge or where pressure impedes the free flow of lymph. He discusses the question of infection without nodules but SANDGROUND (p 768) always found a nodule when microfilariae had been discovered in the skin or conjunctiva, though sometimes only after assiduous search. Single nodules may be compounded of several

small ones each with separately walled off worms. He believes that *O. volvulus* is a parasite of cattle and eland as well as of man.

ADAMS (p 769) reports a man with eosinophilia of 33 per cent. without microfilariæ in the blood but with 9 *Aff. volvulus* in an excised piece of bulbar conjunctiva, and others in 3 of 48 skin snips. They were also seen within the eye on slit lamp examination. Symptoms were delayed probably 3 to 5 years after infection.

HISSETTE (p 768) notes that in the eye inflammatory exudate may be present where there are no larvae and larvae may exist without obvious lesions. There is a slight and slow reaction to living larvae and a clear appreciable reaction to dead ones. The pupil is typically oval or pyriform there may be punctate keratitis vascular keratitis and choroïdo-retinitis ending in optic atrophy which is the cause of the blindness which ensues. MARBAIX and APPELMANS (p 767) describe the histological appearances of a piece of conjunctiva infected with *Onchocerca*. Infiltration of the connective tissue with large reticulo-endothelial cells lymphocytes polymorphonuclears and eosinophils nodules with necrotic centres and giant cells and microfilariæ surrounded by more or less cellular infiltration were found. Diagnosis must rest on the finding of microfilariæ. ADAMS (p 769) states that treatment consists of the removal of adult worms which are not affected by any known drug though larvae may be killed with temporary improvement of symptoms by antimony and plasmoquine. LAKE (p 765) considers that certain arsenicals sterilize but do not kill the mother worms. This could be tested in a patient with onchocerca nodules by excising a nodule giving the drug treatment and then excising a second nodule and comparing the condition of the females in the two.

MOORTHY (p 769) discusses the development of *Dracunculus medinensis* in cyclops and describes abnormal forms the illustrated abstract cannot be further summarized. TREW (p 391) remarks on the importance of the step well in the causation of guineaworm infection on the presence of 56 worms in one person at the same time on the immunity to infection shown by certain people and on the value of injecting into the worm itself 1 in 1000 corrosive sublimate and using a dressing of the same solution. GORE (p 772) uses ichthyol as a compress for inflamed skin over guineaworms. MOORTHY and SWEET (p 771) in dogs infected with *D. medinensis* found adult worms in chamber of the left ventricle of the heart, in the meninges and more commonly in the subscapular and retroesophageal areas and elsewhere. Epileptic symptoms may possibly be caused in man by meningeal infection. They consider that copulation takes place in the tissues and not in the intestine and that male worms after fertilizing the females die and are absorbed. The same may be true of unfertilized or even fertilized females. Calcification is rare.

Trichuris and Enterobius Infections—DESPORTES (p 678) reports 52.4 per cent and 9.06 per cent infections with *Trichuris* and *Enterobius* in caeca and appendices preserved by BRUMPT from post mortems carried out in Paris in 1909.

DINVIK and DRINVIK (p 678) investigated the factors of temperature absence of oxygen and drying on the eggs of *Trichuris*. Dried eggs survive for a long time.

VAZQUEZ PAUSA (p 380) found that *Trichuris* infestation was cured in 95 per cent. by doses of 4 to 5 gm. Ferri et Ammon Cit. daily which also benefits the associated anaemia. MAPLESTONE and MUKERJI

(p 282) consider that tetrachlorethylene is probably unsatisfactory in Trichurus infection but gives 80 per cent. of cures in Enterobius infestation. WRIGHT *et al* (p 381) also advocate tetrachlorethylene in doses of 0.1 cc for each year of age as a single-dose treatment for Enterobius infection. They use magnesium citrate as the purgative administered at the same time.

WRIGHT and CRAM (p 678) show that Enterobius infection is often familial and that eggs are found on clothing furniture etc. Tetrachlorethylene is perhaps the most efficient anthelmintic for single-dose treatment but there is need for a cheap effective and safe anthelmintic.

CRAM *et al* (p 382) by the use of the Cellophane N.I.H. swab found a high proportion of persons harbouring Enterobius in Washington. Repeated examinations may be necessary but the swab method is better in diagnosis than the examination of faeces for eggs.

Trichinella Infections—SCHEFFLEY (p 679) estimates the incidence of Trichinella infection in man in the U.S.A. as about 20 per cent. Neither the pressed muscle nor the gastric digestion methods are capable of detecting all infections. This heavy infestation rate was not suspected during life and the incidence in swine must be high possibly 2 to 4 per cent. VAN SOMEREN (p 679) observed that gastric digestion of the wall of trichinella cysts allows the escape of a jelly like substance. The larva then becomes active and passes tail first through the opening made by digestion.

NICOLESCO *et al* (p 382) advise the examination of the sediment from blood laked with acetic acid and centrifuged for the diagnosis, by discovery of larvae of early Trichinella infection. SAWITZ (p 383) compares the results of skin testing with Trichinella antigen and of post mortem findings. Five per cent of 200 in each series gave evidence of infection and the sex and age incidences were similar. No negroes reacted to the test, but this may be due to the difficulty of reading it in a dark skin.

JONES and WELLS (p 384) describe the symptoms of Trichinella infection: puffiness of the eyelids, tenderness of muscles and eosinophilia with positive precipitin reaction and skin test. WANTLAND (p 384) shows that polycythaemia and increase in the percentage of haemoglobin occurred in 7 of 12 rabbits infected with *Trichinella spiralis* and that hyper eosinophilia was associated with marked symptoms. Increase in clotting time and erythrocytic macrocytosis were observed.

PIERCE and McNAUGHT (p 384) show that alcohol interferes with the liberation of larvae of Trichinella by gastric digestion but that sufficient concentrations in the human stomach are not maintained for the long periods necessary to kill them.

Gnathostoma Infections etc—AFRICA *et al* (p 773) consider that *G. spinigerum* requires a fresh water fish as a second intermediate host. They regard certain snakes as unsuitable hosts in which development to a certain stage only is possible. Suitable and unsuitable hosts are probably infected not by drinking water containing infected cyclops but by eating fresh water fish which in turn have eaten cyclops. MAPLESTONE and BHADURI (p 772) describe a case of infection with *Gnathostoma* and point out that the swellings even though widely separated usually cease on the removal of a single worm. Swelling of the pharynx with dyspnoea were seen in half of 25 cases analysed.

KOFOID *et al* (p 392) failed to effect transmission of *Thelazia californiensis* by means of cock-roaches and by injection or instillation of larvae into the conjunctival sac of dogs. C Wilcocks

HELMINTHIASIS

PRÉCIS OF ABSTRACTS IN THIS SECTION

COUTELEN (p 715) describes granules in the laminated cuticular layer of hydatids which stain with silver and are probably produced by cells of the germinal layer

Discussing the diagnosis of *Echinococcus alveolaris* BÜHLER and v HASSELBACH (p 715) show that only histological examination can be accurate but a tumour of the liver unassociated with any other growth deep jaundice with comparatively slight subjective disturbance X ray evidence of calcification and a long history should suggest the correct diagnosis.

CHUNG and TUNG (p 715) found that both hydatid and cysticercus cyst fluid gave strongly positive skin reactions in patients with echinococcosis cysticercosis or intestinal taeniasis. The complement fixation test with hydatid cyst fluid may be used to detect cysticercosis in man but since the undiluted fluid may give false positive reactions with syphilitic or other sera a dilution of 1:4 should be used. These tests are therefore group immunological reactions rather than specific reactions for hydatid disease alone. SERGENT *et al* (p 716) on the other hand consider that a positive result to a *first* intradermal injection of hydatid fluid is definite evidence of the presence of hydatid but that repetition of the test in a negative reactor may lead eventually to a positive result in the absence of hydatid disease through activation by the earlier injections

SAWITZ (p 716) reports the finding of a hydatid cyst in the liver of a man in Louisiana who died with a clinical picture of cirrhosis with ascites. GÓMEZ LÓPEZ and LUVA (p 716) describe a case of hydatid cyst of the base of the lung in Venezuela the first to be confirmed there. Of 7 hydatid cysts treated by MORISCO *et al* (p 717) 4 were in the lung and 3 in the liver. One of the latter simulated lithiasis with jaundice vomiting and pain

MEIJER (p 717) states that *Diphyllobothrium erinacei* (synonyms *D. mansoni* or *D. railletii*) is present in the Dutch East Indies. The plerocercoid is found in frogs rats swine and shrews

HIYEDA and TERADA (p 717) use Raigan a sort of mushroom (*Omphalia lapidescens*) for *Taenia* infection. The dose is 20 grains of the powdered plant or 0.4 grains of the active principle. It acts apparently by destroying the tissues of the worms and was successful without ill effects in over 100 cases treated.

Seventeen cases of infection with *Cysticercus cellulosae* are reported by HANASAKI (p. 718) and of these 6 showed evidence of infection by adult worms. A massive infection with cysticercus was revealed by

X-ray in a man of 68 reported by BRETON and LAVIER (p 718) There was general muscular atrophy and the cysts were most frequent in the muscles about the pelvis, back and pectoral region. Remarkable athletic powers were shown by and remained unimpaired in the patient recorded by EVANS (p 719) in whom several hundred cysts were found by X-ray in the thigh, thorax, arm and neck. AUSTONI (p 719) describes a case of cysticercosis in a girl of 10 years, who died of the infection. ALBERT (p 719) records a large cysticercus of the liver with abscess and subsequent peritonitis. The patient described by SEGAL (p 719) had a cysticercus infection of the right iliac bone with sequestrum formation, which was diagnosed radiologically as chronic osteomyelitis.

ROMAN (p 720) infected a white mouse by administering oncospheres of *H. nana*.

KOURI and DOVAL (p 720) report infection of 3 children with *Davainea* (species not stated). One suffered from asthma and anaemia, male fern and carbon tetrachloride expelled the worm.

LEÓN (p 720) describes the characters of *Raillietina guineensis* León of which the definitive host is man and the intermediate host unknown.

BEARUP and MORGAN (p 721) report 3 human infections with *H. diminuta* and 2 with *D. caninum* in Australia.

PETROV (p. 721) records the finding of *Diphyllbothrium skrjabini* (normally a parasite of dogs) in man, and of a new species *D. nensi*.

LAME (p. 721) emphasizes the four essentials for successful diagnosis of *Ascaris* and *Trichuris* infections by D.C.F. the presence of fertile eggs, the proper disintegration of faeces, the use of a vessel large enough to prevent over-concentration and a floating fluid whose *ascertained* specific gravity is just over 1.200. If these are fulfilled the collection of *Ascaris* eggs by D.C.F. is 4 to 6 times greater than by the Willis technique and the results are much more constant. Salt solution three-quarters saturated which is the optimum for hookworm eggs, is not heavy enough for *Ascaris* and *Trichuris*. He mentions air-borne infection and the breeding of cockroaches (possible carriers of *Ascaris* eggs) in borehole latrines.

YOSHIDA and TOYODA (p 722) give results of the hatching of *Ascaris* eggs in various media.

PINES (p 722) records asphyxia due to *Ascaris* in the trachea, a large ileo-caecal swelling due to masses of *Ascaris* and a hypogastric abscess containing a decomposing worm. FLAMINKI (p 723) describes a case of appendicitis due to *Ascaris*. CALADO (p 723) describes a case of intestinal obstruction due to *Ascaris*, but only 12 were expelled after an anthelmintic. LECERCLE (p 723) ascribes a case of acute haemorrhagic pancreatitis to an *Ascaris* in the bile ducts near the duct of Wirsung. CHANCO (p 723) extracted an *Ascaris* from the umbilicus of a child.

VAXXI (p. 724) produced severe haemorrhagic allergic reactions in sensitized rabbits by the injection of coelomic fluid of *Parascaris equorum*. In line with experimental results certain symptoms (urticaria, convulsions and asthma) in man are attributed to allergy to the body fluid of the worms. MACHEBOEUR and MAMDOUL (p 724) show that the toxic substance contained in the coelomic fluid and tissues of *Ascaris megalocephala* can kill a guinea-pig in a few minutes if given intravenously. It is not precipitated by trichloroacetic acid and will not pass through a collodion membrane. *Monstera expansa* has no such toxic substance.

STARKOFF (O) La preparazione dei plattelminti col metodo di Dammin. [Mounting of Platyhelminths by Dammin's Method.]—*Ann d'Igiene*. 1938. Sept.-Oct Vol. 48 No 9-10 pp 609-611 With 2 figs.

A recommendation for Italian readers of Dammin's method (thus *Bulletin* 1938, Vol. 35 p 602) for the permanent mounting of platyhelminths.
Clayton Lane

COUTELEN (F) Sur la structure et sur la morphogenèse de la membrane cuticulaire des hydatides échinococciques [The Structure and Morphogenesis of the Cuticular Membrane of Hydatids.]—*C. R. Soc Biol* 1938. Vol. 129 No 25 pp 149-151

The laminated cuticular layer of a hydatid contains granules which stain with silver and are probably put out in successive bursts by specialized or by all cells of the germinal layer. The granules break up into finer ones and those zones which lie between the lamellae of the membrane are probably those in which the granules were originally densest.

BÜHLER (F) & HASSELBACH (H) Zur Diagnostik des *Echinococcus alveolaris* [Diagnosis of *Echinococcus alveolaris*]—*Muench Med Woch* 1938 Oct 23. Vol 85 No 43 pp 1665-1668

An experience of four cases of alveolar hydatid of the liver leads to these suggestions for help in a difficult diagnostic problem.

In a dweller in the Alps with this infection there will be found some of these conditions. A tumour of the liver with no evidence of another to which it could be secondary. Deep jaundice with comparatively slight subjective troubles. Good appetite. No cachexia, eosinophilia. An X-ray plate shows calcification and there is an unusually long history. In this way an explanatory laparotomy will not leave the condition labelled as cancer of the liver with undiscovered primary focus. Only histological examination can give a right diagnosis.

CHUNG (Huei-Lan) & TUNG (Tsun) The Non-Specificity of the So-called Specific Biological Tests for Hydatid Disease.—*Trans Roy Soc Trop Med. & Hyg* 1939 Apr 6 Vol. 32. No 6 pp 697-706 [11 refs.]

"The Ghedini Wernberg's complement fixation reaction and the Cason's intradermal reaction are group immunological reactions to somatic cestode infections rather than specific reactions for hydatid disease alone. Both hydatid cyst fluid and cysticercus cyst fluid gave a strongly positive complement fixation reaction with blood of either echinococcosis patients or cysticercosis patients. Both hydatid cyst fluid and cysticercus cyst fluid gave a strongly positive cutaneous reaction on patients with either echinococcosis, or cysticercosis, or intestinal taeniasis. The cerebrospinal fluid as well as the blood of most of the patients with cerebral cysticercosis gave a strongly positive complement fixation reaction. The serum of rats infected with *Cysticercus fasciolaris* gave a weakly positive complement fixation reaction with hydatid cyst fluid. The serum of four out of nine kala-azar patients gave a positive complement fixation reaction with hydatid cyst fluid of a 1/8 dilution. This positive reaction may be related to the high globulin content of the blood of kala-azar patients. Extracts of different tapeworms are not satisfactory antigens for the

X-ray in a man of 68 reported by BRETON and LAVIER (p 718) There was general muscular atrophy and the cysts were most frequent in the muscles about the pelvis back and pectoral region. Remarkable athletic powers were shown by and remained unimpaired in the patient recorded by EVANS (p 719) in whom several hundred cysts were found by X-ray in the thigh thorax, arm and neck. AUSTOXI (p 719) describes a case of cysticercosis in a girl of 10 years, who died of the infection ALBERT (p 719) records a large cysticercus of the liver with abscess and subsequent peritonitis. The patient described by SEGAL (p 719) had a cysticercus infection of the right iliac bone with sequestrum formation, which was diagnosed radiologically as chronic osteomyelitis.

ROMAN (p 720) infected a white mouse by administering oncospheres of *H. nana*.

KOURI and DOVAL (p 720) report infection of 3 children with *Davainea* (species not stated). One suffered from asthma and anaemia male fern and carbon tetrachloride expelled the worm.

LEÓN (p 720) describes the characters of *Raillietina gintersis* León of which the definitive host is man and the intermediate host unknown.

BEARUP and MORGAN (p 721) report 3 human infections with *H. diminuta* and 2 with *D. caninum* in Australia.

PETROV (p. 721) records the finding of *Diphyllobotrium skrjabini*, (normally a parasite of dogs) in man, and of a new species *D. nexas*.

LANE (p. 721) emphasizes the four essentials for successful diagnosis of *Ascaris* and *Trichurus* infections by D.C.F. the presence of fertile eggs, the proper disintegration of faeces the use of a vessel large enough to prevent over-concentration and a floating fluid whose ascertained specific gravity is just over 1.200. If these are fulfilled the collection of *Ascaris* eggs by D.C.F. is 4 to 6 times greater than by the Willis technique and the results are much more constant. Salt solution three-quarters saturated, which is the optimum for hookworm eggs, is not heavy enough for *Ascaris* and *Trichurus*. He mentions air borne infection and the breeding of cockroaches (possible carriers of *Ascaris* eggs) in borehole latrines.

YOSHIDA and TOYODA (p. 722) give results of the hatching of *Ascaris* eggs in various media.

PIRES (p 722) records asphyxia due to *Ascaris* in the trachea, a large ileo-caecal swelling due to masses of *Ascaris* and a hypogastric abscess containing a decomposing worm. FLAMINI (p. 723) describes a case of appendicitis due to *Ascaris*. CALADO (p. 723) describes a case of intestinal obstruction due to *Ascaris*, but only 12 were expelled after an anthelmintic. LECERCLE (p 723) ascribes a case of acute haemorrhagic pancreatitis to an *Ascaris* in the bile ducts near the duct of Wirsung. CHANCO (p 723) extracted an *Ascaris* from the umbilicus of a child.

VANXI (p. 724) produced severe haemorrhagic allergic reactions in sensitized rabbits by the injection of coelomic fluid of *Parascaris equorum*. In line with experimental results certain symptoms (urticaria, convulsions and asthma) in man are attributed to allergy to the body fluid of the worms. MACHEBOEUR and MANDOUZ (p 724) show that the toxic substance contained in the coelomic fluid and tissues of *Ascaris megalocephala* can kill a guinea pig in a few minutes if given intravenously. It is not precipitated by trichloroacetic acid and will not pass through a colloidal membrane. *Moniezia expansa* has no such toxic substance.

STARKOFF (O) La preparazione dei plattelminti col metodo di Dammin [Mounting of Platyhelminths by Dammin's Method.]—*Ann d'Igiene* 1938 Sept-Oct. Vol 48 No 9-10 pp 609-611 With 2 figs.

A recommendation for Italian readers of Dammin's method (this *Bulletin* 1938 Vol 35 p 602) for the permanent mounting of platyhelminths.
